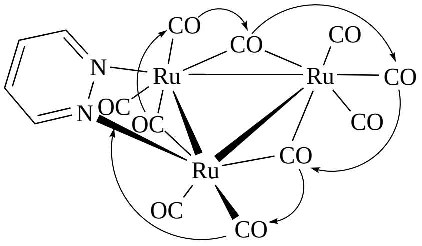
The most stable carbonyl for ruthenium is the trimeric tetracarbonyl $Ru_3(CO)_{12}$ (**1**), with $Ru(CO)_5$ (**2**) and $Ru_2(CO)_9$ (**3**) being much less stable. Compounds (**2**) and (**3**) are prepared from $Ru_3(CO)_{12}$ and revert to it on standing or irradiation. No neutral homoleptic (*see Homoleptic Compound*) ruthenium carbonyl of higher nuclearity, in particular no analog of $Os_6(CO)_{18}$, is known.

Known carbonyl hydrides of ruthenium include the unstable $HRu(CO)_4$, as well as the trinuclear $H_2Ru_3(CO)_{11}$, tetranuclear $H_2Ru_4(CO)_{13}$ and $H_4Ru_4(CO)_{12}$, and complexes of even higher nuclearity, as well as substitution and deprotonation derivatives. A special feature of ruthenium carbonyl chemistry is the existence of series of carbonyl halides of varying stability; many mono- and dinuclear carbonyl halides are known.

2.1.1 *Ru₃(CO)₁₂*

As stated above, the one stable binary carbonyl of ruthenium is $Ru_3(CO)_{12}$ (**1**). This is readily formed from halides or coordination compounds of Ru^{III} by carbonylation at elevated temperature and pressure.[6–8] This commercially available carbonyl complex is an air-stable orange solid that is soluble in most organic solvents. Its structure consists, like the osmium analog but unlike $Fe_3(CO)_{12}$, of a regular Ru–Ru–Ru triangle with only terminal CO groups. Each $Ru(CO)_4$ corner is composed of two equatorial and two axial CO groups, with clearly different bonding parameters. Equatorial groups have shorter Ru–C bonds as well as C≡O bond distances in comparison to the axial CO groups, a difference that can be traced to a 'π-competition effect', that is, less back bonding (*see Back Bonding*) for the *trans* axial CO groups, which compete for metal electrons, whereas equatorial CO groups *trans* to a Ru–Ru bond can make full use of ruthenium d-electrons for back bonding.

Despite the absence of bridging CO ligands, exchange of axial and equatorial CO groups is rapid on the NMR timescale, giving rise to a single ^{13}CO signal down to −100 °C. It is found that when either two axial or equatorial positions are occupied by a donor ligand, CO exchange involving these positions is considerably slower. Thus, the pyrazine derivative depicted in Scheme 1 exhibits three bridging carbonyls; a low-temperature process occurs at −150 to −90 °C that affects bridging and equatorial CO groups only, and can be separated from the complete scrambling of all carbonyls at higher temperature. This process, designated as a 'merry-go-round' mechanism of



Scheme 1

CO interchange, can alternatively be viewed as the stepwise movement of the metal core (with the axial groups) by 60°.

2.1.2 Ru(CO)$_5$

$Ru(CO)_5$ (**2**) was first unambiguously characterized by Calderazzo in 1967.[9] The compound was obtained by carbonylating $Ru(acac)_3$ in heptane using a H_2/CO mixture. The ensuing heptane solution showed IR absorptions at 2035 and 1999 cm^{-1} from the newly formed pentacarbonyl. On standing, in particular under the action of light, (**2**) reverts to (**1**) with loss of CO, as can be readily monitored with IR spectroscopy (*see Infrared Spectroscopy*). $Ru(CO)_5$ can be prepared as a pure liquid (mp −17 °C) by high-pressure carbonylation of (**1**), but the initially colorless liquid rapidly turns yellow on standing owing to the reformation of (**1**).

The $Ru_3(CO)_{12}/Ru(CO)_5$ equilibrium (equation 1) has been much investigated, and the thermodynamic parameters are presented in Scheme 2.[10] Establishment of the equilibrium is accelerated considerably by using a 2% admixture of H_2 to the CO. The reaction may proceed through one or more carbonyl hydride intermediates (Section 2.1.4). The value of the equilibrium constant suggests that (**2**) is stable at room temperature towards conversion into (**1**) under a few bar of CO. Substitution reactions of (**2**) proceed at or slightly above ambient temperature. ^{13}C NMR chemical shifts as well as ν_{CO} stretching frequencies in $M(CO)_5$ along the series iron, ruthenium, osmium suggest that backbonding from the metal decreases; this correlates with the lower thermal stability of the heavier pentacarbonyls.

$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} + 3CO \underset{< 100°}{\overset{h\nu}{\rightleftharpoons}} \underset{(\mathbf{2})}{3Ru(CO)_5} \qquad (1)$$

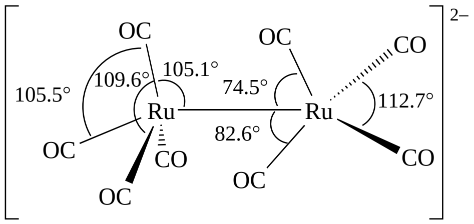
$$K = \frac{[Ru(CO)_5]^3}{[Ru_3(CO)_{12}][CO]^3} = 36.6 \text{ at } 100\ °C;\ 13.0 \text{ at } 175\ °C$$

$$\Delta G^R = 5.12 \text{ kJ mol}^{-1}\ (25\ °C)$$

Scheme 2

2.1.3 Ru$_2$(CO)$_9$

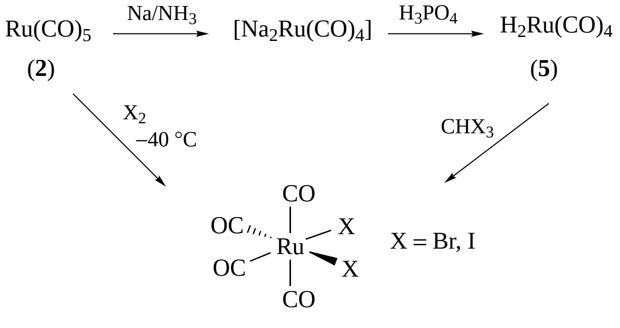
The ruthenium analog (**3**) of $Fe_2(CO)_9$ is obtained as an elusive species through low-temperature UV irradiation of (**2**) in heptane. It loses CO much more readily than (**2**), converting into (**1**) at ambient temperature. Spectroscopic data have been obtained only in mixtures with (**1**), but the presence of a single absorption at 1814 cm^{-1} for bridging CO, along with bands at 2077 and 2018 cm^{-1} for terminal CO, is in accord with a structure similar to the osmium analog with one bridging and eight terminal CO groups. The more stable anion $[Ru_2(CO)_8]^{2-}$ (**4**) has been prepared from treatment of (**1**) with $Na_2[Ru(CO)_4]$; its structure is unique for complexes of this composition. Whereas the iron and osmium analogs show the expected one axial/three equatorial D_{2d} arrangement of CO groups, the structure of the ruthenium anion has only C_s molecular symmetry; the Ru–Ru vector occupies one equatorial position of a trigonal bipyramid (*see Trigonal Bipyramidal*) and one axial ligand of a square pyramid (*see Square Pyramidal*).[11]



(**4**)

2.1.4 Carbonyl Hydrides and Cluster Carbonylate Anions[12,13]

Mono- and Dinuclear Compounds. The pentacarbonyl is a starting material for mononuclear ruthenium carbonyl complexes. As outlined in Scheme 3, reduction with sodium in liquid ammonia yields a pale-colored anion solution (**5**),



(**6**)

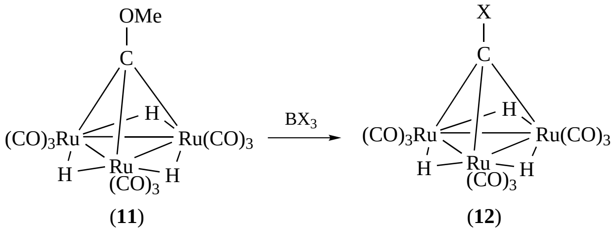
Scheme 3

from which the unstable *cis*-dihydride $H_2Ru(CO)_4$ is obtained by acidification with H_3PO_4. With haloforms, the dihydride converts to the same carbonyl halides (**6**) (Scheme 3) as are obtained from (**2**) with halogen or other halogenation reactions starting from (**1**) (Section 2.1.5).

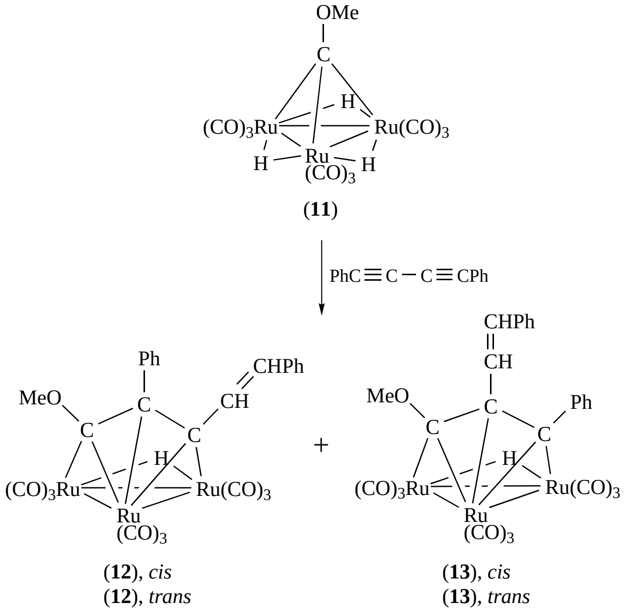
Trinuclear Compounds. A versatile and much-studied compound is the hydrido ruthenium carbonyl anion $[HRu_3(CO)_{11}]^-$ (**7**), which is best obtained by treatment of (**1**) with $NaBH_4$ in THF and isolated as the Me_4N^+ salt.[14] Compound (**7**) has a bridging hydride and a bridging CO across the same edge of the $Ru_3(CO)_{10}$ triangle, which is shorter than the other two. The general trend for bridged metal–metal bond lengths is a shortening by CO bridges and widening by H bridges, where the former obviously has the larger effect in cases where they compete.

Reprotonation of (**7**) with strong acid occurs first at the bridging CO to give an elusive μ-C–OH intermediate that rearranges to the neutral dihydride (**8**) (Scheme 4). This is much less stable than the monoanion and decomposes at ambient temperature to (**1**) and the tetranuclear hydrides $H_2Ru_4(CO)_{13}$ (**9**) and $H_4Ru_4(CO)_{12}$ (**10**).

Tetrahedrane (**11**) is the ruthenium analog of the much-studied tricobaltnonacarbonyl clusters $Co_3(CO)_9CR$ (*see* ***Cobalt: Organometallic Chemistry***). The substitution chemistry of (**11**) has been studied.[15] A starting material is prepared from (**11**) by reaction with BX_3 (equation 2), which gives the chloro and bromo compounds (**12**). In addition, (**11**) can also be treated directly with compounds such as diynes to yield interesting substitution products. For example, when (**11**) is refluxed in THF with diphenylbutadiyne, cis- and trans-alkene isomers of two alkyne insertion regioisomers are formed (equation 3).[16] The product seems to arise from dehydrogenation of one end of the diyne to yield cis and trans enynes and an unsaturated monohydride cluster intermediate, which then reacts with the enynes to yield the allylic derivative products (**12**) and (**13**).

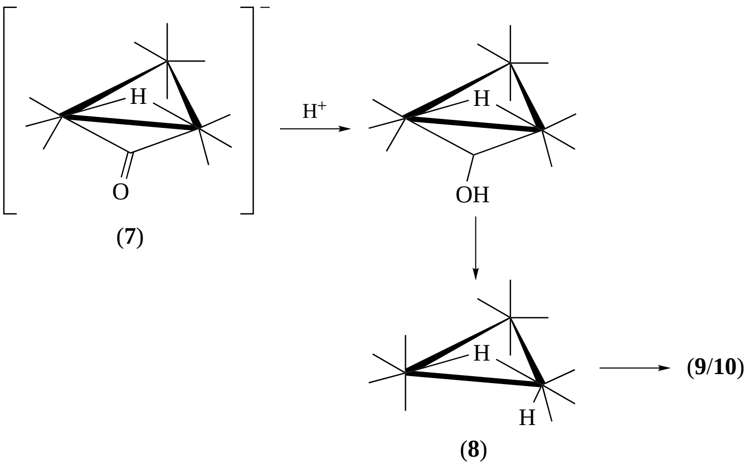


(2)



(3)

The cluster anion (**7**) has been invoked as an intermediate in the water gas shift reaction (*see Water Gas Reaction*) catalyzed by (**1**).[17,18] In the cycle represented by equations (4–6), (**7**) is formed from (**1**) and hydroxide by a reaction that can be



Scheme 4

followed in THF and has been shown to generate CO_2 in this solvent (this is analogous to the well-studied reaction of (**1**) with methoxide). Hydrogen evolution from (**7**) is observed when CO is present, which leads to the assumption of a more easily protonated open-chain intermediate $[HRu_3(CO)_{12}]^-$ that closes the cycle (equation 6).

$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} + OH^- \longrightarrow \underset{(\mathbf{7})}{[HRu_3(CO)_{11}]^-} + CO_2 \qquad (4)$$

$$\underset{(\mathbf{7})}{[HRu_3(CO)_{11}]^-} + CO \longrightarrow [HRu_3(CO)_{12}]^- \qquad (5)$$

$$[HRu_3(CO)_{12}]^- + H_2O \longrightarrow Ru_3(CO)_{12} + H_2 + OH^- \qquad (6)$$

The interest in (**7**) as a hydroformylation (*see Hydroformylation*) catalyst comes from the fact that the unsubstituted (no phosphine ligands) trinuclear anion gives a very high linear/branched ratio of the resulting aldehyde, along with negligible alkene hydrogenation. This result is not easily achieved in other, mostly mononuclear, systems. Furthermore, this was the first system where the integrity of the trinuclear cluster throughout the catalytic cycle was proven;[19] deuteration experiments were used to establish this.

Higher Nuclearity Clusters. The three most thoroughly investigated carbonyl hydrides are $H_2Ru_4(CO)_{13}$ (**9**), $H_4Ru_4(CO)_{12}$ (**10**), and $H_2Ru_6(CO)_{18}$ (**14**). They are prepared by either direct reaction between $Ru_3(CO)_{12}$ and hydrogen, a method that gives the best yields of (**10**), by acidification of anions from alkali reduction of (**1**), or by complex reactions involving (**1**) and various alcohols, ketones, or amines, which induce valence disproportionation (*see Disproportionation*) and CO redistribution. Reaction of (**1**) with ethanol provides ready access to the dihydride (**9**). This in turn can be converted to the tetrahydride (**10**) with hydrogen gas (equation 7).

$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} \xrightarrow{EtOH} \underset{(\mathbf{9})}{H_2Ru_4(CO)_{13}} \xrightarrow{H_2} \underset{(\mathbf{10})}{H_4Ru_4(CO)_{12}} \qquad (7)$$

Treatment of (**10**) with KH in THF effects stepwise deprotonation to a mono- (**15**) and dianion (**16**); excess base gives (**17**) (Scheme 5). When (**1**) is treated with KOH followed by acidification with concentrated sulfuric acid in CH_2Cl_2, the purple neutral hydride (**14**) is produced.[20]

$H_2Ru_4(CO)_{13}$ (**9**) possesses 11 terminal and two semibridging CO groups that both bend towards a common $Ru(CO)_2$ apex. The tetrameric tetrahydride $H_4Ru_4(CO)_{12}$ (**10**) has four bridging hydrogens alongside four longer edges of a distorted tetrahedron. This generates two shorter Ru–Ru distances and a D_{2d} molecular symmetry. The disposition of the CO groups is eclipsed to a triangular face, with one of them *trans* to a nonbridged and two trans to a bridged Ru–Ru edge. Comparison of (**10**) with the structure of $H_2Ru_6(CO)_{18}$ (**14**) shows that the carbonyl orientation is different, with one CO *trans* to an

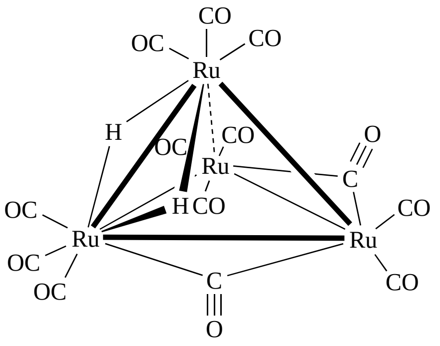
$$\underset{(\mathbf{10})}{H_4Ru_4(CO)_{12}} \xrightarrow[THF]{KH} \underset{(\mathbf{15})}{[H_3Ru_4(CO)_{18}]^-} \xrightarrow[THF]{KH}$$

$$\underset{(\mathbf{16})}{[H_2Ru_4(CO)_{12}]^{2-}} \xrightarrow[THF]{KH} \underset{(\mathbf{17})}{K_4[Ru_4(CO)_{12}]}$$

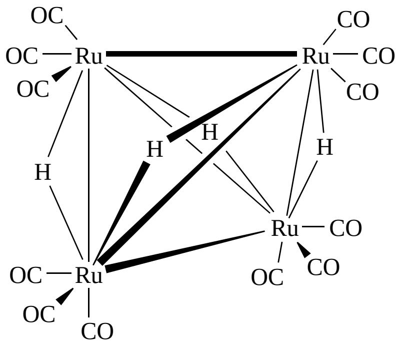
$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} \xrightarrow[THF]{conc.\ KOH} \xrightarrow[CH_2Cl_2]{conc.\ H_2SO_4} \underset{(\mathbf{14})}{H_2Ru_6(CO)_{18}}$$

Scheme 5

octahedral face. This is because the two hydrogens in (**14**) are face bridging, and CO ligands will preferentially locate *trans* to a hydride ligand in accord with the established structural trans effect (*see Trans Effect*).[21]

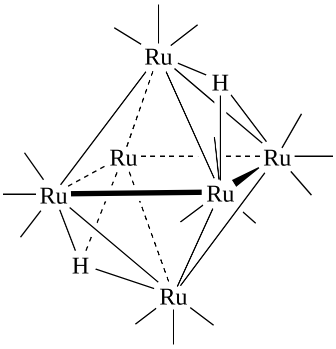


(**9**)



(**10**)

Ruthenium clusters with even higher nuclearity have also been isolated. When (**1**) is refluxed in ethanol for 18 h, the hexaruthenium hydrido complexes $[HRu_6(CO)_{18}]^-$ (**18**) and $[H_2Ru_{10}(CO)_{25}]^{2-}$ (**19**) are produced, along with metallic ruthenium (equation 8). The dihydride complex (**19**) represents the first noncarbido decaruthenium cluster. A trianion with 11 ruthenium centers (**20**) is synthesized by thermolysis of (**1**) in undried acetonitrile (equation 9), and



(**14**)

the relationships between these high-nuclearity ruthenium hydrido carbonyl clusters have been explored.[22]

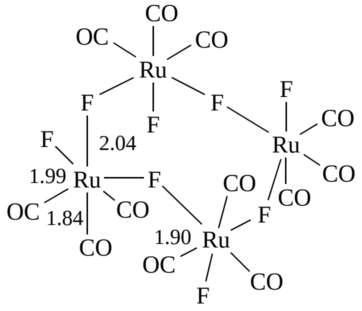
$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} \xrightarrow{\text{EtOH reflux}} Ru^0 + \underset{(\mathbf{18})}{[HRu_6(CO)_{18}]^-} + \underset{(\mathbf{19})}{[H_2Ru_{10}(CO)_{25}]^{2-}} \quad (8)$$

$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} \xrightarrow{\text{MeCN}} \underset{(\mathbf{18})}{[HRu_6(CO)_{18}]^-} + \underset{(\mathbf{20})}{[HRu_{11}(CO)_{27}]^{3-}} \quad (9)$$

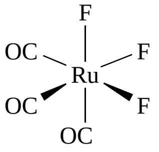
The clusters (**18**), (**19**), (**20**), and $[H_2Ru_8(CO)_{21}]^{2-}$ (**21**) are all products from reacting $Ru_3(CO)_{12}$ under different conditions. (**18**), the major product in the synthesis of all of these complexes, has an octahedral core of ruthenium atoms, with an interstitial hydride. The hydride seems to have some stabilizing effect on the octahedral complex, since all products of higher nuclearity are based on this octahedral framework. As seen in Scheme 6, the structure of the octaruthenium dihydride complex (**21**) resembles an octahedron with an additional Ru_2 unit. Another Ru_2 unit is added to this complex to produce the metal core of the decaruthenium (**19**); and another addition of a single ruthenium gives the core geometry of the undecaruthenium complex (**20**).[22]

2.1.5 Halocarbonyl Complexes of Ruthenium

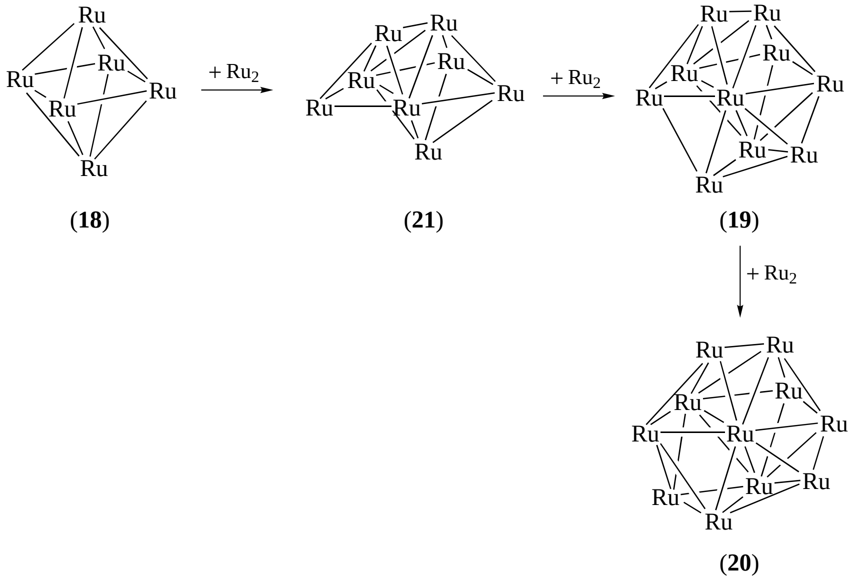
Carbonyl halides of Ru^{II} are readily obtained, are stable for all halides, and thus lend themselves as valuable starting materials for the preparation of other ruthenium complexes, in particular those containing σ-donating ligands. The fluoride derivatives are the most outstanding, as there are few examples of fluorocarbonyl complexes in general. Carbonylation of tetrameric RuF_5 or fluorination of (**1**) with XeF_2 in Freon ($CClF_2CCl_2F$) affords the tetrameric complex $[Ru(CO)_3F_2]_4$ (**22**). It resembles that of $[RuF_5]_4$, in which three fluorine atoms at each ruthenium are replaced by CO. Use of a larger excess of XeF_2 in the fluorination of (**1**) gives the monomeric, paramagnetic Ru^{III} fluorocarbonyl $Ru(CO)_3F_3$ (**23**). Solid-state susceptibility measurements are in accord with one unpaired electron in a low-spin, d^5 configuration.[23]



(**22**)



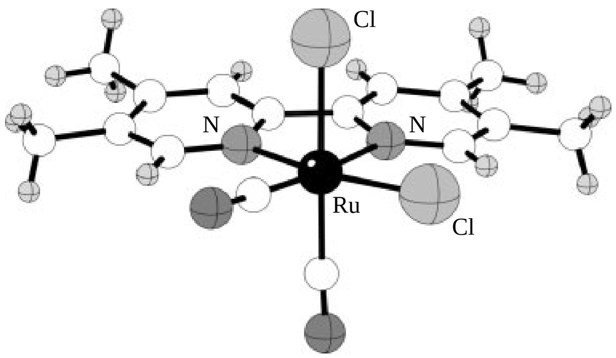
(**23**)



Scheme 6

The main types of halocarbonyl compounds found with the heavier halogens are depicted in Scheme 7. One example has already been presented in Scheme 3. Though methods of preparation other than those shown in Scheme 7 are also successful, reduction with formic acid/hydrohalic acid[24] gives a clear picture of the successive events leading to individual members of the series. Not all compounds listed for chlorine in Scheme 7 can be obtained for bromide and iodine, and in some cases stereoisomers are found with iodine only (cis/trans for $Ru(CO)_4I_2$).

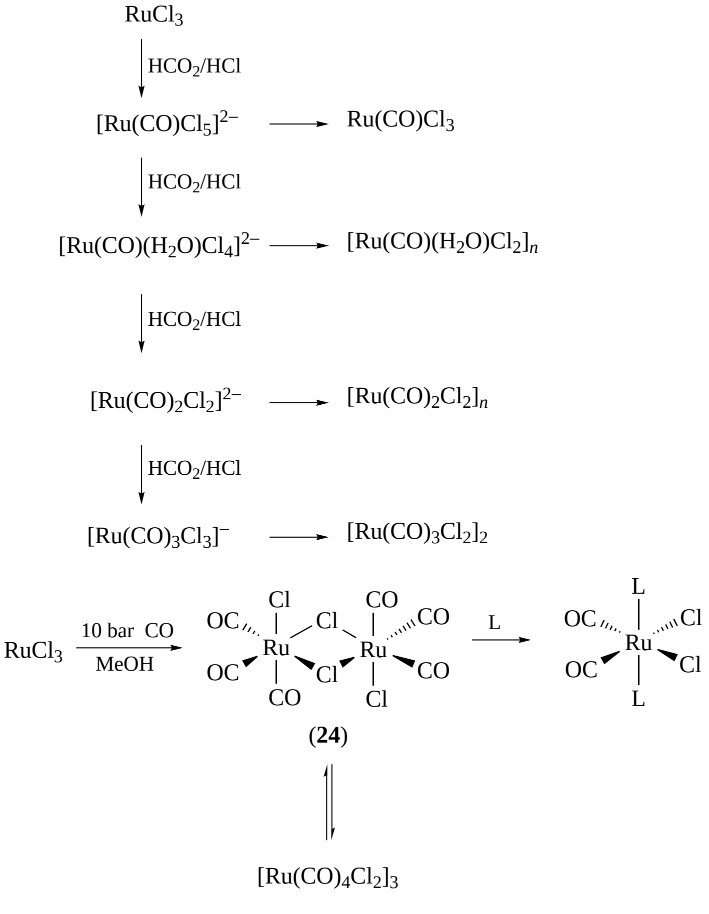
Tetracarbonyl compounds $Ru(CO)_4X_2$ (**6**) (Scheme 3) have a *cis*-octahedral structure, established through an X-ray structure determination of the iodide. The second well-established group of halocarbonyls is dimeric tricarbonyls $[Ru(CO)_3X(\mu\text{-}X)]_2$ (cf. (**24**) in Scheme 7) with C_{2h} symmetry, as determined by X-ray crystallography (*see X-ray Crystallography*). Owing to its easy cleavage with even weak donor ligands (e.g. THF) and substitution to $Ru(CO)_2L_2X_2$, it is a useful starting material for ruthenium carbonyl chemistry. Treatment of (**6**) with an assortment of bidentate ligands has allowed the synthesis of a variety of carbonyl complexes, including $Ru(tmbpy)(CO)_2Cl_2$ (**25**) and $[Ru(dmbpy)(CO)_2Cl]_2$ (**26**). These substituted bipyridine ligands allow for control over the electronic and steric properties of the complex, and the monomeric complexes have been shown to be effective precursors for water gas shift and CO_2 reduction catalysts.[25]



(**25**)

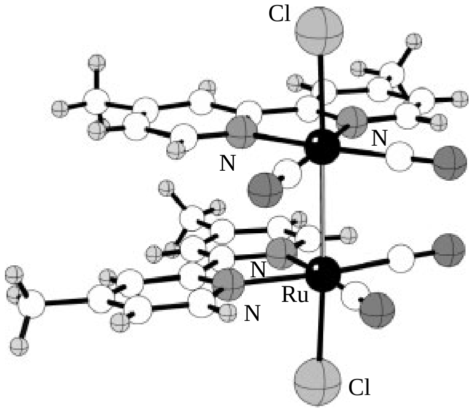
2.1.6 *Carbido and Nitrido Clusters*[13,26]

Several carbido clusters featuring a Ru_5C or Ru_6C core have been described and structurally characterized (*see* ***Cluster Compounds: Inorganometallic Compounds***

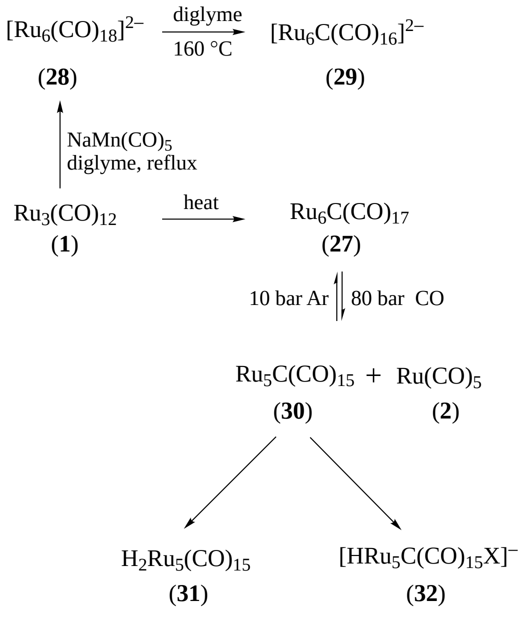


Scheme 7

Containing Transition Metal & Main Group Elements). Pyrolysis of (**1**) in arene solvents gives the carbido carbonyl $Ru_6C(CO)_{17}$ (**27**) together with $Ru_6C(CO)_{14}(\eta^6\text{-arene})$ in low yields (Scheme 8). Carbido clusters are also formed by heating (**1**) with $NaMn(CO)_5$ in refluxing diglyme. Under milder conditions, this reaction has furnished $[Ru_6(CO)_{18}]^{2-}$ (**28**). A brown suspension formed in an early stage of the reaction is believed to be this dianion, which then, on prolonged heating, is converted into red, soluble $[Ru_6C(CO)_{16}]^{2-}$ (**29**). At higher CO pressure, (**27**) is carbonylated to the pentaruthenium carbido carbonyl $Ru_5C(CO)_{15}$ (**30**) with formation of (**2**). Under argon pressure this reaction is reversible. Compound (**30**) is hydrogenated to a dihydride (**31**) or adds HX to give a halo carbido carbonyl (**32**).

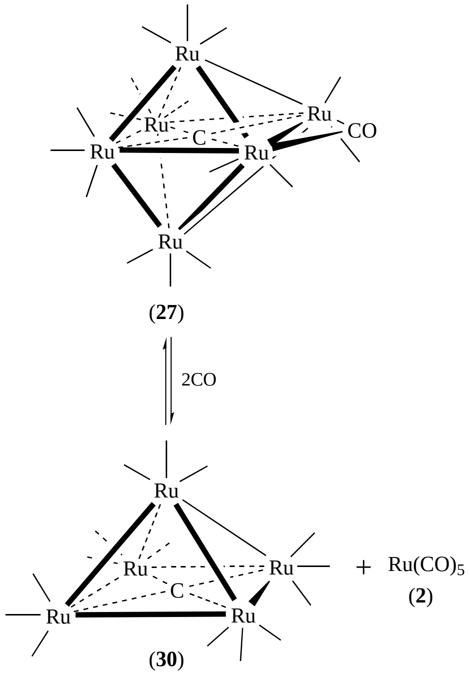


(**26**)



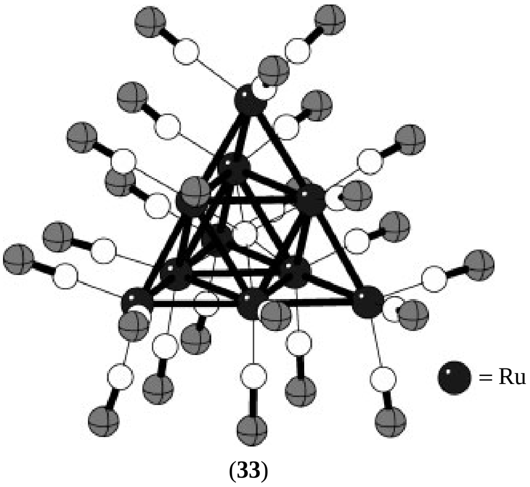
Scheme 8

$Ru_5C(CO)_{15}$ (**30**) is a regular square pyramid with all CO groups terminal and has basically the same structure as the iron and osmium analogs. Interestingly, the nonparallel edges of the pyramid are at a minimum length in the ruthenium (2.3 Å) as compared to the iron (2.62 Å) and the osmium (2.85 Å) congeners. The carbon atom protrudes out of the basal Ru_4 plane by 0.11 Å (equation 10).



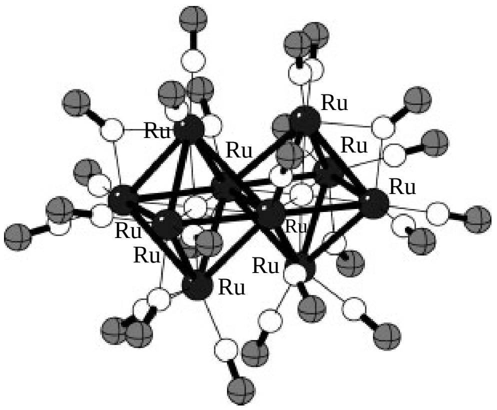
(10)

Homoleptic hepta-, octa-, and nonaruthenium carbido clusters remain unknown. Two structurally similar decaruthenium clusters $[Ru_{10}C(CO)_{24}]^{2-}$ and $[HRu_{10}C(CO)_{24}]^-$ (**33**) were synthesized by treatment of (**1**) with mesitylene.[27] They are isostructural with the osmium analogs. The dicarbido cluster, $[Ru_{10}(C)_2(CO)_{24}]^{2-}$ (**34**), was formed by thermolysis of $[Ru_6(CO)_{18}]^{2-}$ in refluxing diglyme.[28] Synthesis of (**34**) was also accomplished by treatment of (**1**) with an excess of CaC_2.



(**33**)

It is formed by the unusual cleavage of the C_2^{2-} dianion of CaC_2. The core of (**34**) consists of two octahedra that share one edge and each have an interstitial carbido atom.[29]



(**34**)

Nitrido clusters are known with a Ru_4N, Ru_5N, or Ru_6N core. As shown in Scheme 9, treatment of (**1**) with the PPN azide (PPN[N_3]) in THF, followed by evaporation of THF and redissolution in ether, the red complex $[Ru_4(NCO)(CO)_{13}]^-$ (**35**) is produced. One CO in (**35**) is easily displaced by H_2 giving $[H_2Ru_4(NCO)(CO)_{12}]^-$ (**36**), isolated as the PPN salt. Protonation of the latter gives neutral trihydride $H_3Ru_4(NCO)(CO)_{12}$ (**37**) and some nitrogen-free (hydrido)carbonyl by-products. Refluxing (**35**) in THF converts it to the nitride cluster anion $[Ru_4N(CO)_{12}]^-$ (**38**), which in turn can be protonated to the neutral hydride (**39**). The hexaruthenium nitride complex $[Ru_6N(CO)_{16}]^-$ (**40**) is obtained directly from (**1**) and PPN[N_3] in refluxing THF. Carbonylation under slight pressure (20 bar CO) cleaves (**40**) into (**1**) and the pentaruthenium nitrido anion $[Ru_5N(CO)_{14}]^-$ (**41**). Treatment of (**40**) with (**1**) yields the decaruthenium complex $[Ru_{10}N(CO)_{24}]^-$ (**42**) as shown in Scheme 9.

For nitrido clusters, open butterfly structures with a Ru_4 core are observed in (**38**) and the precursor molecules (**35**) or (**37**), where one nitride or isocyanate ligand bridges the open wings of the butterfly. Ru_5N cores, exemplified by $[Ru_5N(CO)_{14}]^-$ (**41**), are of a similar square pyramidal arrangement as Ru_5C clusters. The nitrido atom in the former is displaced out of the basal plane by as much as 0.21 Å (i.e. about twice as much as the carbon atom in (**30**)) making the transition to a distorted octahedron. The decanuclear complex (**42**) exists as a tetracapped octahedron, which is almost indistinguishable from the formally isoelectronic complex $[Ru_{10}HC(CO)_{24}]^-$. The hexaruthenium complex (**40**) has not yet been structurally characterized.

2.2 Substitution at Ruthenium Carbonyls

2.2.1 *Derivatives of $Ru(CO)_5$*

As previously mentioned, monosubstitution of $Ru(CO)_5$ (**2**) is thermally facile, and a range of the usual L-donor ligand substituted products $Ru(CO)_{5-n}L_n$ ($n = 1, 2$) is prepared in this way. If L is a phosphine, it occupies an axial position of the trigonal bipyramid (*see Trigonal Bipyramidal*) (with

$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} + PPN[N_3] \longrightarrow \longrightarrow \underset{(\mathbf{35})}{[Ru_4(NCO)(CO)_{13}]^-} \xrightarrow{H_2/rt}$$

$$\underset{(\mathbf{36})}{[H_2Ru_4(NCO)(CO)_{12}]^-} \xrightarrow{H^+} \underset{(\mathbf{37})}{H_3Ru_4(NCO)(CO)_{12}} (+\ H_4Ru_4(CO)_{12} + H_4Ru_4(CO)_{13})$$

$$\underset{(\mathbf{35})}{[Ru_4(NCO)(CO)_{13}]^-} \xrightarrow{\text{THF reflux}} \underset{(\mathbf{38})}{[Ru_4N(CO)_{12}]^-} \xrightarrow{H^+} \underset{(\mathbf{39})}{HRu_4N(CO)_{12}}$$

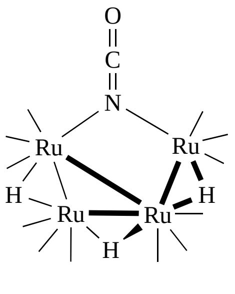
$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} + PPN[N_3] \xrightarrow{\text{THF reflux}} \underset{(\mathbf{40})}{[Ru_6N(CO)_{16}]^-}$$

$$\underset{(\mathbf{40})}{[Ru_6N(CO)_{16}]^-} + 2\,CO \xrightarrow{\text{20 bar}} \underset{(\mathbf{41})}{[Ru_5N(CO)_{14}]^-} + 1/3\ \underset{(\mathbf{1})}{Ru_3(CO)_{12}}$$

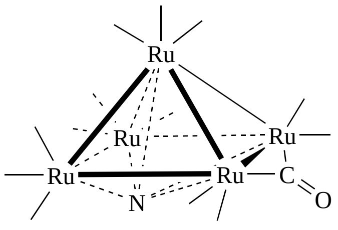
$$\underset{(\mathbf{1})}{Ru_3(CO)_{12}} + \underset{(\mathbf{40})}{[Ru_6N(CO)_{16}]^-} \xrightarrow{\text{diglyme reflux}} \underset{(\mathbf{42})}{[Ru_{10}N(CO)_{24}]^-}$$

Scheme 9

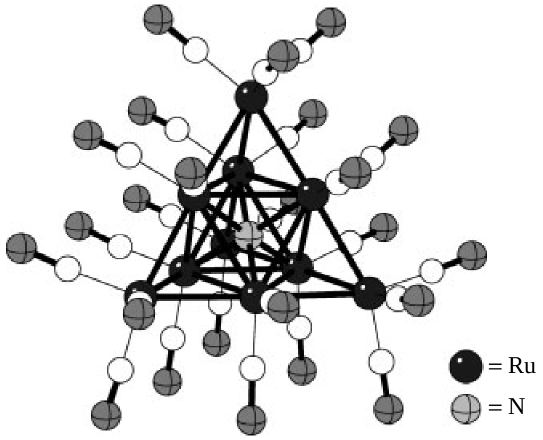
exceptions found in chelating ligands). The preparation of $Ru(CO)_4PPh_3$ (**43**) and $Ru(CO)_3(PPh_3)_2$ (**44**) from (**2**) is shown in Scheme 10 as an example of one of the early studies of its reactivity.[30] Thermal substitution led to the bisphosphine derivative from which the dihydride was obtained under forcing conditions.



(**37**)



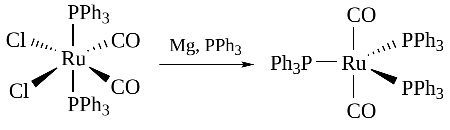
(**41**)



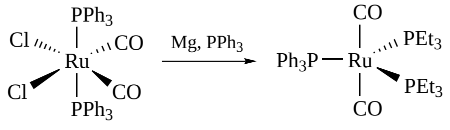
(**42**)

A route to phosphine- and similarly substituted derivatives that avoids the use of ruthenium carbonyl is performed by the direct reaction of hydrated $RuCl_3$ with PPh_3 in alcoholic solution in the presence of a source of CO. This general method consists of the reductive ligation (*see Reductive Ligation*) of the metal in the presence of ligand, notably PPh_3. The extent of reduction, to Ru^{II} or Ru^0 in this case, as well as the ligand set around the metal, depends on the particular conditions. The three complexes $RuHCl(CO)(PPh_3)_3$ (**45**), $RuH_2(CO)(PPh_3)_3$ (**46**), and $Ru(CO)_3(PPh_3)_2$ (**44**) (Scheme 11) are all obtained by the same basic procedure, with differences in alkali presence and reaction duration. $Ru(CO)_3(PPh_3)_2$ (**44**) and $RuH_2(CO)(PPh_3)_3$ (**46**) are active hydroformylation (*see Hydroformylation*) catalysts.[31]

Trisubstituted pentacoordinated complexes with phosphine ligands can be synthesized by reduction of $RuCl_2(CO)_2L_2$ (**47**) with magnesium in the presence of L, where L = PPh_3 (**48**), $PMePh_2$, PEt_3, or P^iPr_2Me (equation 11). The presence of L′ (L′ = PPh_3, P(2-furyl)$_3$, or $AsPh_3$) in the magnesium reduction allows for the synthesis of mixed phosphine derivatives, such as the synthesis of (**50**) from (**49**) in equation (12).[32]

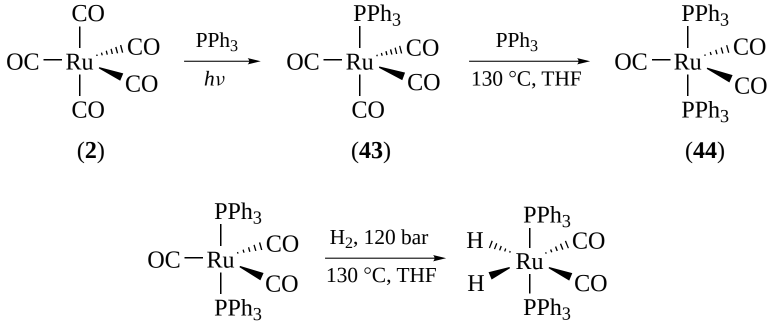


(**47**) (**48**) (11)

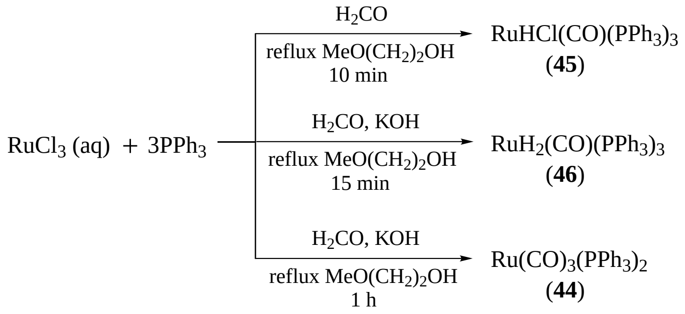


(**49**) (**50**) (12)

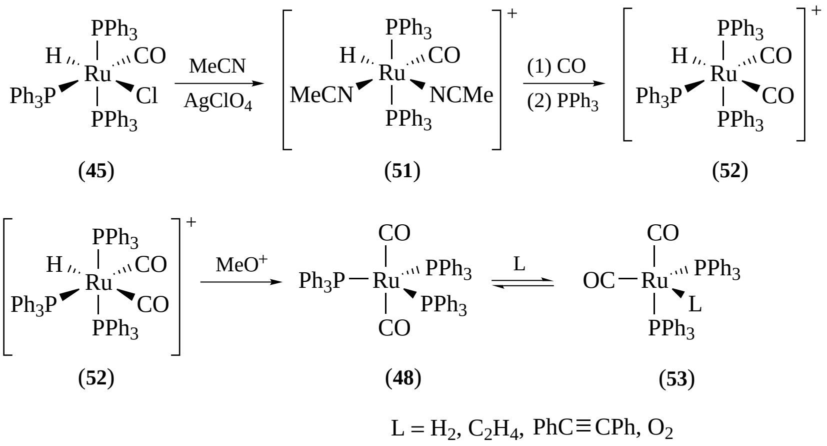
Another method for isolating complexes of the type $Ru(CO)_2L_3$ starts with the (hydrido)carbonyl halide complex (**50**). It can be dehalogenated by Ag^+ in the presence of a stabilizing intermediate ligand (e.g., acetonitrile). The cationic acetonitrile complex (**51**) substitutes easily to give the trisphosphine complex (**52**). Deprotonation of the latter with methoxide gives the neutral *trans*-dicarbonyltrisphosphine (**47**). One of the equatorial phosphine ligands is labile and exchanges with a variety of other ligands to form complexes (**53**), as indicated in Scheme 12. Of particular interest is the dioxygen adduct (**53**) (L = O_2), formed by exposure to



Scheme 10



Scheme 11



Scheme 12

oxygen. It can function as an oxygen transfer agent or as a catalyst in oxygenation reactions.

2.2.2 *Derivatives of $Ru(CO)_4X_2$*

A second large class of mononuclear ruthenium complexes is those formally derived from $Ru(CO)_4X_2$,that is, six-coordinated Ru^{II}. The synthesis often involves cleavage of carbonyl halide complexes or carbonyl phosphine halide complexes, which are directly obtained from $RuCl_3$ with a potential reducing agent and a CO donor, such as formic acid, in the presence of phosphine. The variation of ligands accommodated at a ruthenium center in these complexes is enormous, and is a characteristic of the general stability of octahedral low-spin d^6 complexes of the heavier transition metals. The high ligand field stabilization of Ru^{II} enables combinations of such π-acceptor ligands together with even the hardest σ-donors, such as carbonate, sulfate, or nitrate.[4] Ru^{II} carbonyl and phosphine complexes are known with myriad coligand combinations, having O (oxoanions mentioned, carboxylates, quinones), N (amines, amides, hydrazines, hydrazides, triazenes, formamidates, ureas), or S (thiocarbonyls, CS_2, thio- and dithiocarbonates, carbamates, thiophosphinates, thiophosphates) binding functionalities.

2.2.3 *Derivatives of $Ru_2(CO)_9$*

Although the parent carbonyl $Ru_2(CO)_9$ is virtually unknown, a number of complexes derived by substituting various CO groups of the dinuclear unit for one- or two-electron ligands are of interest owing to some unique transformations they exhibit. The syntheses of these materials begin with (**1**), which is cleaved by the appropriate ligands or reagents.

By treating (**1**) with hydrides $HE^{IV}R_3$ (E^{IV} = Si, Ge, Sn, Pb), Knox obtained the σ-$E^{IV}R_3$ derivatives $Ru(CO)_4(E^{IV}R_3)_2$ and $[Ru(CO)_4(E^{IV}R_3)]_2$,[33] the latter with a long unbridged Ru–Ru single bond, formally analogous to $Mn_2(CO)_{10}$ (*see* ***Manganese: Organometallic Chemistry***), and with some similarities in their reactivity pattern owing to the ready cleavage of the metal–metal bond in both complexes. Reactions were studied with cycloalkenes and are partly outlined in Section 3.3.

A system lacking π-ligands is obtained by cleavage of (**1**) with certain bisphosphines $R_2P–E–PR_2$, which lead to

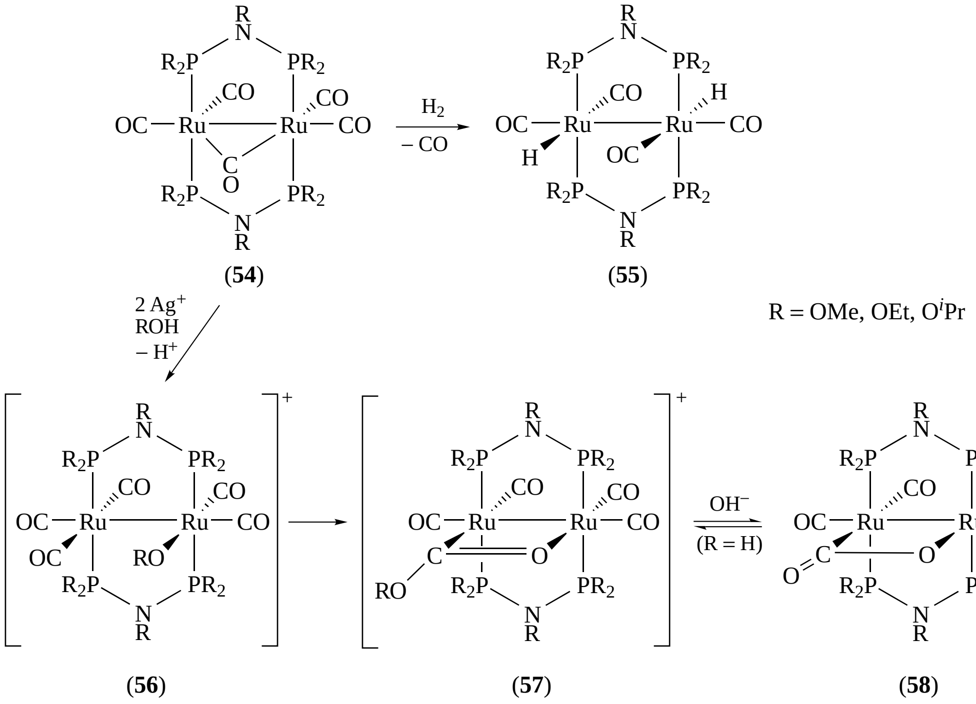
complexes $Ru_2(CO)_4(\mu\text{-}CO)(\mu\text{-}R_2P\text{–}E\text{–}PR_2)_2$ (**54**). These are formally related to $Ru_2(CO)_9$, in that four carbonyl groups are replaced by two bridging phosphines. A Ru–Ru bond is required to adjust the metal to the 18 valence electron rule (*see Eighteen Electron Compounds*), but this can be readily opened and closed in the course of substitution reactions when the so-called ‘A-frame’ is tightly held together by bridging phosphines. Moreover, the bridging carbonyl group is easily displaced to generate coordinatively unsaturated ruthenium centers, such as its replacement by hydrogen to give (**55**) (Scheme 13).[34] An intriguing case is provided if Ag^+ oxidation of (**54**) is followed by deprotonation. The resulting alkoxo (hydroxo) complex (**56**) rearranges by CO insertion to an η^2-formate or formic acid complex (**57**). This latter can be deprotonated to yield a complex with a $\mu_2 - \eta^2\text{-}CO_2$ bonding arrangement (**58**), an unusual bonding situation for CO_2 (Scheme 13).[35]

The reactions of an analogous A-frame type complex $[Ru_2(CO)_4(\mu\text{-dppm})_2(\mu\text{-}O_2CMe)]^+$ (**59**) have been studied extensively and are outlined in Scheme 14. When (**59**) is treated with $[Et_3O][BF_4]$ in MeCN, the dication (**60**) is formed, which readily converts to (**61**). Reaction of (**61**) with excess of an anion yields coordinatively unsaturated complexes instead of the expected substitution products $[Ru_2(\mu\text{-}CO)_2(\mu\text{-dppm})_2X_4]^{2-}$. The bond between the ruthenium centers is single, while the Ru–X bonds are multiple, probably double, as indicated by bond distances and angles in the crystal structure.[36] An interesting rearrangement occurs when (**59**) is treated with a bidentate ligand such as acetate, bpy, acac, or 8-quinolate (quin). The product is a complex with bridging carbonyls, where the new ligand binds in a bidentate fashion to only one of the ruthenium atoms and the acetate ligand migrates to a the opposite ruthenium (**62**). When a second equivalent of the bidentate ligand is added, the acetate is replaced to form (**63**).[37]

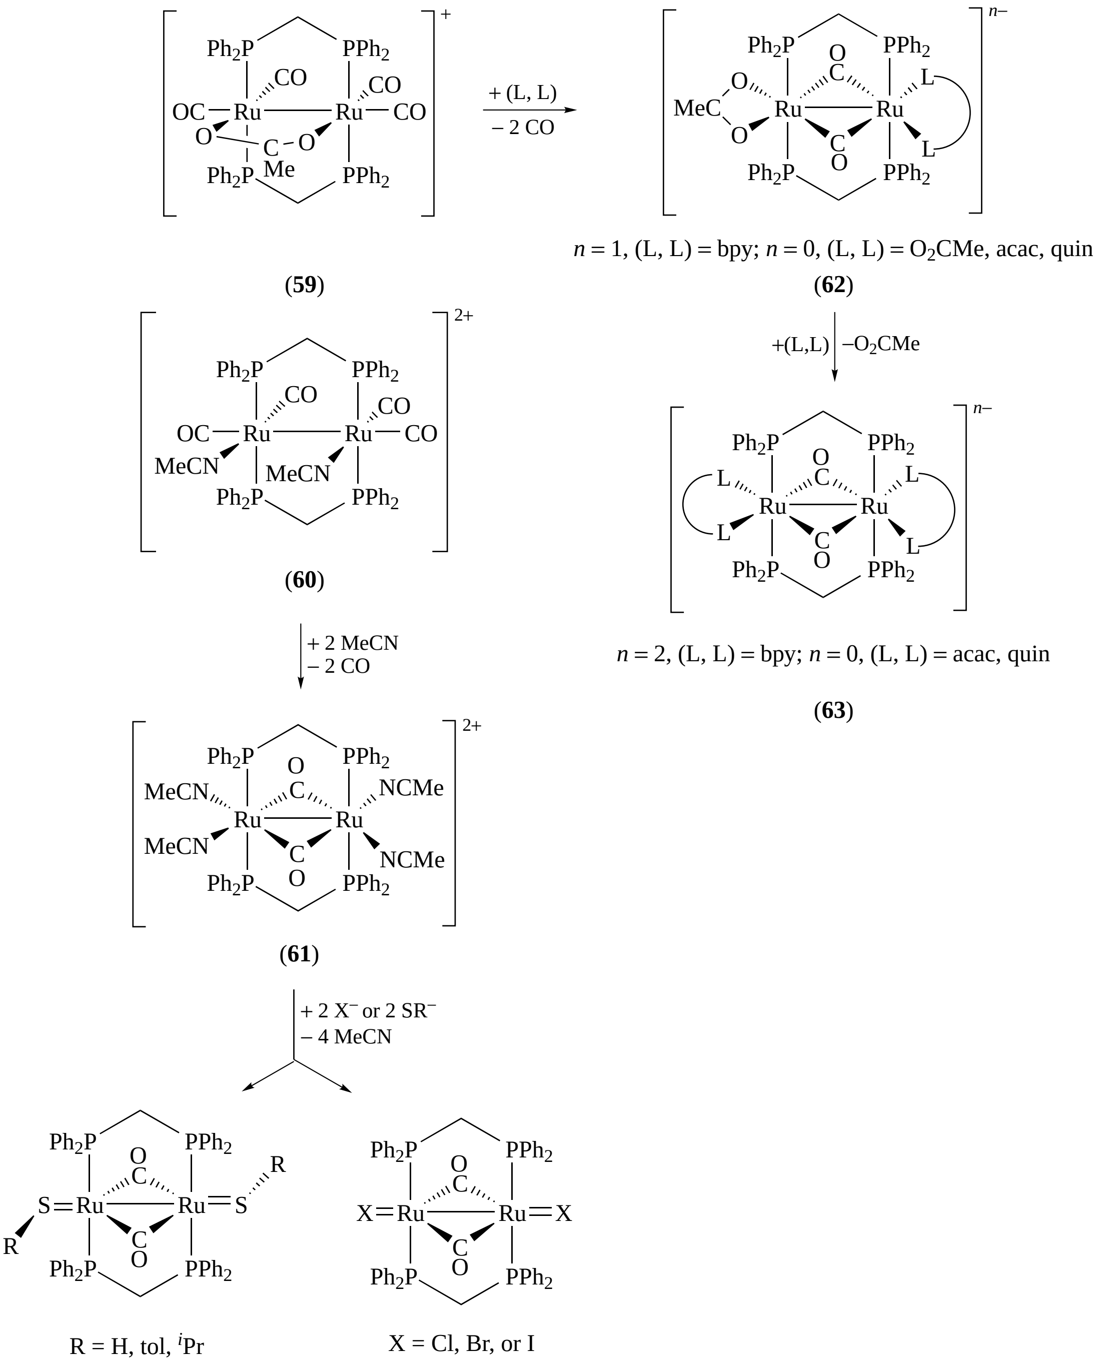
2.2.4 *Derivatives of $Ru_3(CO)_{12}$*

Substitution at (**1**) has been investigated extensively from a preparative as well as a mechanistic point of view, and most common substitution techniques, including photochemical activation and electron-transfer catalysis, have been employed. Simple thermal substitution leads to a mixture of products, but with special methods, up to 6 of the 12 CO ligands can be replaced without cleaving the trinuclear unit.

Numerous studies of photochemical substitution at (**1**) have been performed.[38] As observed for other polynuclear carbonyls, the photochemistry (*see Photochemistry*) of (**1**) is wavelength dependent. Irradiation at longer wavelength (close to the absorption maximum at 392 nm) presumably gives metal–metal bond cleavage as the primary photoevent, whereas short-wavelength irradiation around 300 nm effects clean CO substitution. At the longer wavelength there is mostly photofragmentation into mononuclear species, whereas at the shorter wavelength if any net change is observed then cluster substitution prevails. Photolysis of (**1**) at 405 nm under 1 atm CO, for example, quantitatively gives (**2**) with a solvent-dependent quantum yield of 0.028 mol einstein^{-1} in isooctane

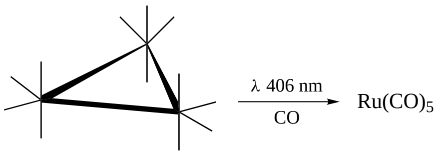


Scheme 13



Scheme 14

(equation 13).



(13)

(**1**) (**2**)

The synthesis of triruthenium derivatives via thermal substitution at (**1**) is complicated by the frequent formation of product mixtures. Thus, on heating (**1**) with a phosphine, phosphite, or a related Lewis basic ligand (*see Lewis Acids & Bases*), L, the products are either trinuclear tris- or bis-substituted complexes ($Ru_3(CO)_9L_3$ and $Ru_3(CO)_{10}L_2$), or mononuclear complexes (mostly $Ru(CO)_3L_2$), and often mixtures thereof. It appears that the first substitution

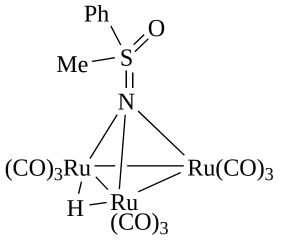
step is the slowest, so the major product tends to be $Ru_3(CO)_9L_3$. A second problem with thermal substitution is the high temperatures that must be reached for substitution to occur.

A better approach to substitution at (**1**) is the use of catalytic routes. Induction with Me_3NO has proved successful for (**1**) in some cases, but of particular value for a clean reaction with (**1**) was electron-transfer catalyzed substitution using Ph_2CONa in low concentration as a reductive activator. The likely intermediate is the 49-electron species $[Ru_3(CO)_{12}]^-$, which quickly reacts to form $[Ru_3(CO)_{11}L]^-$. Electron-transfer occurs again to form $Ru_3(CO)_{11}L$ and to regenerate $[Ru_3(CO)_{12}]^-$ to repeat the cycle. The same type of reaction cycle can be induced with [PPN]X, where X = acetate, cyanide, or halides. The $[PPN][Ru_3(CO)_{12-n}X]$ ($n = 1, 2, 3$) species is the intermediate, and X is displaced by the appropriate ligand to obtain the substitution product.

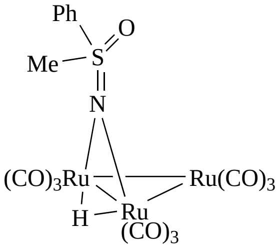
The degree of substitution is determined by the initial ratio of (**1**) to ligand, and up to three (or in one instance, four) CO groups are replaced straightforwardly. This method can be employed sequentially, allowing for the preparation of mixed-ligand clusters. More forceful conditions must be employed to replace more CO ligands.

As a characteristic feature of (**1**), carbonyl substitution, even with some phosphines, is often accompanied by E–H, C–H, or even C–C bond cleavage; the substitution products are trinuclear or dinuclear units with bridging – ER groups and bridging hydrogen. Furthermore, CO groups in (**1**) are susceptible to nucleophilic attack by protic agents if a hydride bridge can be formed via a hydrogen shift. Thus, as given in Scheme 15, primary amines either add to a CO to give a formamidoyl bridge, as in (**64**), or just add across one Ru–Ru bond, substituting two CO groups, as with aniline in (**65**).[39] The adjacent functionalities NHR and CO are able to bridge a face of the triangle along with the formation of hydride bridges.[40]

Treatment of (**1**) with methylphenylsulfoximine (MePhS(O)NH) in THF yields the cluster $(\mu^2\text{-H})Ru_3(CO)_9[\mu^3\text{-NS(O)MePh}]$ (**66**). The product isolated is either enantiomerically pure or a racemic mixture, depending on whether (**1**) was reacted with optically pure or racemic starting material. Reversible carbonylation of (**66**) produces the cluster $(\mu^2\text{-H})Ru_3(CO)_9[\mu^2\text{-NS(O)MePh}]$ (**67**). Both of these optically active trinuclear clusters have potential as catalysts for enantioselective reactions.[41]



(**66**)



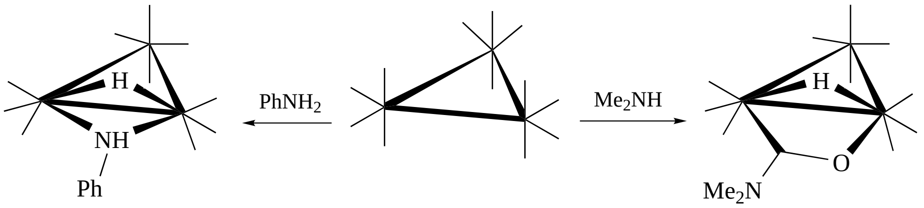
(**67**)

Reaction of (**1**) with α,β-diimines (such as Diazadienes (dad)) (Scheme 16) occurs mostly through the nitrogen atoms with some acceptor character imposed by the diene system. Products of the reaction of (**1**) with dad depend on the substituents on dad and on the reaction conditions. In contrast to the mononuclear complex $Ru(CO)_3$dad (**68**) and trinuclear $Ru_3(CO)_8$(dad) (**69**), where dad acts as an eight-electron ligand analogous to the iron congener, the dinuclear complex $Ru_2(CO)_6$(dad) (**70**) is obtained in which dad is coordinated in an unusual σ-/π-mode through both nitrogens and one carbon, thereby acting as a six-electron ligand.

3 ALKENE AND CYCLOALKENE COMPLEXES

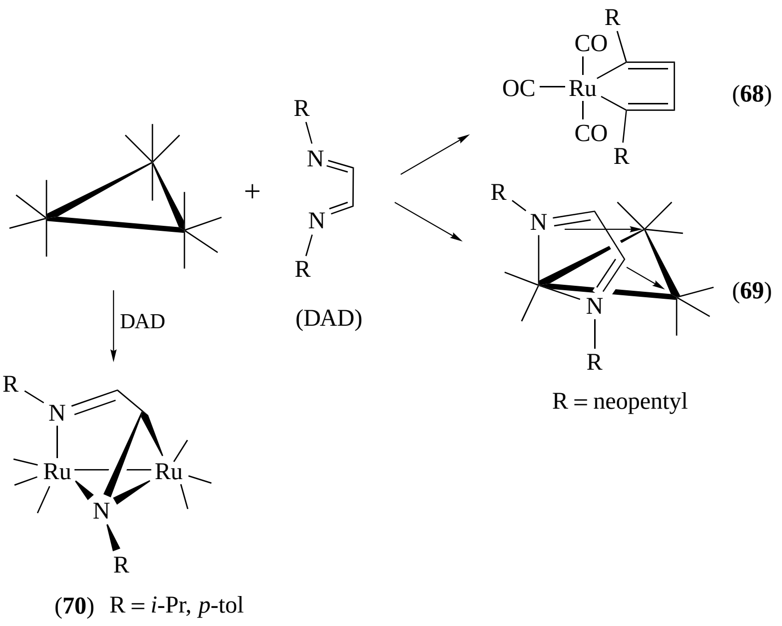
3.1 Alkene Complexes of Ru^II^

Ruthenium complexes of alkenes, dienes, or cyclodienes in oxidation states 0 and II are known. From a preparative view, an important class of compounds is the oligomeric or polymeric complexes of composition $[(dialkene)RuX_2]_n$, which often serve as reagents for further transformations. Their synthesis is similar to the procedure that has been detailed for phosphine complexes; that is, when $RuCl_3$(aq) is refluxed in alcohol in the presence of the diene, an insoluble brown to orange oligomeric complex is deposited. However, the use of



(**65**) (**1**) (**64**)

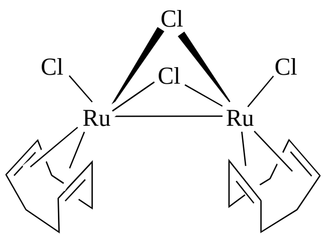
Scheme 15



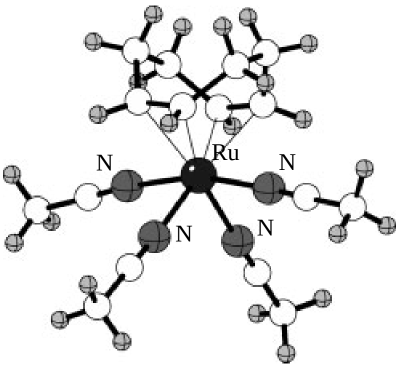
Scheme 16

cyclohexadiene produces the oligomer $[(C_6H_6)RuCl_2]_n$ (see Section 6.3). Because these polymers are formed in high yield directly from commercially available $RuCl_3$, this method is one of the best entries into organometallic ruthenium chemistry and is valuable in many cases where reaction of $Ru_3(CO)_{12}$ leads to product mixtures or is unsuitable for other reasons. The oligomers are cleaved by various donor ligands, L, notably amines or nitriles, to form soluble ionic or molecular monomers, ranging in composition from $[(diene)RuLX_3]^-$ to $(diene)RuL_2Cl_2$ and $[(diene)RuL_4]^{2+}$.

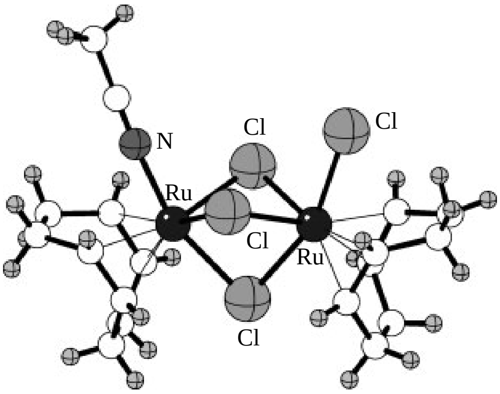
A soluble dimer $[Ru(cod)Cl_2]_2$ (**71**), having the same formula as the insoluble polymer, has been isolated as a product from the reductive complexation of cod to ruthenium by Zn in EtOH/THF. The compound has been structurally characterized, and the Ru–Ru distance of 2.791 Å in this compound is in the range found for Ru–Ru single bonds, whereas a double bond would be required to satisfy the effective atomic number rule (*see Effective Atomic Number Rule*).[42]



(**71**)



(**72**)

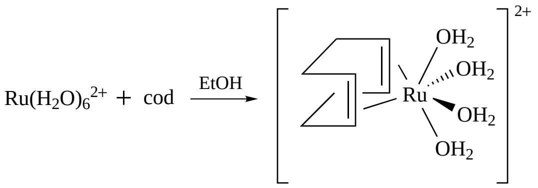


(**73**)

Refluxing (**71**) in cod and acetonitrile yields the monomeric complex $[(cod)Ru(CH_3CN)_4]^{2+}$ (**72**), which is useful in the synthesis of a variety of organometallic complexes owing to facile substitution of the acetonitriles.[43] Through

a different synthetic method, a chloride-bridged diruthenium acetonitrile complex (**73**) is isolated. It was formed by reaction of (cod)Ru(cot) with naphthalene, followed by addition of acetonitrile. Compound (**73**) consists of two Ru^{II} centers with octahedral geometries. The complex undergoes two reversible one-electron oxidations, which is in contrast with other dimeric Ru^{II} complexes of this type.[44]

Another class of ruthenium alkene complexes contains those derived from the hexaaqua ion $[Ru(H_2O)_6]^{2+}$. The thermodynamically stable complex $[(cod)Ru(H_2O)_4]^{2+}$ (**74**) forms directly from $[Ru(H_2O)_6]^{2+}$ and cod in alcohol at ambient temperature (equation 14). In (**74**), the redox potential of Ru^{II} has shifted more positive for the oxidation to Ru^{III} and more negative for the reduction to Ru^{I} or Ru^{0}, so as to impose a high stability towards disproportionation (*see Disproportionation*) (in contrast to the readily disproportionating aqua ion $[Ru(H_2O)_6]^{2+}$). The X-ray crystal structure (*see X-ray Crystallography*) of the Tosylate $(Ots)^-$ salt disclosed quite different R–OH_2 distances of 2.095(2) and 2.156(2) Å for water *gauche* or trans to the alkene double bond, showing the structural trans effect (*see Trans Effect*) of the latter on a σ- (and π-) donor ligand trans to it.[45]



(14)

(**74**)

3.2 Alkene Complexes of Ru^0

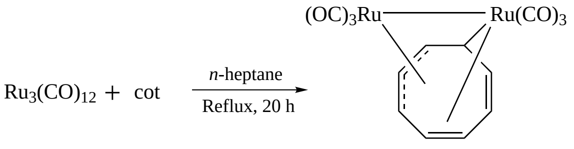
Mononuclear carbonyl alkene complexes of Ru^0 exhibit moderate to low stability. The same is true for carbonyl phosphine complexes with unsubstituted alkenes, such as $Ru(CO)_2(PPh_3)_2(C_2H_4)$. An entry into the substitution chemistry of carbonyl alkene complexes is the thermal preparation of $(cod)Ru(CO)_3$ by refluxing (**1**) and cod in benzene. Isolation of the pure product requires double chromatography of a nearly colorless material of low-melting point and gives the product in about 60% yield.[46] Facile exchange of the cod ligand for conjugated dienes occurs in high yield.

A versatile reductive complexation method that leads directly to cycloalkene Ru^0 complexes consists of treatment of $RuCl_3$ with activated Zn in ethanol or methanol (or mixtures with THF) in the presence of an alkene (Scheme 17).[47,48] Starting from a diene, a dehydrogenation is required to provide the metal with 18 valence electrons (*see Eighteen Electron Compounds*), and this is accomplished by hydrogenating one of the cycloalkenes to a monoalkene, which as the weakest ligand is replaced by another diene. An extension of this method was found by prolonged refluxing of $RuCl_3$ in ethanol in the presence of Cyclooctatetraene (cot). The product was the insoluble oligomer $[(C_8H_{10})RuCl_2]_n$, where the cot ligand was hydrogenated to form cyclooctatriene. The same procedure also gives the analogous cycloheptatriene complexes.

3.3 Diene and Cyclodiene Complexes Derived from $Ru_3(CO)_{12}$

Simple alkene complexes, where one alkenic group replaces a carbonyl in (**1**) or (**2**) are unstable, as already stated, and have been characterized only in solution. For example, the monoethylene complex $Ru(CO)_4(\eta\text{-}C_2H_4)$ can be made photochemically in solution by irradiating (**1**) or (**2**) in the presence of an excess of ethylene. This compound decomposes below room temperature but its stability is enhanced in the presence of excess CO; presumably CO dissociation is the initial step of the decomposition. The compound serves as an intermediate for the preparation of more stable alkene complexes from electron-deficient alkenes by simple exchange at low temperature in solution. $Ru(CO)_4(\eta\text{-alkene})$ complexes with electrophilic alkenes can also be isolated from $Ru(CO)_4(\eta\text{-}C_2H_4)$ in this way.

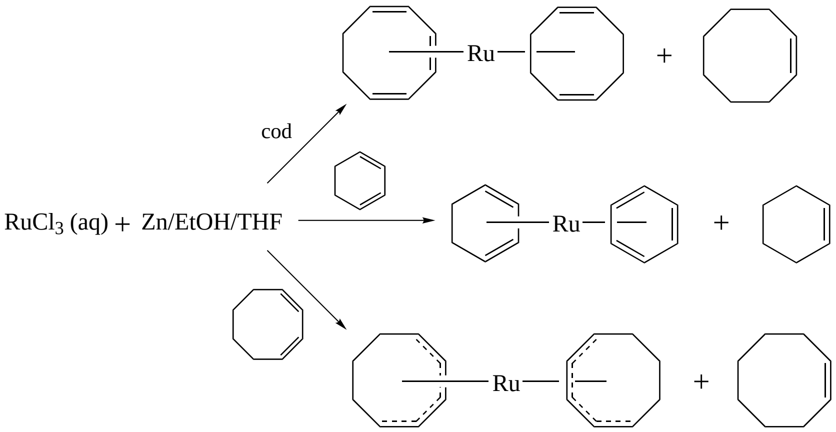
A number of mono-, di-, and trinuclear carbonyl cycloalkene complexes derived from (**1**) have been prepared and studied, some in considerable detail owing to interesting modes of fluxionality of the cyclopolyene ligand. Reaction of $Ru_3(CO)_{12}$ with cycloalkenes gives products in which the triangle of ruthenium atoms is preserved and those in which it is cleaved into mono- and dinuclear units (e.g., (**75**) in equation 15). Products can also form by increasing the number of metal centers, such as the reaction of $Ru_3(CO)_{12}$ with C_8H_{14}, which forms the trinuclear cluster $[H_2Ru_3(CO)_9(\mu^3\text{-}\eta^2\text{-}C_8H_{12})]$ and the hexanuclear carbido-cluster $[Ru_6C(CO)_{15}(\mu^3\text{-}\eta^2\text{-}C_8H_{12})]$.[49]



(15)

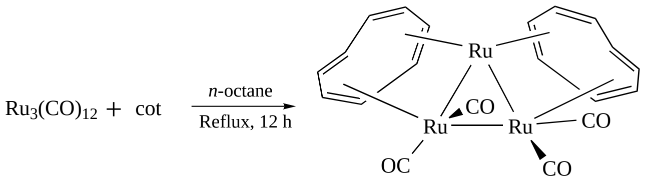
(**1**) (**75**)

Like all complexes of this type, (**75**) is fluxional (*see Fluxional Molecule*) at ambient temperature with respect to the cot ligand. The low-temperature limiting spectrum of (**75**) is in accord with the solid-state structure as inferred from the analogous iron compound that had been determined by X-ray analysis (*see X-ray Crystallography*), showing one allylic and one 'en-ylic' bound $Ru(CO)_3$ group with an interposed, noncomplexed double bond. This bonding mode is characteristic for many metal fragments coordinated to cot, cyclooctatriene, or other cyclotrienes.[50]



Scheme 17

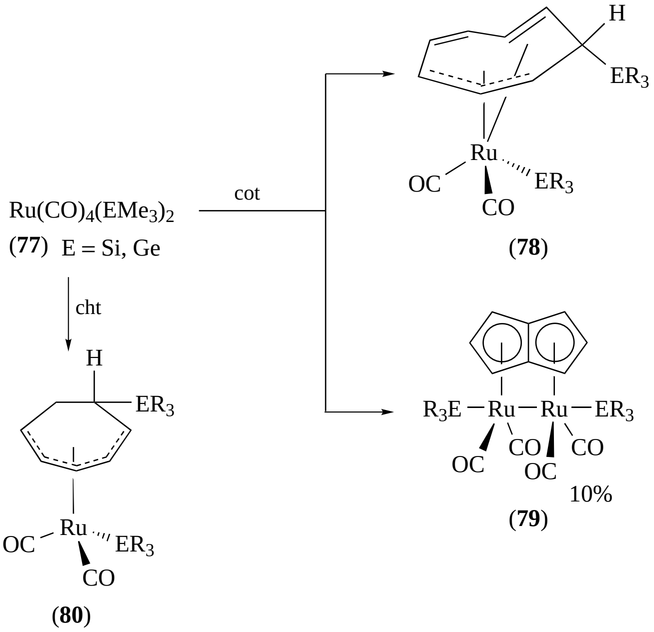
Of particular interest is the bis(cot) compound (**76**) formed from reaction of $Ru_3(CO)_{12}$ and cot in *n*-octane reflux (equation 16). This molecule is fluxional (*see Fluxional Molecule*) at room temperature and below. A solid-state structure determination[51] established the near C_2 molecular symmetry (a C_2 axis passing through the carbonyl-free ruthenium atom and intersecting the opposite Ru–Ru vector). Only one enantiomer of the chiral molecule was found in the crystal, thus spontaneous resolution had occurred during crystallization (this could be accomplished by interconversion of enantiomers through the interchange of CO groups). One ruthenium atom is complexed only to alkenes, and the Ru–Ru distances to the other two metal atoms are longer than the bond between the two $Ru(CO)_2$ groups. Since the alkene is a weaker π-acceptor (*see π-Acid Ligand*) compared to CO, it takes less electron density out of the metal–metal antibonding HOMO.



(**1**) (**76**)

(16)

In addition to hydrogen shifts, ring contraction is observed in reactions of cycloalkenes with ruthenium carbonyl centers containing E^{IV} ligand derivatives $Ru(CO)_4(ER_3)_2$ (**77**) and $[Ru(CO)_4ER_3]_2$. Heating of either (**77**) or $[Ru(CO)_4ER_3]_2$ with cot gives a mixture of two complexes (**78**) and (**79**) (Scheme 18), the latter in most cases in low yield.[52] In (**78**) one of the substituent groups ER_3 ($GeMe_3$ or $SiMe_3$) has migrated to the cot ring and is found stereospecifically in the *endo* position. For cot as the ligand, complexation is through an allyl fragment and an isolated double bond as shown in (**78**), leaving one uncomplexed double bond in between,



Scheme 18

whereas for the complex derived from cycloheptatriene (cht), a conjugated dienyl system is formed, as in (**80**).

The second major reaction product from the reaction of cot with (**77**) is the dinuclear complex (**79**) with a coordinated pentalene ligand (C_8H_6) that is highly unstable as a free hydrocarbon. In (**79**), the pentalene ligand has lost its substituent; however, since the pentalene complex can be generated from (**78**) in somewhat higher yield (about 30%) than in the direct reaction between (**77**)/$[Ru(CO)_4ER_3]_2$ and cot, it seems that (**78**) is an intermediate in the formation of (**79**). The ER_3 group appears to be a necessary prerequisite for dehydrogenative ring contraction. The exact mechanism of this reaction is not known.

4 RUTHENOCENE

4.1 General Properties and Preparation

The sandwich complex ruthenocene, $RuCp_2$ (**81**), is more stable than its iron analog ferrocene (*see Ferrocene*). With a decomposition temperature around 600 °C, ruthenocene is among the most stable organometallic compounds known. Similarities to ferrocene not only include structural features but also reactivity, such as facile electrophilic substitution at the cyclopentadiene ring. As a substituent, the ruthenocenyl group $RuCp(C_5H_4)$ (Rc) is slightly less electron releasing than ferrocene ($\sigma_p - 0.05$ vs. -0.10 for ferrocene), but in direct metal–R interactions ruthenium forms stronger bonds. Thus, protonation of ferrocene with strong acids has yielded spectroscopic evidence for metal protonation at low temperature and rearrangement to a 16 valence electron $CpFe^+$ cation, whereas metal-protonated ruthenocenium cations, in particular those derived from penta- and decamethylruthenocene are readily isolated as salts.[53]

The common metathesis reactions for the preparation of metallocenes, treating a metal salt MX_2 with NaCp, are hampered in the case of ruthenium by the lack of suitable Ru^{II} salts. (RuI_2 is commercially available, but is still not commonly used in the synthesis of ruthenocene.) Thus, ruthenocene has been obtained from $Ru(acac)_3$ and NaCp in very low yield[1,54,55] and later from $RuCl_3$ and NaCp in 50–60% yield. It has now become apparent that alkene polymers, in particular $[Ru(nbd)Cl_2]_x$, but also $[Ru(cod)Cl_2]_x$ and hydrazine derivatives (Section 3.1), can serve as Ru^{II} precursors.[56] Equally successful in many cases is reductive complexation of cyclopentadiene in ethanol in the presence of Zn (Section 3.2), which furnishes the metallocene in about 80% yield. Decamethylruthenocene (**82**) was first obtained by the Zn reduction route in 20% yield,[57] but can now be prepared conveniently from halide complexes $[Cp^*RuCl_2]_2$[53] or $[Cp^*RuCl]_4$, a common method for the preparation of symmetrical and unsymmetrical sandwich compounds of ruthenium featuring one alkyl-substituted ligand.

4.2 Structure

The molecular and crystal structure of (**81**) is simpler than that of ferrocene as only one polymorph featuring eclipsed conformation of the cyclopentadienyl rings, has been found at ambient and low (100 K) temperature. The larger metal–carbon distance (2.186 Å in (**81**) vs. 2.03 or 2.06 Å in ferrocene) corresponds to the larger metal covalent radius (*see Covalent Radii*) and may also be responsible for the fact that an eclipsed conformation is found for the solid-state structure of decamethylruthenocene (**82**),[56] as opposed to decamethylferrocene where more closely spaced methyl groups impose the staggered D_{5d} conformation.

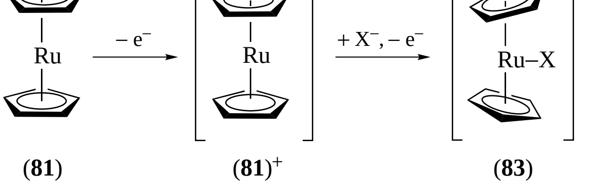
4.3 Redox Reactions and Bent Metallocenes (*see Bent Metallocenes*): $RuCp_2X^+$

Like ferrocene, ruthenocene is stable to reduction, and no anion or controlled reductive cleavage has yet been reported. One of the major differences between ruthenocene and ferrocene is their behavior in oxidation reactions. The facile and reversible one-electron oxidation of ferrocene is used as the principal electrochemical standard in nonaqueous solvents.[58] In contrast, an apparently irreversible two-electron oxidation of ruthenocene occurs under all but the most selective conditions. This behavior, at first sight in disagreement with the tendency of the heavier transition metals to stabilize higher oxidation states, is rationalized by considering the nature of the ^2E (d_{xy}) ground state of the radical cation (as proved by EPR (*see Electron Paramagnetic Resonance*)) for the cation $(\mathbf{82})^+$.[57] Since there is increasing ligand character in the degenerate $d_{xy}/d_{x^2-y^2}$ orbital pair with the 4d and 5d transition metals, single occupancy of these levels causes higher chemical reactivity.

For ruthenocene, the subsequent reaction (Scheme 19) is addition of a nucleophile (*see Nucleophile*) to the metal center. Generally, the nucleophile is a halide (X^-), but it can be mercury from a mercury electrode; a second oxidation then gives the cations $[RuCp_2X]^+$ (**83**) or $[Cp_2Ru–Hg–RuCp_2]^{2+}$, respectively. In the absence of a stabilizing nucleophile, disproportionation (*see Disproportionation*) prevails. The halide complexes are isolable, and the iodide and chloride cations $[RuCp_2X]^+$ have been structurally characterized.[59,60] The crystal structure of the bromide analog exists only with permethylated ligands.[61]

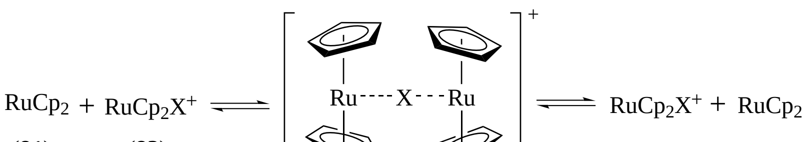
Bimolecular exchange between $[RuCp_2X]^+$ and $RuCp_2$ occurs as an inner-sphere (*see Inner-sphere Reaction*) electron transfer. The effects of varying the transferred atom (X), counterion, solvent, and substitution on the cyclopentadienyl ligands have been studied. It was found that the exchange rate constant is lowest with chlorine, and increases down the periodic table to iodine. Among complexes with the same halide, exchange rates increase with the number of methyl groups on the cyclopentadienyl ligands. This trend seems to be a consequence of the electronic effects of methylation on reaction energetics and shows that the mechanism is through the bridged transition state (Scheme 20).[62]

A different mode of stabilization for the monocations is dimerization. While the osmocene (*see Osmocene*)



(**81**) (**81**)$^+$ (**83**)

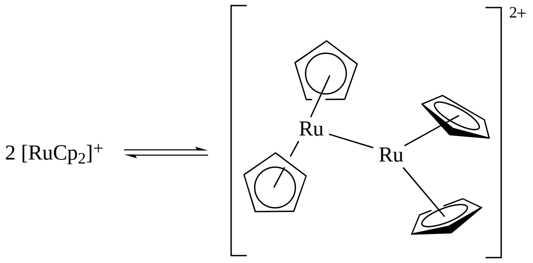
Scheme 19



(**81**) (**83**)

Scheme 20

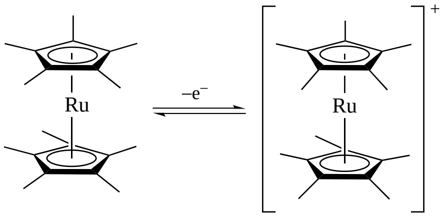
dimer $[Cp_2Os\text{–}OsCp_2]^{2+}$, formed through one-electron oxidation, has been isolated and structurally characterized, the corresponding ruthenocenium dimer, although not structurally authenticated, has been studied. As indicated with CV experiments, the electrochemical oxidation of (**81**) produces mainly the dimer dication (**84**) in equilibrium with the monocation $(\mathbf{81})^+$ complex, as shown in equation (17). Complex (**84**) and the osmium analog represent the only two unbridged metal–metal bonded metallocenes.[63]



(17)

$(\mathbf{81})^+$ (**84**)

A reversible one-electron oxidation (equation 18) was observed with (**82**) in a nonnucleophilic solvent (such as CH_2Cl_2).[57] With rigorous exclusion of even the weakest nucleophiles (e.g., PF_6^-), using $[(3,5\text{-}(CF_3)_2C_6H_3)_4B]^-$ as the supporting electrolyte in cyclic voltammetry, a reversible one-electron oxidation of (**81**) is possible as well.[64]



(18)

(**82**) $(\mathbf{82})^+$

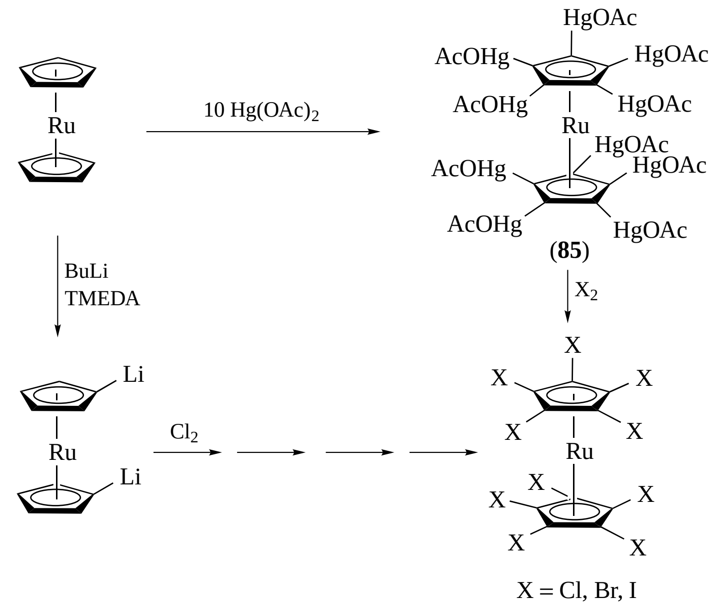
4.4 Substitution

As mentioned above, ruthenocene is susceptible to electrophilic substitution in a manner similar to ferrocene. Thus, common reactions for activated aromatics, such as acylation ($RCOCl/AlCl_3$), sulfonation (SO_3 in dioxane), aminomethylation ($CH_2(NMe_2)_2$), Vilsmeier–Haack formylation (DMF/$POCl_3$), arylation via diazonium salts, as well as mercuration and lithiation, have been performed with (**81**).[4,65] The perhalogenated ruthenocene has commonly been obtained from the decaacetoxymercury derivative (**85**), which is formed as a highly insoluble product from mercuration of (**81**) with $Hg(OAc)_2$ in methylene chloride.[66] Halogenation of (**85**) with halogens (X_2) gives the perhaloruthenocenes (**86**) in one step, with yields from 40 to 70% depending on the halide. Repeated lithiation and successive quenching of the metallated ruthenocene with C_2Cl_4 to give finally perchlororuthenocene is another method for the synthesis of (**86**) (Scheme 21).

Although monolithiated metallocenes are well known, cyclopentadienyl ligands with higher lithiation are rare. Pentalithiocyclopentadienyl ligands have been isolated from the treatment of (**85**) or $Cp^*Ru[C_5(HgOAc)_5]$ (**87**) with methyllithium (Scheme 22). $Ru(C_5Li_5)_2$ and $Cp^*Ru(C_5Li_5)$ complexes have been isolated, respectively, with this synthetic route. They can easily be converted to halogenated complexes by treatment with electrophiles such as bromine or methyl iodide.[67] In addition to the lithiation method, ruthenocene complexes with unevenly substituted cyclopentadienyl ligands have been isolated using $RuCp(\eta^4\text{-butadiene})Cl$ (**88**). Refluxing (**88**) with $Tl(OC_6F_5)$ in THF yields $RuCp((2\text{–}6\text{-}\eta^5)\text{-}C_6F_5O)$, which is converted to the crystallographically characterized complex $RuCp(\eta^5\text{-}C_5F_5)$ with flash vacuum pyrolysis.[68]

A notable substitution product of ruthenocene is ethynylruthenocene, which can be bound to estradiol, a form of estrogen studied for breast cancer treatment. With the rigid alkyne spacer, the steroid's affinity to the estrogen receptor was surprisingly unchanged upon addition of the metallocene. The addition of organometallic complexes to biomolecules may allow for the selective tuning of properties of the molecule.[69]

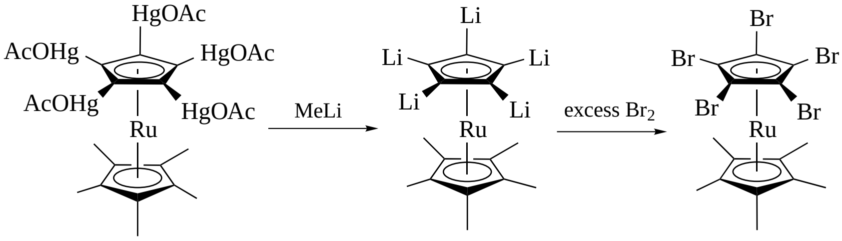
Another interesting example of a substituted ruthenocene complex is produced upon the treatment of $Cp^*{}_2Ru_2Cl_4$ with excess Norbornadiene (nbd) in refluxing ethanol. The resulting $Cp^*Ru(\eta^5\text{-}C_5H_4C_9H_{11})$ complex has a cyclopentadienyl ring with a tricyclo[4.2.1.0^{2,5}]-non-7-en-3-yl substituent. This unique substituent is a result of nbd coupling, C–C bond cleavage, hydrogen migration, and hydrogen loss. The dimerization or trimerization of norbornadiene is common among transition metal complexes, but the formation of a substituted metallocene from the nbd coupling is unprecedented.[70]



(**85**)

(**86**)

Scheme 21



(**87**)

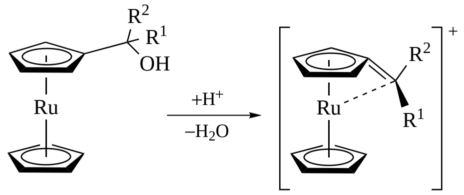
Scheme 22

4.5 α-Ruthenocenyl Carbonium Ions and η^6-Fulvene Complexes

Similar to ferrocene, the ruthenocene derivatives (**89**) substituted with a CR^1R^2 group are greatly stabilized in comparison to noncomplexed carbenes or carbonium ions. In fact, from the enhanced barrier to internal rotation in the α-ruthenocenyl carbonium ion Ru–$CHMe^+$ ($>130\,kJ\,mol^{-1}$) compared with the related ferrocene derivative ($70\,kJ\,mol^{-1}$), even greater stabilization in ruthenocene is expected.

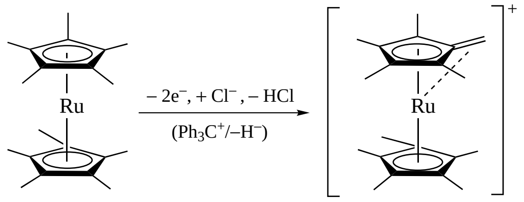
The common preparative route to these cations by proton-cation induced OH abstraction from an α-hydroxymethyl group (equation 19) is complemented for methylruthenocenes by the direct and facile deprotonation of a ring methyl group in the cation (equation 20). Thus, oxidation of (**82**) in the presence of a halide ion rapidly converts the initially formed ruthenocenium cation $(\mathbf{82})^+$ into the respective fulvene, which is oxidized by excess $(\mathbf{82})^+$ to the fulvenyl or α-methylene cation (**90**). Complex (**90**) can also be obtained directly from (**82**) by hydride abstraction through Ph_3CBF_4 in high yield (equation 20).[71] An X-ray structure determination (*see X-ray Crystallography*) of (**90**) showed the existence of one shorter Ru–C bond, a displacement of ruthenium towards this bond, and inward bending of this atom from the otherwise planar C_5Me_4 ring.[72] Owing to their easy preparation and facile addition of various nucleophiles, these cationic fulvene complexes can be of high synthetic value. In an attempt to analyze the effect of end groups on charge localization of polymethines, the crystallographically characterized1,3-(diruthenocenyl)allylium cation was synthesized. It consists of a (η^6-fulvene)(η^5-cyclopentadienyl)ruthenium cation bridged by vinylene to a symmetrical ruthenocene. This is a unique molecule in that it is a symmetrically substituted species that adopts an unsymmetrical structure and localizes the charge at

only one end.[73]



(19)

(**89**)

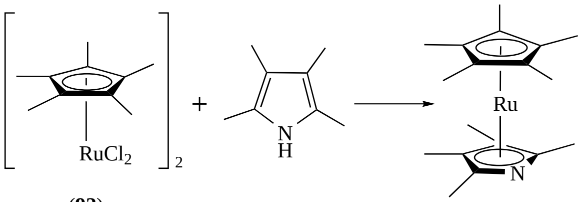


(20)

(**82**) (**90**)

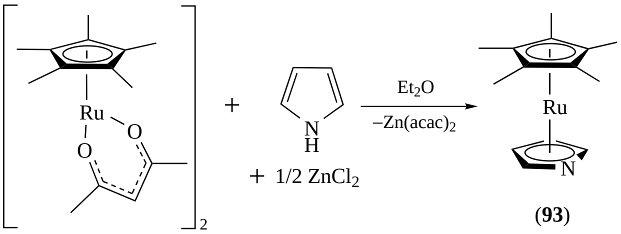
4.6 Heteroruthenocenes and Ruthenocene-Related Dienyl Complexes

Among the few known heteroruthenocenes are cationic thiophene- and bis(thiophene)ruthenium, electronic analogs to arene ruthenium sandwich complexes (Section 5), and derivatives featuring a tetramethylpyrrole (tp) ligand, Cp*Ru(tp) (**91**) and $Ru(tp)_2$,[74] prepared by an adaptation of the Zn reduction method to the chloro complex $[Cp^*RuCl_2]_2$ (**92**) (equation 21). The methyl groups are necessary to prevent σ-complexation of the pyrrole ligand; however, under suitable conditions ($[Cp^*Ru(acac)]_2/Zn^{2+}$/pyrrole in ether), the preparation of at least Cp*Ru(pyrrole) (**93**) has been equally successful (equation 22).



(**92**) (**91**)

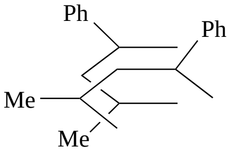
(21)



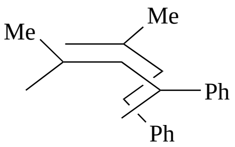
(22)

A series of so-called 'half-open ruthenocenes',[75] notably $Cp^*Ru(\eta^5\text{-}C_5R_7)$, are prepared similarly from Cp*Ru precursor complexes $(Cp^*RuCl)_4$ or $(Cp^*RuOMe)_2$ and dienyl alkali salts or dienes and a mild base to effect dehydrohalogenation. Half-open ruthenocenes are versatile, allowing for incorporation of substituents onto, as well as heteroatoms into, the pentadienyl fragment. X-ray crystallographic studies (*see X-ray Crystallography*) have found that the C_5R_7 ligands are essentially planar with rather short Ru–dienyl bond lengths (2.12−2.19 Å). Varying the composition of the pentadienyl ligand allows for adjustments to the chemistry of the complex. For example, oxodienyl complexes are generally more reactive than all-carbon analogs, owing to the weaker coordination of the oxygen.[76]

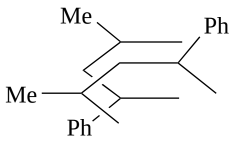
Open ruthenocenes, $Ru(\eta^5\text{-}C_5R_7)_2$, with asymmetric substitution of the pentadienyl ligands (*see Pentadienyl Ligand*) allow for the synthesis of diastereomeric products. The treatment of (**1**) with 2-methyl-4-phenylpentadiene and zinc dust yielded bis(2-methyl-4-phenylpentadienyl)ruthenium (**94**). The product consists of a pair of diastereomers, which were easily separated by fractional crystallization because of their substantially different solubilities. One isomer could exist as a pair of enantiomeric rotamers, each with C_1 symmetry (**94a**) and (**94b**), while the other could be a pair of diastereomeric rotamers, both with C_2 symmetry (**94c**) and (**94d**). Both of the former rotamers are observable, but (**94c**) is the only form of the latter, and interconversion to (**94d**) does not occur. The possibility of isomerization with photochemical initiation still remains to be investigated.[77]



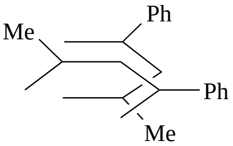
(**94a**)



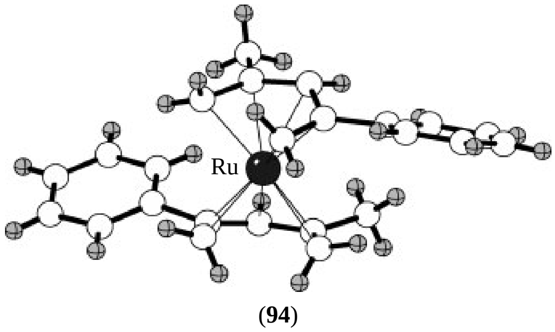
(**94b**)



(**94c**)



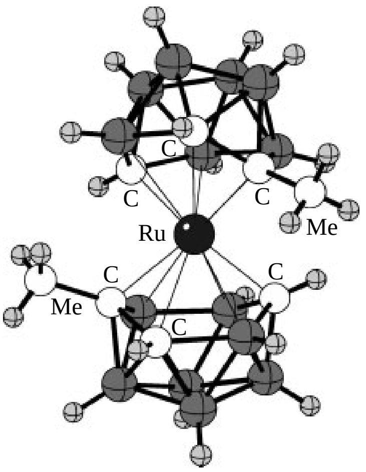
(**94d**)



(**94**)

The tricarbadecaboranyl ligand ($C_3B_7H_{10}$) has been compared with the cyclopentadienyl anion, as both have

the same charge and similar electron-donating ability. However, metal complexes with tricarbadecaboranyl exhibit greater oxidative, chemical, thermal, and hydrolytic stability compared to metallocenes. Nonetheless, the cage-slippage of the tricarbadecaboranyl ligand between η^6 and η^4 coordination modes mirrors a similar η^5 to η^3 slippage in metallocenes. The ruthenocene-like complex *commo-Ru*-(2-Me-*closo*-1,2,3,4-$RuC_3B_7H_9)_2$ (**95**) was synthesized by treating $RuCl_2(cod)_x$ with Li(6-Me-*nido*-5,6,9-$C_3B_7H_9$) in glyme.[78]



(**95**)

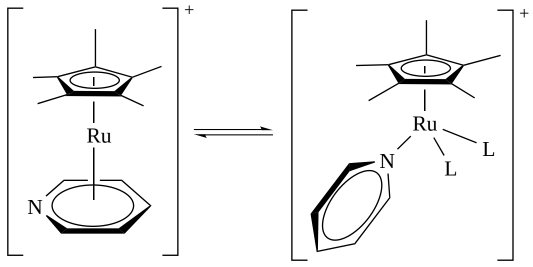
An interesting characteristic of ruthenocene is that it is a photoinitiator for the anionic polymerization of ethyl 2-cyanoacrylate. Solutions with millimolar concentrations of the complex in neat cyanoacrylate polymerize to a hard, plastic solid within seconds upon exposure to light. The low concentration of ruthenocene required for the polymerization makes it desirable in applications such as coating and adhesives that require solvent-free solutions of monomer.[79]

5 (ARENE)(CYCLOPENTADIENYL) AND BIS(ARENE) RUTHENIUM COMPLEXES

5.1 [Ru(arene)(cyclopentadienyl)]$^+$ Complexes

This type of sandwich complex, first reported with iron as the central metal, has now become widespread with ruthenium as well. Early routes to ruthenium complexes were modeled on iron chemistry, and used the $AlCl_3$-catalyzed exchange of a cyclopentadienyl ligand for an arene in ruthenocene, or reaction of $CpRu(CO)_2Cl$ with $AlCl_3$/arene. These methods are less successful with ruthenium than with iron, however, owing to the greater stability of ruthenocene. A mixture of arene, pentamethylcyclopentadiene, and $RuCl_3$ in the Zn reduction method gives good yields of the mixed-sandwich cations. A great variety of [Ru(arene)(cyclopentadienyl)]$^+$ complexes, including functionally substituted arenes, polyphenyls, and paracyclophanes, phenols, condensed polyaromatics, as well as the six-electron heterocycles thiophene and pyridines, have been complexed to ruthenium.

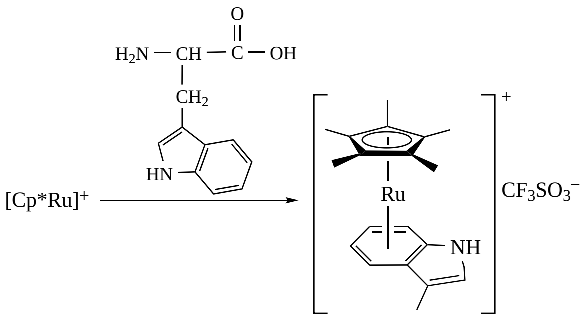
With the less tightly bound polyarenes or heteroarenes, displacement of the arene has been observed. Thus, sensitive dications with these types of ligands can only be prepared and handled in nonnucleophilic environments. Behavior in the pyridine complexes is particularly interesting. Here a rearrangement from the initially formed π-complex (**96a**) to a σ-complex (**96b**) occurs (equation 23).[80] However, heating of (**96b**) (L = acetonitrile) under vacuum gives (**96a**).[81] It thus appears that the pyridine π-complex is stable in the absence of additional σ-ligands, including excess pyridine.



(23)

(**96a**) (**96b**)

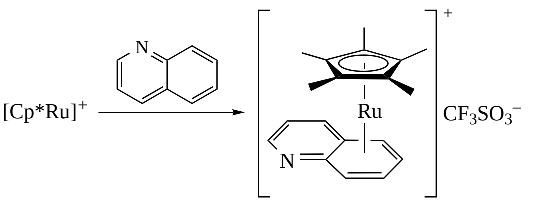
Recently, organometallic ruthenium chemistry has found its way into biological applications. Treating [Cp*Ru(MeCN)$_3$][CF_3SO_3] with amino acids in THF yields η^6-coordinated amino acid complexes of the type [Cp*Ru(η^6-HaaOH)][CF_3SO_3], where HaaOH = L-HPheOH (phenylalanine) or L-HTrpOH (tryptophan), as shown in equation (24). Similarly, dipeptide and cyclopeptide complexes can be synthesized under parallel conditions. These types of complexes are essentially Cp*Ru^{II} labeled peptides, which could have a notable impact on the analysis of protein receptor sites.[82]



(24)

Ruthenocene derivatives have also been studied as potential second-order nonlinear optical materials. Using the [Cp*Ru]$^+$ fragment, several aromatic systems have been synthesized and studied for this goal. The [Cp*Ru]$^+$ fragment was synthesized by treating [Cp*Ru(OMe)]$_2$ with triflic acid. Various aromatic

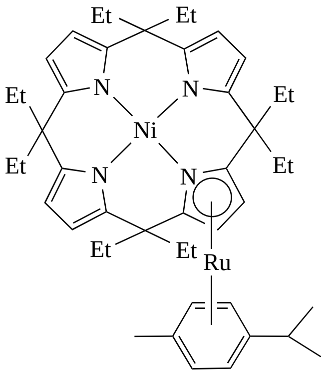
complexes were then added to this reaction mixture to form sandwich derivatives of the type shown in equation (25).[83]



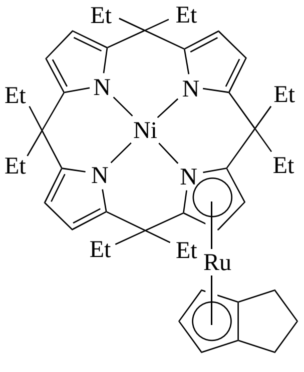
(25)

5.2 Neutral Ru(arene)(cyclopentadienyl) Complexes

An interesting derivative of the pyrrole ring that has found its way into ruthenocene chemistry is *meso*-octaethylporphyrinogen. The tetraanion is of interest because it allows for η^1, η^3, or η^5 binding and can donate from 8 to 24 electrons. It has an internal N_4 site that easily binds nickel(II). Treatment of the lithiated porphyrinogen with $Ru(Cl)(p\text{-cymene})_2(\mu\text{-Cl})_2$ or $Ru(Cl)(cod)_2(\mu\text{-Cl})_2$ binds one of the pyrrole rings to the Ru(*p*-cymene) (**97**) and the Ru(cod) fragments, respectively. Once the ruthenium is bound, the cod ligand undergoes rearrangement to form an η^5-cyclopentadienyl-like ligand (**98**). With a Ni^{II} and Ru^{II} center, it is an overall neutral molecule.[84]



(**97**)



(**98**)

5.3 Bis(arene) Complexes

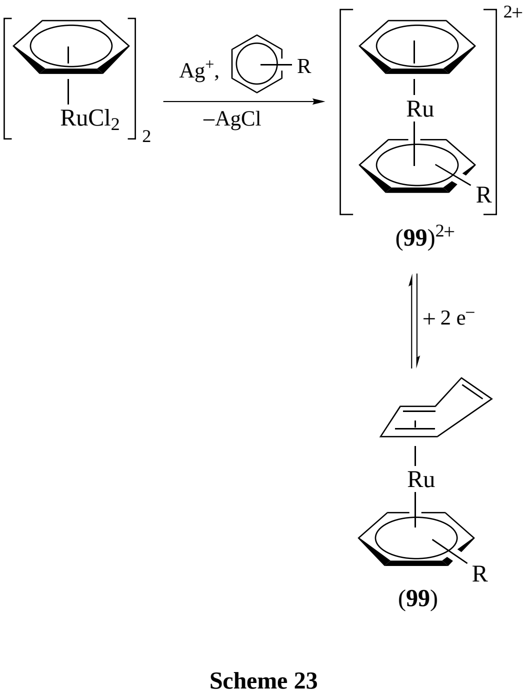
Bis(arene) complexes of ruthenium (**99**), first prepared in relatively low yield by the Fischer–Hafner synthesis (*see Fischer–Hafner Synthesis*) ($MCl_3/AlCl_3$/arene) are now readily available through solvento cations $[(arene)RuS]^{2+}$ (S = acetone, nitromethane), which in turn are made from the dimeric half-sandwich halides $[(arene)RuCl_2]_2$ (Section 6.3) with Ag^+ with the appropriate arene as solvent (Scheme 23). This method allows a whole range of functionalities to be incorporated to at least one of the arenes. The dications $(\mathbf{99})^{2+}$ are of relatively high solvolytic stability and are decomposed by DMSO only to form $[(arene)Ru(DMSO)_3]^{2+}$.

Whereas $[CpRu(arene)]^+$ cations are not easily reduced electrochemically (with $[CpRu(polyarene)]^+$ being an exception), the bis(arene) complexes have aroused interest owing to their two-electron redox change that converts one arene from an η^6- into a bent η^4-ligand. An electrochemical investigation of this process revealed that the second electron transfer is slower than the first one. In neutral $Ru(\eta^6\text{-arene})(\eta^4\text{-arene})$ complexes (**99**), the bonding mode between η^4- and η^6-arene ligands interchanges, giving a new type of fluxionality ($\Delta G^\ddagger = 67\,kJ\,mol^{-1}$ for arene = C_6Me_6) as indicated in Scheme 23.

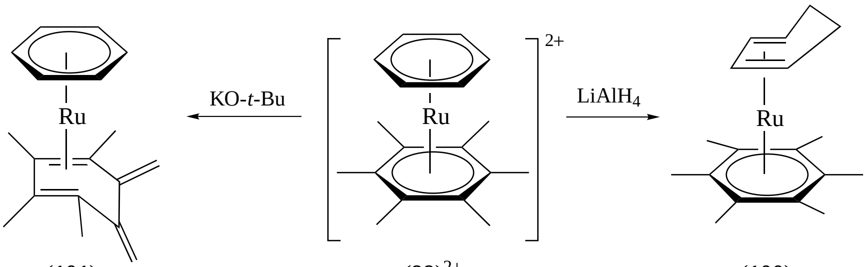
Bis(arene) ruthenium complexes $(\mathbf{99})^{2+}$ are electrophilic and add various nucleophiles (*see Nucleophile*), including hydride, to form (**100**) (Scheme 24). Methyl groups of methylated arene rings are acidic and can be deprotonated, giving the corresponding *exo*-methylene complexes (**101**). This is similar to the chemistry developed for analogous iron complexes, and is reminiscent of the α-ruthenocenyl carbonium ions (Section 4.5).

5.4 Triple-Decker Complexes

Ruthenium has played a central role in the development of 30 valence electron triple-decker cations of the iron group. These compounds were first prepared by Rybinskaya *et al.*,[85,86] through reaction of a 12 valence electron $[CpRu]^+$ fragment with a metallocene. The well-known photofragmentation of $[CpFe(arene)]^+$ was used to generate $[FeCp]^+$, which was then complexed to ruthenocene in situ. The structure of the triple-decker shows three exactly parallel rings, two of them (one outer and the inner) eclipsed and



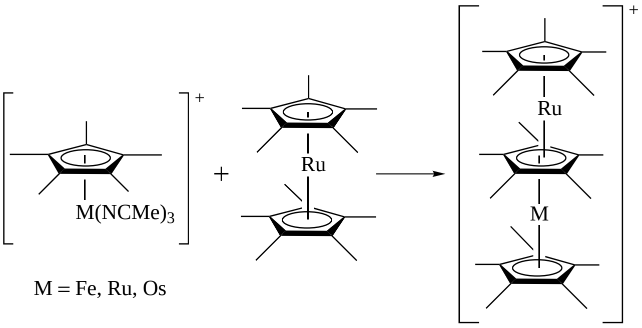
Scheme 23



(101) (99)2+ (100)

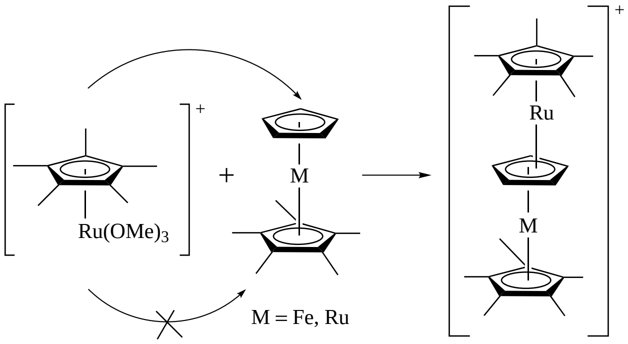
Scheme 24

perfectly staggered to the third one, with Ru–C and Ru–ring distances that on average do not differ significantly from those in ruthenocene or decamethylruthenocene (equation 26).



(26)

It was initially thought that the stability of the complexes required permethylation of the Cyclopentadiene (Cp) rings in the middle deck; however, careful choice of the stacking reagent allows for the preparation of partly methylated derivatives as well.[87] Thus, when $[Cp^{*}Ru]^{+}$ (as $(Cp^{*}RuOMe)/H^{+}$) is treated with either pentamethylruthenocene or ferrocene, attack is exclusively at the less-hindered site, making the Cp ring the bridging ligand (equation 27). The stacking reaction proceeds with kinetic control, and the activation barrier for attack at the substituted ring ligand appears to be considerably higher.



(27)

6 HALF-SANDWICH COMPLEXES (*See Half-sandwich Complexes*)

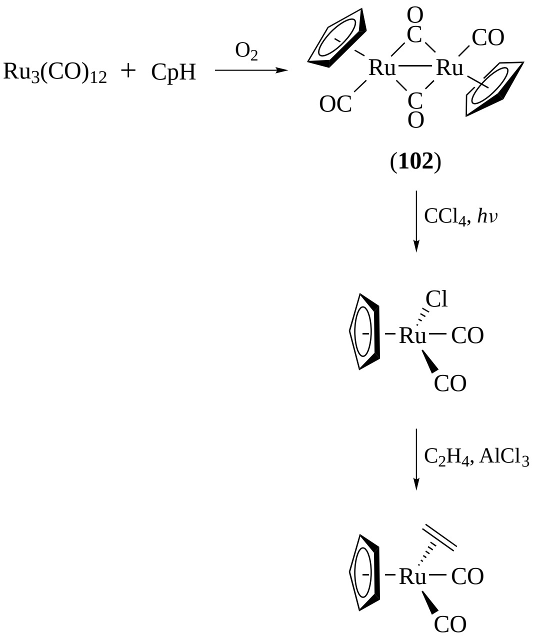
6.1 General Characteristics

Half-sandwich complexes of ruthenium are widespread with both Cp and arene ligands.[65] In the former, electron count considerations dictate the composition of $CpRuL_2X$ or $[CpRuL_2]_2$, where L are usually common π-acceptor ligands and X varies from fluorine to alkyl, hydride, and aryl ligands. If the binding atom in X contains lone pairs, these can substitute for L, leading to bridged structures, such as $[CpRuLX]_2$ or even $[CpRuX]_4$, the latter most common with X=S, SR, Se, and so on, but also exemplified by the chloro complex. The oxidation state of ruthenium can be Ru^{II}, Ru^{III}, and even partially Ru^{IV} in the tetrameric sulfur clusters (see Section 6.4).

It appears as if the potential ligands that can be accommodated in the (arene)Ru series may be even more extended than that in the CpRu series owing to the higher charge and the somewhat harder nature of the central metal, although the oxidation state is as yet confined to Ru^{II}. Apart from the molecular dimers $[(\eta\text{-arene})RuX_2]_2$, the most common starting materials for (η-arene)Ru chemistry are ionic complexes of the type $[(\eta\text{-arene})Ru(\mu\text{-}X)_3Ru(\eta\text{-arene})]^{+}$, similar to the closely related Cp* analogs of the cobalt group. Mononuclear complexes are of the type $(\eta\text{-arene})RuLX_2$, $[(\eta\text{-arene})RuL_2X]^{+}$, and $[(\eta\text{-arene})RuL_3]^{2+}$.

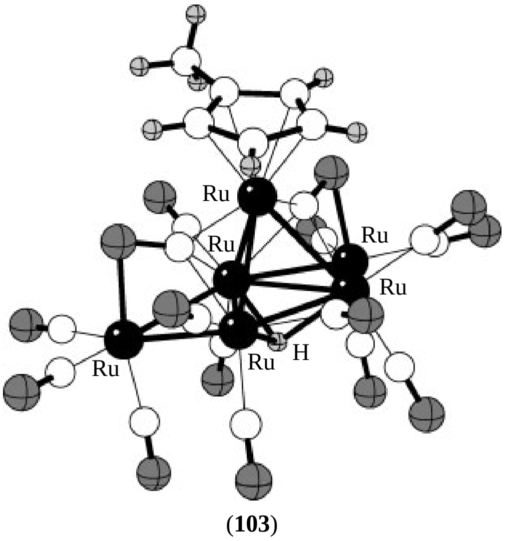
6.2 Half-Sandwich Complexes with Cyclopentadienyl Ligands

As outlined above, the most widespread complex type (similar to iron analogs) is $CpRuL_2X$ where L = CO, phosphines, dienes, or other similar ligands and X = hydride, alkyl groups, or halogens. Reaction of $Ru_3(CO)_{12}$ with cyclopentadiene in the absence of oxygen yields $CpRu(CO)_2H$; the presence of oxygen allows for the synthesis of dimeric $[CpRu(CO)_2]_2$ (Scheme 25). Halogenated complexes $CpRu(CO)_2X$, where X = Cl, Br, or I, are



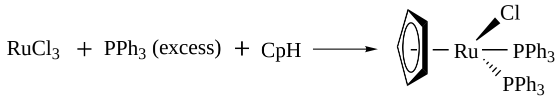
Scheme 25

formed upon treating $[CpRu(CO)_2]_2$ (**102**) with halogenated solvents. The halogen can be substituted with an olefin by reaction with olefins in the presence of AlX_3, yielding $CpRu(CO)_2L$, L = C_2H_4, $CH_2 = CHMe$, or cyclohexene (Scheme 25). Interestingly, the reaction of $Ru_3(CO)_{12}$ with cyclohexene results in a $Cp^{Me}Ru$ cluster derivative, where the cyclohexene undergoes ring contraction to form a methylcyclopentadienyl ligand on a hexaruthenium hydride cluster $[Ru_6(\mu_3\text{-}H)(\mu_4\text{-}\eta^2\text{-}CO)_2(CO)_{13}(\eta^5\text{-}C_5H_4Me)]$ (**103**).[88]



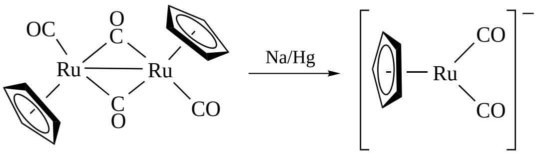
(**103**)

Whereas one CO group in complexes of type $CpRu(CO)_2Cl$ is readily substituted for phosphine, bis(phosphine) complexes, for example, $CpRu(PPh_3)_2Cl$, are best prepared in a one-step reaction from $RuCl_3$, CpH, and PPh_3 (equation 28). This air-stable crystalline solid provides a convenient starting point for further transformations.[89,90] The $CpRu(PR_3)_2$ fragment is more nucleophilic than $CpRu(CO)_2$; thus derivatives of $CpRu(PR_3)X$ with less electronegative (*see Electronegativity*) X ligands, like alkyl and hydride, are more highly stabilized compared to the respective derivatives of $CpRu(CO)_2Cl$.



(28)

Reduction of (**102**) requires rather strong reducing agents and leads to the anion $[CpRu(CO)]^-$ (**104**) (equation 29). This reactivity is qualitatively similar to that of the iron analogs, but the ruthenium complexes are less nucleophilic. Analogous anions with a diene ligand have been prepared and are strong, highly reactive nucleophiles.[91] Substitution of CO by acceptor ligands leads to additional complexes of the same type. All these transformations are also known with substituted Cp ligands.[92]



(29)

(**102**) (**104**)

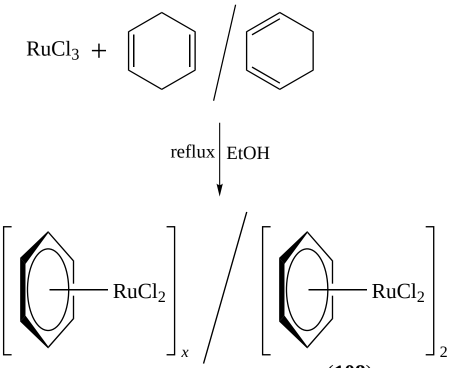
Half-sandwich ruthenium complexes have the ability to act as substrates for C–C bond cleavage or activation. Treatment of the methylated cyclopentadienyl complex $[Cp^*RuCl_2]_2$ with $LiAlH_4$ yields the tetrahydride-bridged complex $Cp^*Ru(\mu\text{-}H)_4RuCp^*$. Treating this complex with ethylene produces $Cp^*Ru(CH_2{=}CH_2)(CH{=}CH_2)_2RuCp^*$, which can undergo C–C coupling in toluene at 60 °C under 1 atm of ethylene to form the dinuclear ruthenacyclopentadiene complex $Cp^*Ru(CH_2{=}CH_2)(CMe{=}CHCH{=}CMe)RuCp^*$.[93]

The 1,5 cyclooctadiene complex $[Cp^*Ru(\eta^2:\eta^2\text{-}C_8H_{12})(CO)]OTf$ was isolated upon treatment of $Cp^*Ru(\eta^4\text{-}butadiene)X$ (X = Cl, Br) with butadiene, AgOTf, and CO. A similar [4 + 4] cycloaddition (a thermally forbidden reaction (*see Woodward–Hoffmann Rules*)) is observed when $Cp^*Ru(isoprene)Cl$ is treated with isoprene, AgOTf, and CO. Likewise, the reaction of 1,3-pentadiene with $Cp^*Ru(\eta^4\text{-}1,3\text{-}pentadiene)Cl$ results in linear dimerization to form $[Cp^*Ru(4\text{-}methyl\text{-}(1,3\text{-}\eta\text{:}6\text{-}8\text{-}\eta^3)\text{-}nonadienediyl)]OTf$. These types of dimerization occur with both stoichiometric and catalytic amounts of the ruthenium complex.[94]

The trinuclear pentahydride complex $[Cp^*Ru]_3(\mu\text{-H})_3(\mu_3\text{-H})_2$ (**105**) in Scheme 26 consists of ruthenium centers tightly bound by bridging hydrides. Treatment of the pentahydride complex with excess butadiene in THF results in a trinuclear 1-methyl-1,3-dimetalloallyl complex $[Cp^*Ru]_3(H)_4[\mu_3\text{-}\eta^3\text{-C(Me)CHCH}]$ (**106**). This interaction shows the cooperation of all three ruthenium centers as either coordination sites or activation sites. Similar results are found by treating (**105**) with isoprene.[95] Treatment of (**105**) with five equivalents of cyclopentadiene results in bond cleavage of the cyclopentadiene to form a dark purple crystalline solid $[Cp^*Ru(\mu\text{-H})]_3[\mu_3\text{-}\eta_4\text{-C(Me)=CHCH=CH}]$ (**107**). In this complex, two of the ruthenium centers act as a coordination site, while the third is an activation site.[96]

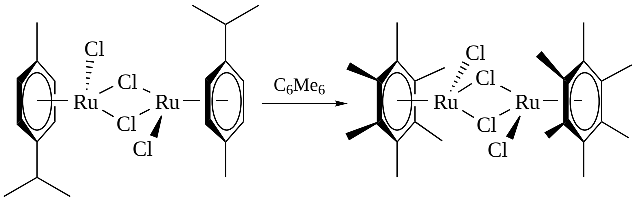
6.3 Half-Sandwich Complexes with Arene Ligands[97]

As mentioned in Section 3.1, reaction of 1,3- or 1,4-cyclohexadiene derivatives with $RuCl_3$ in ethanol yields a brown, highly insoluble polymer of composition $[(\eta\text{-}C_6R_6)RuCl_2]_x$ (equation 30). If this reaction is conducted at ambient temperature, most of the ensuing material is soluble in methylene chloride and consists of the dimer $[(\eta\text{-}C_6H_6)RuCl_2]_2$ (**108**).[98] An improvement of the method uses the readily available natural product α-phellandrene (5-i-propyl-2-methylcyclohexa-1,3-diene) as the cyclodiene in this reaction.[99] The ensuing complex $[(\eta\text{-}p\text{-cymene})RuCl_2]_2$ is not only soluble but also can exchange complexed p-cymene for other arene ligands, notably those with a higher degree of alkylation, as shown in equation (31) for hexamethylbenzene. However, not all functionalities seem not to be tolerated in these exchange processes.



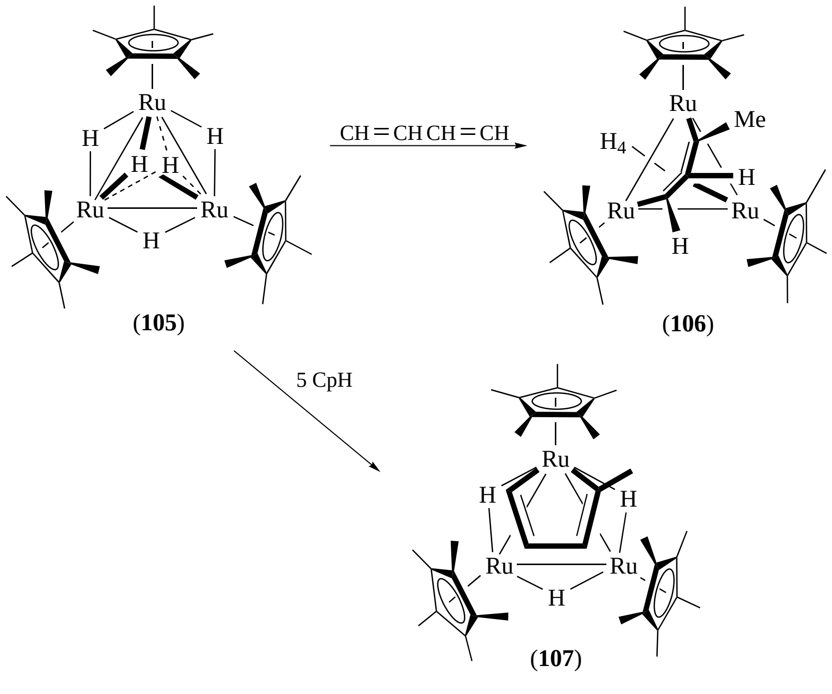
(**108**)

(30)



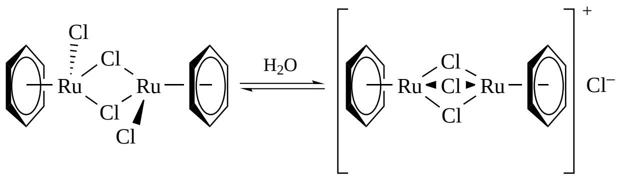
(31)

The reactivity patterns of the (η-arene)RuX_2 moiety resemble those of the isoelectronic Cp^*RhX_2 unit. Thus,



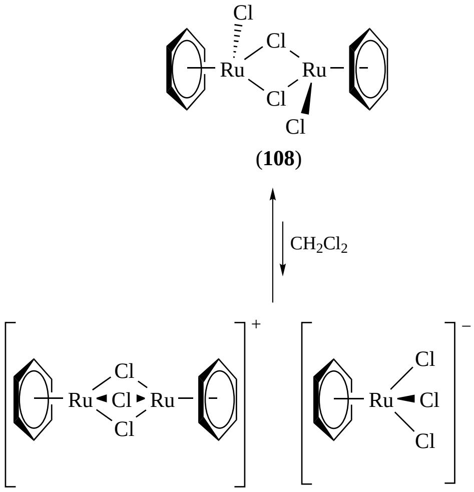
Scheme 26

ionization occurs in hot water to give the chloro-bridged cation (**109**), which can be precipitated as the PF_6^- salt (equation 32). The equilibrium in equation (33) is confirmed by NMR, UV, and cyclic voltammetry measurements.

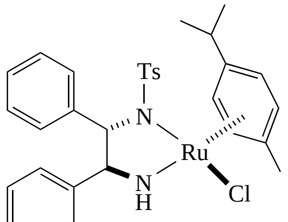


(**108**) (**109**)

(32)



(33)



(**110**)

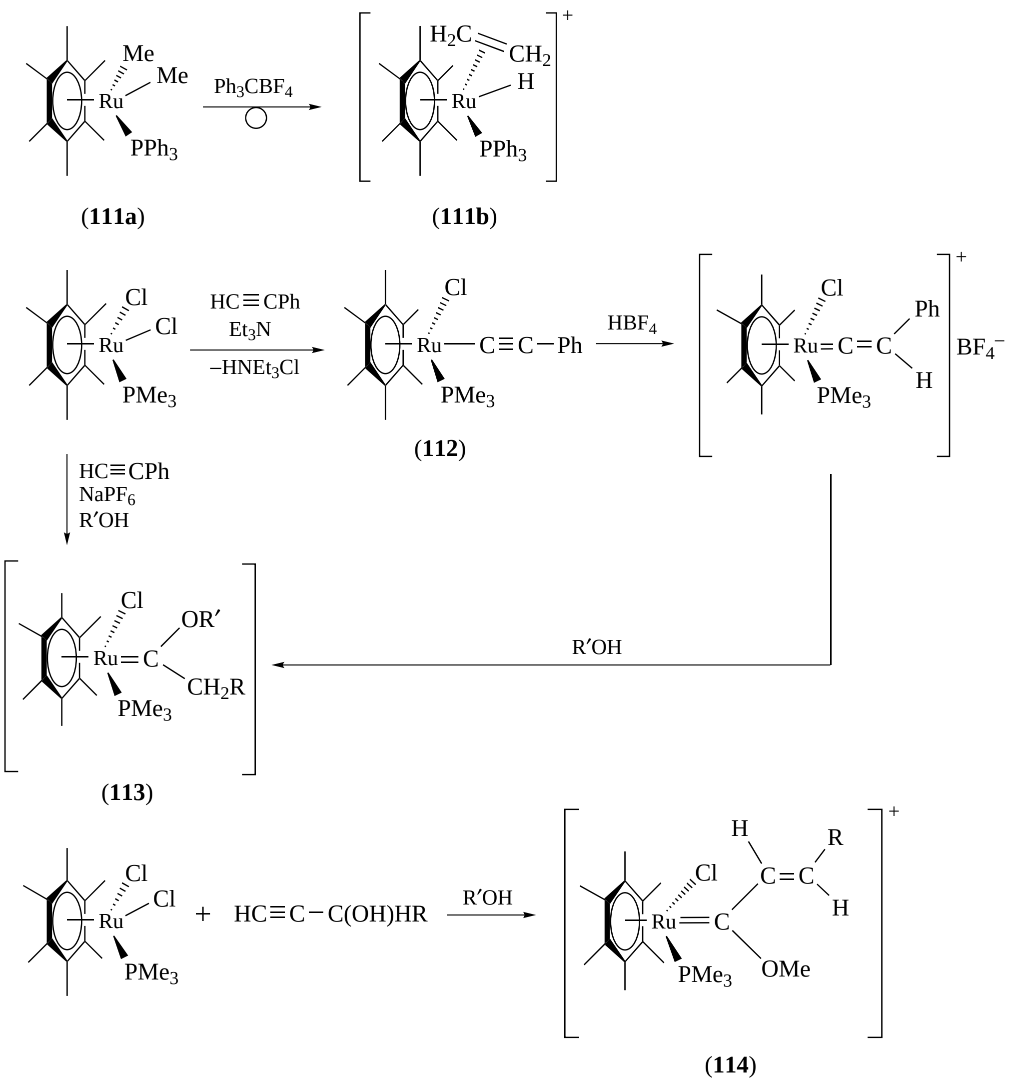
Cleavage of the dimer (**108**) proceeds easily with many donor and acceptor ligands and dehalogenation with Ag^+ ion in weakly coordinating solvents generates reactive solvent cations $[(\eta\text{-arene})Ru(solvent)_3]^{2+}$ for facile complexation. The (η-arene)Ru moiety accommodates all of the common classical σ-donor ligands along the spectrochemical series as coligands. The ability to bind such N- and O-ligands has been used to complex various amines, imines, Schiff bases, and amino acids to (η-C_6H_6)Ru, generating diastereomeric salts from substituted arene complexes. A notable example of this type is the complex (η-p-cymene)RuCl[(1S,2S)-N-p-toluenesulfonyl-1,2-diphenylethanediamine] (**110**). When chiral catalysts of this type are treated with formic acid/triethylamine, they asymmetrically reduce 1,2-diketones to enantiomerically pure chiral 1,2-diols (e.g., benzoins to benzils).[100] These optically active 1,2-diols are valuable in stereoselective organic syntheses and in the production of biologically active compounds.

It should be noted that there is organometallic chemistry associated with the (η-C_6H_6)Ru moiety itself, as exemplified by the orthometalation (*see Orthometalation*) of unsaturated arylphosphine complexes or by the transformations of the dimethyl complex (arene)$RuMe_2PR_3$ (**111a**), which on hydride abstraction rearranges into a cationic (hydrido)ethylene complex (**111b**) (Scheme 27). Much studied is the reaction of (arene)$RuCl_2PR_3$ with alkynes (Scheme 27). The primary acetylides (**112**) are attacked successively by protons and by nucleophiles, commonly alkoxide from a solvent alcohol, to give alkoxycarbene complexes (**113**). The sequence proceeds in one step if the alkyne is added in the presence of PF_6^- salt in alcohol solution. If the alkyne bears a hydroxyalkyl group, vinylvinylidene complexes are formed; this method has been extended to conjugated polyene derivatives (**114**).

A unique ruthenium arene complex is produced when $Ru_6C(CO)_{16}PPh_3$ is refluxed in chlorobenzene. The phosphine complex converts to the η-arene complex $Ru_6C(CO)_{13}[PPh_2(\mu\text{-}\eta^6\text{-}C_6H_5)]$ (**115**). In this reversible reaction, the tertiary phosphine ligand becomes η^6-coordinated to the adjacent ruthenium atom. Treatment of the complex with CO at room temperature drives the complex back to the P-bound form.[101]

The indenyl ligand is often viewed as a Cp analog in that it tends to bind to a metal center via its five-membered ring, as shown in $(\eta^5\text{-}C_9H_7)RuCl(cod)$ (**116**). When $(\eta^5\text{-}C_9H_7)Ru(dppm)H$ was treated with CF_3SO_3H or $HBF_4{\cdot}Et_2O$ at cool temperatures, the η^2-dihydrogen cation $[(\eta^5\text{-}C_9H_7)Ru(dppm)(H_2)]^+$ was produced. Under the same conditions, $(\eta^5\text{-}C_9H_7)Ru(PPh_3)_2H$ produces the dihydrogen cationic complex $[(\eta^5\text{-}C_9H_7)Ru(PPh_3)_2H_2]^+$. Warming either of these complexes to room temperature causes a proton to shift to the indenyl ligand, resulting in the migration of the metal to the six-membered ring of the indene; this is seen in $[(\eta^6\text{-}C_9H_8)Ru(dppm)(H)]^+$ (**117**). The proton migration to the indenyl ligand and rearrangement to the η^6-indene ruthenium complex is the first example of this type.[102]

A more recent addition to the half-sandwich chemistry of ruthenium is given by a number of complexes where the central metal obeys a 16 valence electron count. These coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) metal centers are widely invoked as intermediates or transition states in dissociative substitution processes or in catalytic transformations at transition metal centers. Such complexes are not, however, easily isolated. The most common way to stabilize such species is by coordinating sterically bulky ligands to the metal, thereby preventing further ligand addition. They can also be stabilized in the form of dimeric complexes.



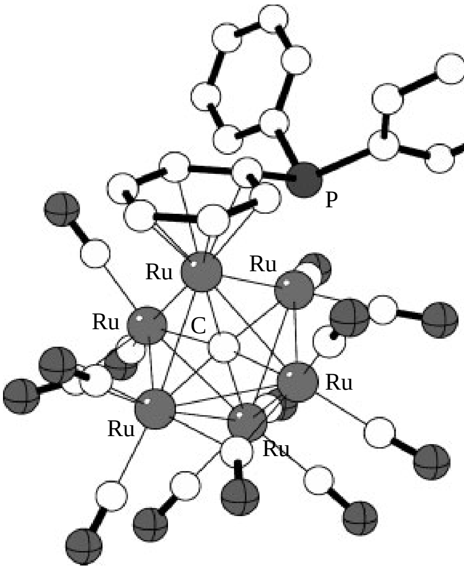
Scheme 27

A common feature of the dimers is a folded Ru–E–Ru–E core (E = O, S, or N) with a dihedral angle between the Ru-E-Ru planes of from 110 to 129°. The butterfly geometry observed in these dimeric complexes results from the retro π-overlap of lone electron pairs into empty metal orbitals and a second-order Jahn–Teller effect (*see Jahn–Teller Effect*) arising from the repulsive interaction of filled metal d-orbitals in a flat (D_{2h}) geometry. This type of geometry is exemplified by the crystallographically characterized complex [(η-*p*-cymene)Ru(μ_2-2,6-di-isopropylphenylamido-*N*,*N*)]$_2$ (**118**).[103]

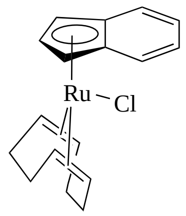
6.4 Higher Valent Half-Sandwich Complexes

Although the great majority of research involves ruthenium in oxidation states 0 to II, the organometallic half-sandwich chemistry of ruthenium also extends to oxidation states III and IV. The Ru^{III} complex (**119**) is formed in the same way as its rhodium analog, that is, by heating $RuCl_3$ with Cp*H in methanol or ethanol (Scheme 28).[104–106] This complex is the most widespread starting material in nearly all preparations containing alkylcyclopentadienyl ruthenium complexes. Complex (**119**) had long been considered a polymer before structural characterization revealed a chloride-bridged dimer. A unique feature of the solid-state structure of this compound, schematically indicated in Scheme 28, was the presence of two isomeric forms in the solid, a paramagnetic isomer with a long, nonbonding Ru–Ru separation of 3.75 Å, and one with a shorter Ru–Ru separation of 2.93 Å. In the latter isomer, the Ru^{III} d^5 centers strongly interact as shown by solid-state NMR to form a diamagnetic (*see Diamagnetism*) complex. In solution, these forms rapidly interconvert in a temperature-dependent equilibrium, as indicated by a

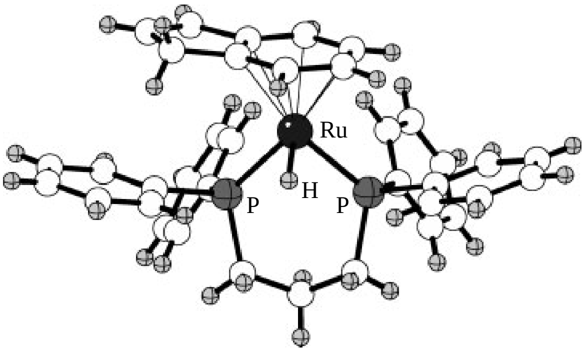
large temperature-dependent chemical shift of the averaged Pentamethylcyclopentadiene (Cp*) signal (opposite to the temperature dependence of the magnetic susceptibility). This latter phenomenon has been used to prove the presence of similar isomers in solution in those cases where only one form is detected in the solid state.



(**115**)

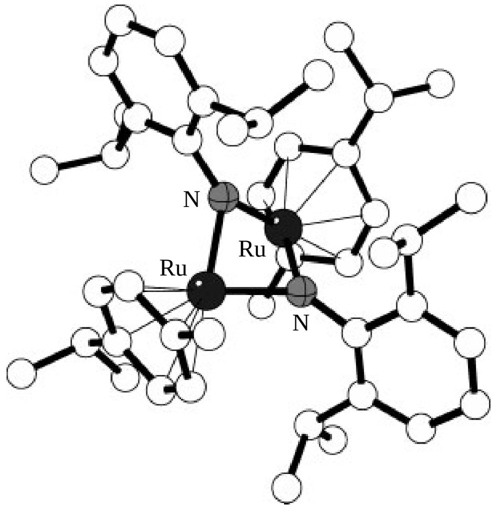


(**116**)

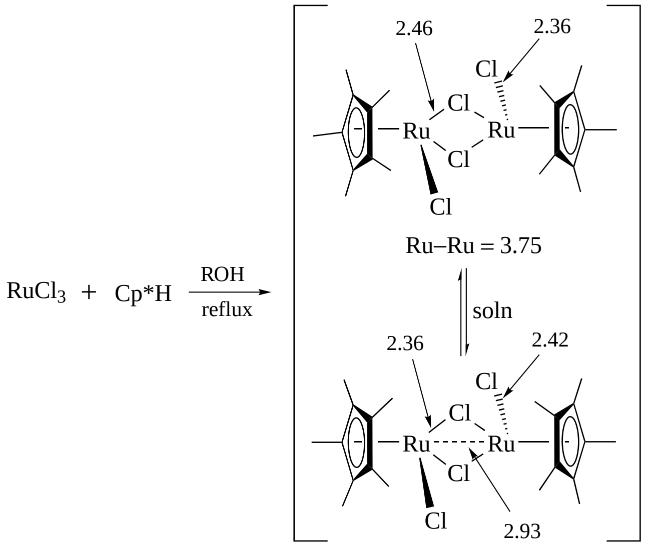


(**117**)

A Ru^{IV} center has been encountered in Cp*Ru(η^4-2,3-disubstituted-1,3-butadiene)Br$_2$ complexes (**120**). These



(**118**)



(**119**)

Scheme 28

compounds are synthesized by the oxidative addition (*see Oxidative Addition*) of Br$_2$ to Cp*Ru(η^4-diene)Br complexes. Interestingly, when the diene in the starting material is 1,3-butadiene, or either monosubstituted- or 1,2-disubstituted-1,3-butadiene, a neutral dibromoruthenium(IV) (η^3-allyl) complex is formed. In this complex, the allyl assumes an *anti* conformation (**121**). When the starting material involves 1,4-disubstituted-1,3-butadiene, the same η^3-allyl complex is formed but with a *syn* configuration (**122**).[107] The complete series of trihalo ruthenium(IV) complexes (Cp*RuX$_3$)$_n$ (X = Cl, Br, I) are obtained from allowing (**119**) to react with the respective halogen.[108]

Glossary

S-Donor ligand: molecule in which a sulfur atom is directly bonded to a metal center

Abbreviations

porph = Porphyrin; pz = Pyrazine; [9]aneS_3 = 1,4,7-trithiacyclononane; [14]aneN_4 = 1,4,7,11-tetraazacyclotetradecane; [18]aneS_6 = 1,4,7,10,13,16-hexathiacyclooctadecane; [18]aneO_6 = 1,4,7,10,13,16-hexaoxacyclooctadecane; [9]aneN_3 = 1,4,7-triazacyclononane.

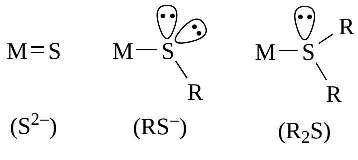
1 INTRODUCTION AND GENERAL FEATURES

A very extensive literature has developed concerning the chemistry of S-coordination compounds. A general feature of S-donor ligands is their ability to bind to a very wide variety of metal centers, particularly of the second and third row transition metals, to form mononuclear, polynuclear, and cluster compounds. Polysulfides $S_n{}^{2-}$, thiolates RS^-, and related anionic S-donors are generally regarded as strong σ- and π-donors. In addition, owing to their polarizability, these S-donor ligands can form a range of polynuclear complexes in which the S-atoms bridge between two metal ions, or face-cap three or more metal centers.[1] The formation of metal clusters is, therefore, a common and extremely important aspect of S-coordination chemistry, particularly since complexes of Fe, Mo, Cu, and Ni are present at the active sites of several metalloenzymes (*see* ***Iron–Sulfur Models of Protein Active Sites***; ***Iron–Sulfur Proteins***; ***Nickel Enzymes & Cofactors***; ***Nickel: Models of Protein Active Sites***; ***Nitrogenase: Metal Cluster Models*** and ***Polynuclear Organometallic Cluster Complexes***). Binding of soft anionic S-donors to soft metal centers is consistent with hard–soft acid–base principles, although covalency in metal–sulfur binding is also important. Thiolate RS^- and hydrosulfide HS^- ligands occur between F^- and Cl^- in the spectrochemical series reflecting their strong π-donor capacity and their abilities to stabilize relatively high metal oxidation states, for example, Mo^{VI}.

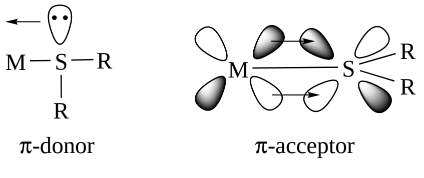
In contrast, thioethers of the type R_2S are generally poor donors to metals centers, the stability of complexes decreasing in the order $S^{2-} > RS^- > R_2S$ (Scheme 1). Macrocyclic ligands tend to form complexes of increased thermodynamic stability and kinetic inertness compared to their open-chain analogs (*see* ***Macrocyclic Ligands***).[2–4]

The relative π-acceptor and π-donor properties of thioether S-donors have been discussed (Scheme 2), and, although weak, their π-acceptor abilities can contribute to the stabilization of low-valent metal states,for example, Mo^0.[2] Thioether ligands, R_2S, are normally found between H_2O and NH_3 in the spectrochemical series, although certain macrocyclic thioether complexes appear to have ligand fields approaching those expected for tertiary phosphine ligands; macrocyclic ligands often impose specific bonding, stereochemical, and conformational restrictions upon the resultant complexes (see Section 8).[2–4]

A series of reviews on S-donor ligands has been published and these are referred to in the appropriate sections below. Reviews on general aspects of S-coordination chemistry have appeared,[5,6] while inorganic texts give good, general overviews on the subject.[7] Comprehensive accounts of S-donor ligands have been published.[8] A



Scheme 1



Scheme 2

review of sulfur donor ligands with transition metal complexes to generate homogeneous catalysts has recently appeared.[9]

2 H_2S, RSH, AND HS^- LIGANDS

Unlike H_2O, H_2S rarely forms simple complexes with transition metal ions owing to facile deprotonation to HS^- and S^{2-}. Additionally, reaction of H_2S with simple metal salts often leads to reduction of the metal and/or the formation of insoluble metal sulfides. A number of H_2S complexes have been reported including $[Mn(\eta\text{-}C_5H_5)(CO)_2(SH_2)]$ (**1**), $[W(CO)_5(SH_2)]$ (**2**), $[Ru(NH_3)_5(SH_2)]^{2+}$ (**3**), and the tetrahedral $[AlBr_3(SH_2)]$ (**4**). The coordinated H_2S ligand in $[W(CO)_5(SH_2)]$ can be alkylated with diazoalkanes to give the corresponding thioether complexes $[W(CO)_5(SR_2)]$ (R = Me, Et). The chemistry of hydrogen sulfide with palladium and ruthenium has been the subject of a short review.[10]

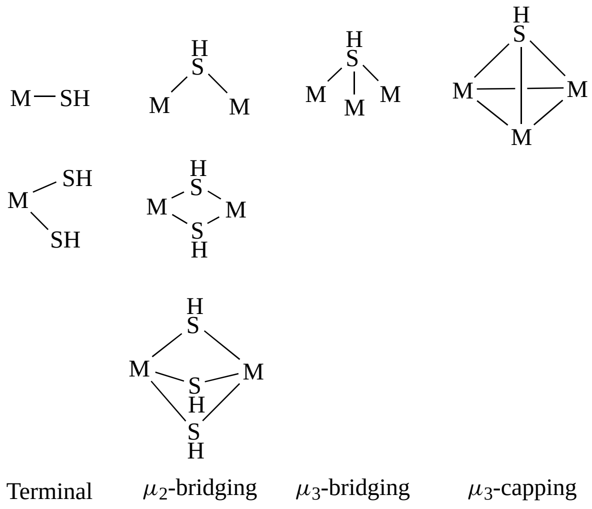
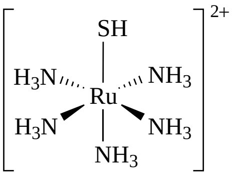
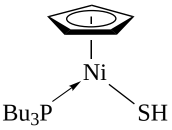


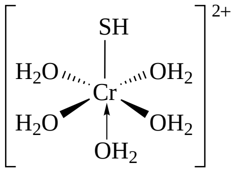
Scheme 3



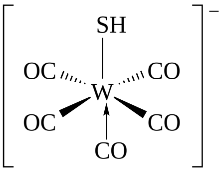
(**5**)



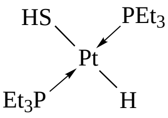
(**6**)



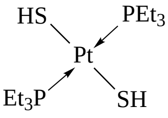
(**7**)



(**8**)



(**9**)

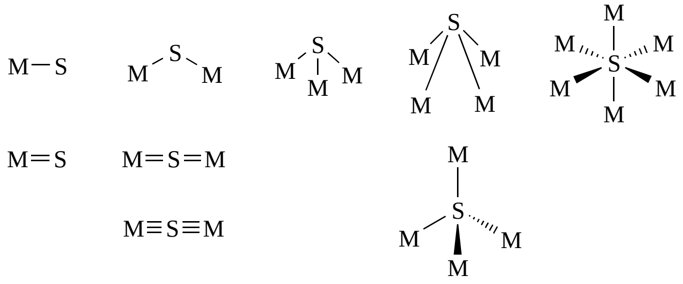


(**10**)

Syntheses of complexes incorporating the hydrosulfide HS^- ligand have to avoid the formation of S^{2-}, species which can oligomerize to give clusters and polymers. The modes of coordination of HS^- to metal centers are given in Scheme 3.

Deprotonation of coordinated H_2S occurs readily to afford species such as $[Ru(NH_3)_5(SH)]^{2+}$ (**5**), $[Ni(\eta\text{-}C_5H_5)(P\text{-}n\text{-}Bu_3)(SH)]$ (**6**), $[Cr(OH_2)_5(SH)]^{2+}$ (**7**), and $[W(CO)_5(SH)]^-$ (**8**). Oxidative addition of H_2S to Pt^0 starting materials affords trans-addition products such as *trans*-$[Pt(H)(PEt_3)_2(SH)]$ (**9**), while *trans*-$[Pt(PEt_3)_2(SH)_2]$ (**10**) has also been isolated.

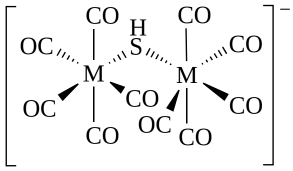
Binuclear and polynuclear species incorporating the HS^- ligand have been reported, including $[M_2(CO)_{10}(\mu\text{-}SH)]^-$ (**11**; M = Cr, Mo, W), $[Mn_2(CO)_8(\mu\text{-}SH)_2]$ (**12**), $[Fe_2(L)_2(\mu\text{-}SH)_3]^+$ (**13**); L = bis(2-diphenylphosphinoethyl)phenylphosphine, and the proposed cubane complex $[PtMe_3(SH)]_4$ (**14**). Polymeric hydrosulfide complexes have been reported for the complex $[Co(SH)([14]aneN_4)](ClO_4)$ ($[14]aneN_4$ = 1,4,7,11-tetraazacyclotetradecane) where the macrocylic donors adopt the equatorial positions with the Co^{II} ions bridged by hydrosulfide anions positioned at the axial sites.[11] Hydrosulfido complexes of transition metals have been reviewed with emphasis being placed on the reactivities of hydrosulfido complexes, including nucleophilic reactions, oxidative coupling, and sulfide cluster formation.[12] The hydrogenation and hydrogenolysis of thiophenic molecules catalysed by soluble



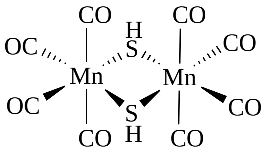
μ_1-terminal μ_2-bridging μ_3-bridging μ_4-bridging μ_6-interstitial

Scheme 4

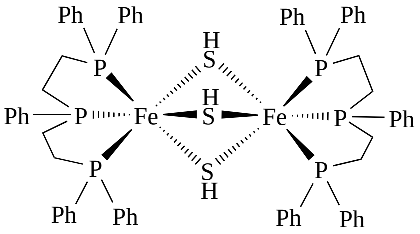
metal complexes has been reviewed and the mechanistic information has been related to heterogeneous hydrodesulfurization catalysis.[13]



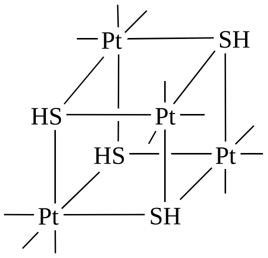
(**11**)



(**12**)



(**13**)



(**14**)

Complexes incorporating thiol RSH ligands are rare since deprotonation at the coordinated S-donor is relatively facile, although $[Ru(NH_3)_5(SHEt)]^{2+}$ and [Fe(TPP)(SPh)(SPhH)] have been reported.

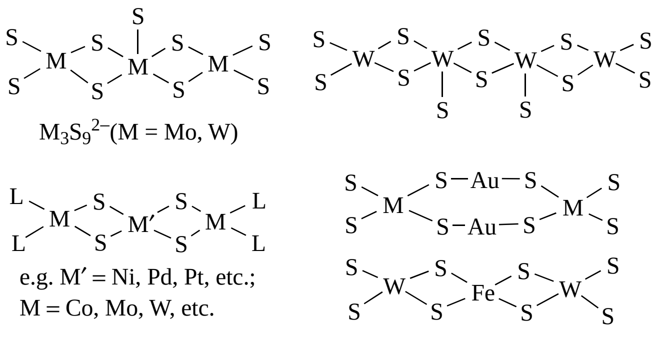
3 SULFIDES: S_N^{2-} (*See Sulfur: Inorganic Chemistry*)

3.1 Monosulfide: S^{2-}

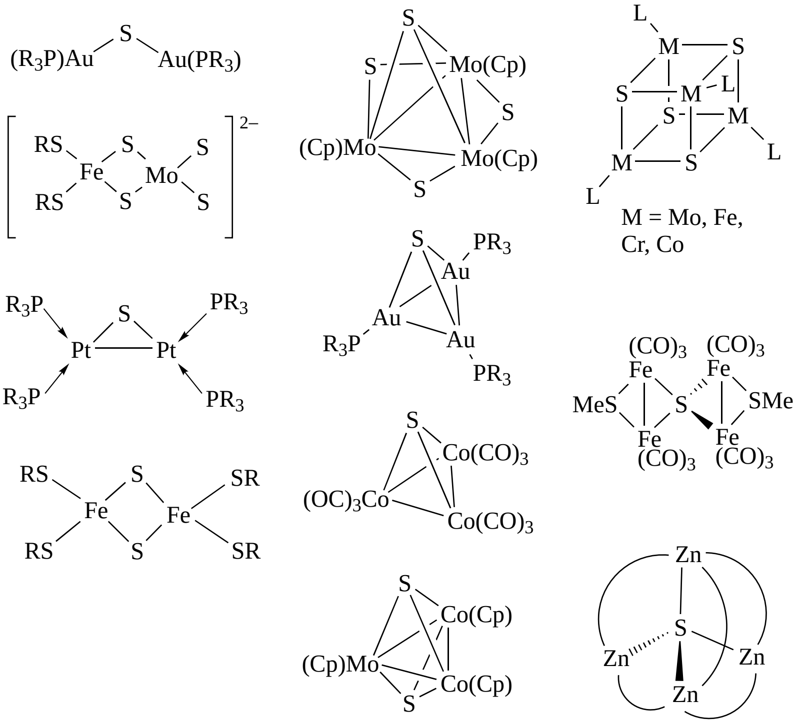
The coordination chemistry of the sulfido ligand S^{2-} is very varied. Scheme 4 illustrates the modes of coordination of S^{2-} to transition metal ions. The monosulfido ligand can act as a two-electron, terminal or μ_2-bridging donor, or up to a six-electron donor if it binds as μ_4-bridging or interstitial donor. It is, therefore, not surprising that a wide variety of binuclear and polynuclear sulfido clusters complexes can be prepared.

Terminally bound sulfide S^{2-} is commonly found in a wide range of metallothio anions, particularly of d^0 metal centers for example $[MS_4]^{3-}$ (M = V, Nb, Ta), $[MS_4]^{2-}$ (M = Mo, W), and $[ReS_4]^-$. The mixed thiooxy and thioseleno anions $[MS_{4-x}O_x]^{n-}$ and $[MS_{4-x}Se_x]^{n-}$ have also been prepared. Additionally, metalloanions can coordinate to other metal centers, so behaving as ligands in their own right. Thus, a wide range of mixed metal clusters and oligomers incorporating bridging S^{2-} ligands can be prepared. Examples of metallothio anion complexes are given in Scheme 5.

Some complexes incorporating μ_2-, μ_3-, and μ_4-bridging S^{2-} ligands are illustrated in Scheme 6. Important examples include $[(OC)_2(Cp)Cr{\equiv}S{\equiv}Cr(Cp)(CO)_2]$ (**15**) incorporating a linear triply bonded Cr≡S≡Cr unit, Roussin's red anion $[Fe_2(NO)_4(\mu_2\text{-}S)_2]^{2-}$ (**16**), $[Fe_4S_4(Cp)_4]$ (**17**), and

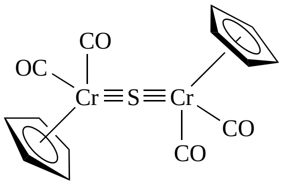


Scheme 5

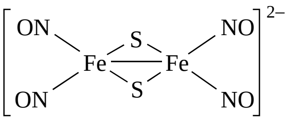


Scheme 6

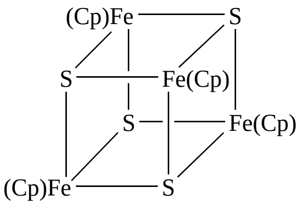
$[Fe_4S_6(Cp)_4]$ incorporating S_2^- and S_2^{2-} moieties. Two reviews describing the use of $[Cp'_2M_2S_4]$ (where M = Fe or Ru and Cp′ = cyclopentadienyl or substituted cyclopentadienyl) as a building block for a host of multinuclear transition metal clusters have been published.[14,15]



(**15**)



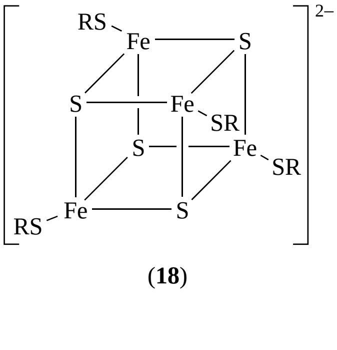
(**16**)



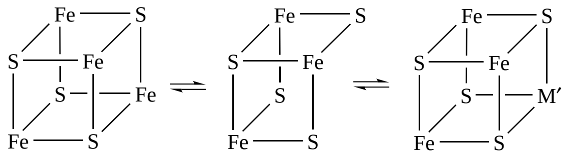
(**17**)

An enormous range of metal–sulfur cluster compounds derived from covalently linked cubane clusters and/or oligomers of metallothio anions has been prepared. Many have been found to be redox active and act as electron sinks via multielectron transfer processes. The electrochemistry of these systems has been comprehensively reviewed.[16]

One of the most important structural motifs in metal-sulfido cluster chemistry is the M_4S_4 cube. Fe_4S_4 cubane clusters have been studied in relation to biological systems in terms of substitution and redox chemistry. For example, the one-electron reduction of $[Fe_4S_4(SR)_4]^{2-}$ (**18**) to $[Fe_4S_4(SR)_4]^{3-}$ leads to a structural reorganization of the cubane structure from D_{2d} compressed to elongated D_{2d} (Scheme 7).[17] Scheme 8 shows subsite-specific reactions that have been reported at the $[Fe_4S_4]$ core.[18] The nature of the [4Fe–4S] and [3Fe–4S] cubane cluster in metalloenzymes such as ferrodoxins, aconitase, nitrogenase, hydrogenases, and sulfite reductase are major areas of research interest. The chemical interconversion of [4Fe–4S] and [3Fe–4S] clusters has allowed the synthesis of heteroatom clusters of type [3FeM′–4S] (equation 1).



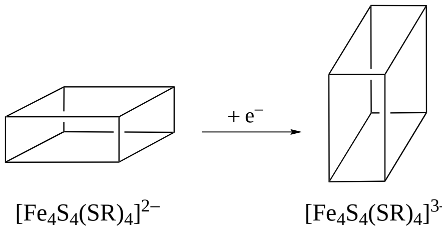
(**18**)



(1)

[4Fe–4S] [3Fe–4S] [3FeM′–4S]

A very wide range of higher metal–sulfur clusters has been prepared for example, $[Ni_9(\mu_4\text{-}S)_3(\mu_3\text{-}S)_6(PEt_3)_6]^{2+}$ (**19**),[11] $[Ni_3(\mu_3\text{-}S)_2(PEt_3)_6]^{2+}$ (**20**), and $[Ni_3(\mu_3\text{-}S)_2(SH)(PEt_3)_5]^{2+}$ (**21**).[12]



$[Fe_4S_4(SR)_4]^{2-}$ $[Fe_4S_4(SR)_4]^{3-}$

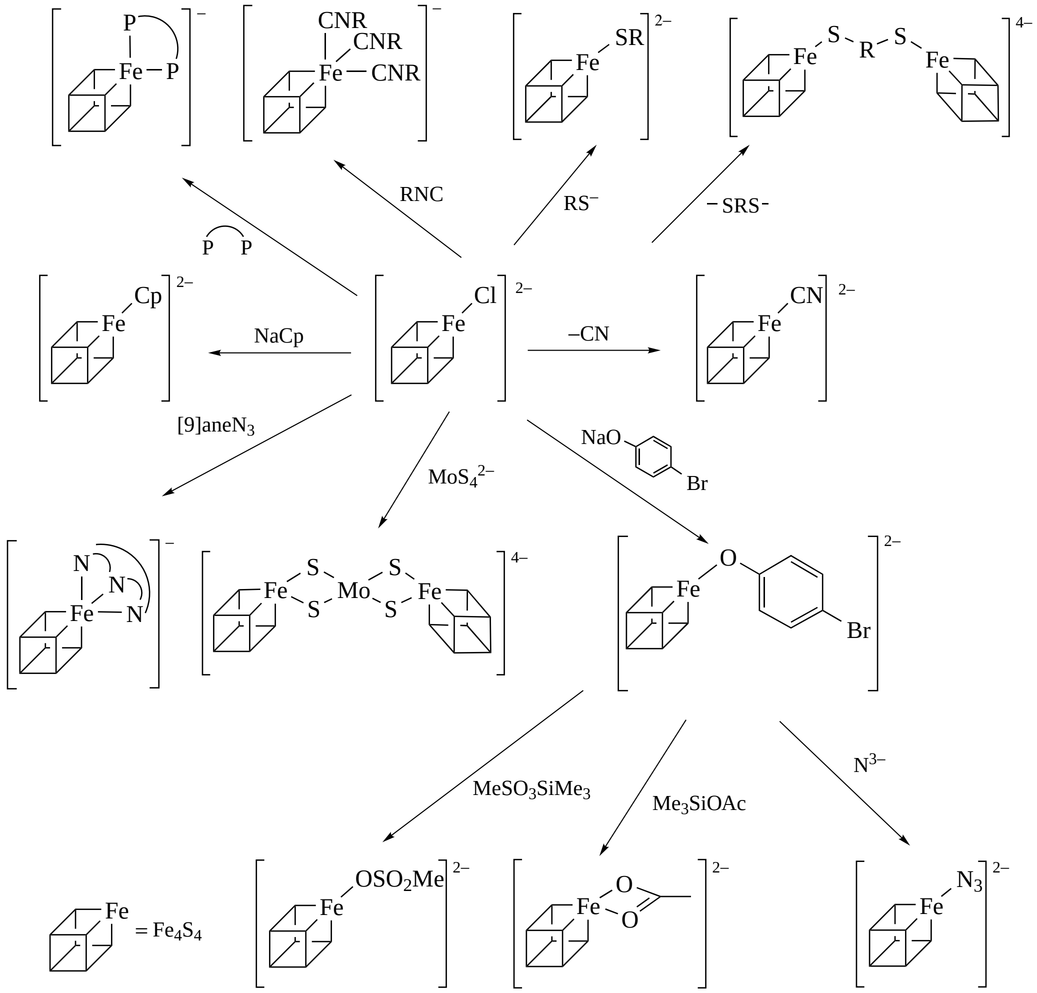
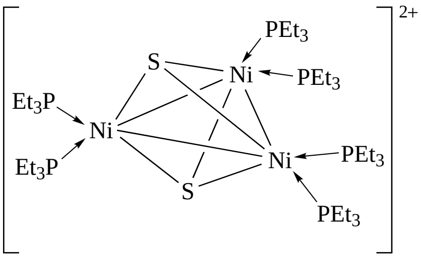
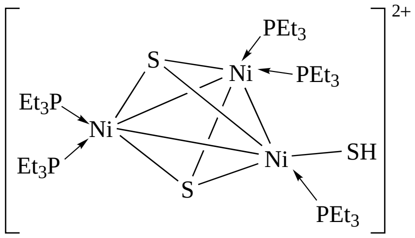


Scheme 8



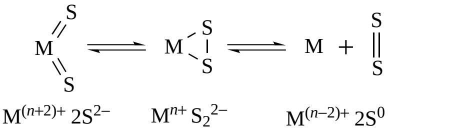
(**20**)



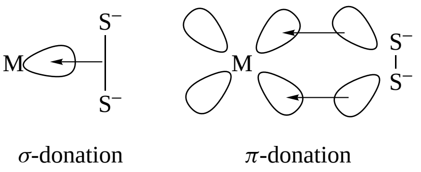
(**21**)

3.2 Disulfide: S_2^{2-}

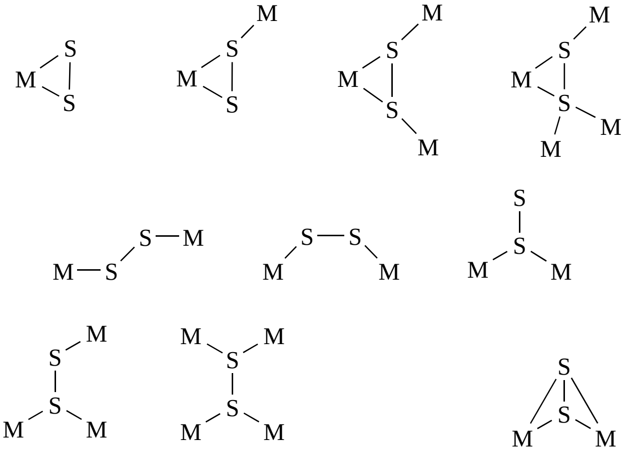
In general, complexes of S_2^{2-} can be prepared by reaction of elemental sulfur with electron-rich metal centers, by high-temperature reaction of metal complexes with S_2Cl_2 and S_8, or by direct reaction of metal salts with polysulfides. The binding of S_2^{2-} to transition metals can be compared to the binding of O_2:σ-donation occurs from the filled π-orbital of the S_2^{2-} fragment coupled to π-donation from the π^*-antibonding orbital on S_2^{2-} to the metal d_π-orbitals (Scheme 9). Thus, coordination to a metal ion leads to a shortening of the S–S distance in S_2^{2-} and makes this fragment more susceptible to nucleophilic attack. The redox interconversion of coordinated S^{2-} and S_2^{2-} to give S_2 (equation 2) is of relevance to the action of desulfurization catalysts and to related biological processes.



(2)



Scheme 9



Scheme 10

Scheme 10 illustrates the range of coordination modes of S_2^{2-} to metal centers, while Scheme 11 illustrates some the complexes that have been characterized.

An unusual μ-η^1-S_2 ligand has been stabilized in the complex $[Fe_2(S_2)_3([9]aneN_3)_2]$ ($[9]aneN_3 = 1,4,7$-tri-azacyclononane). The persulfide ligands are stabilized via hydrogen-bonding to the amine hydrogen atoms, and the polarized structure for the persulfide ligands is supported by their reaction with methyliodide.[19]

3.3 Polysulfides: S_x^{2-}

The coordination chemistry of polysulfides has been reviewed[20] and has been developed for the synthesis of new chalcogenide materials.[21] Polysulfide ligands S_x^{2-} ($x = 2-9$) form a remarkable range of metal complexes which are usually prepared by reaction of metal salts with either elemental sulfur and/or with polysulfides. Scheme 12 illustrates some of the polysulfide complexes that have been prepared and characterized. The complex $[Ti(Cp)_2(S_5)]$ is a versatile starting material and reagent for the synthesis of a wide variety of compounds (Scheme 13). $[Ti(Cp)_2(S_5)]$ and $[Ti(Cp)_2(S_3)]$ are both fluxional in solution, showing a ring flipping of the polysulfide ring (equations 3 and 4).[22]

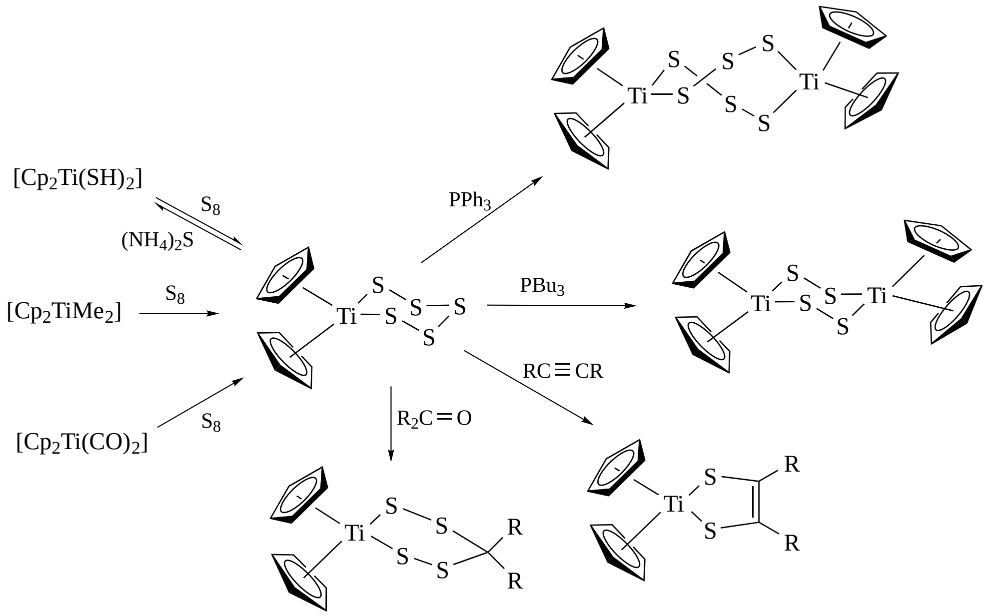
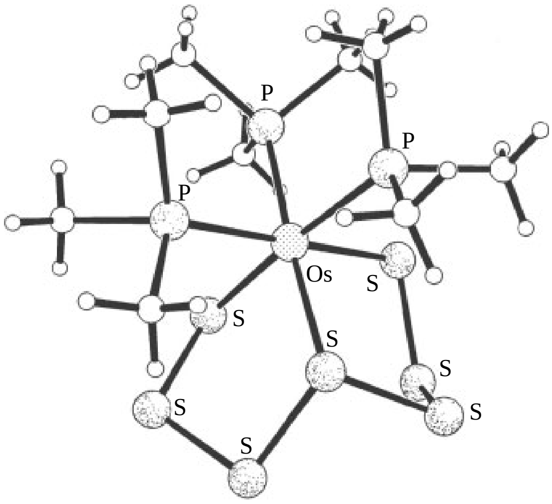
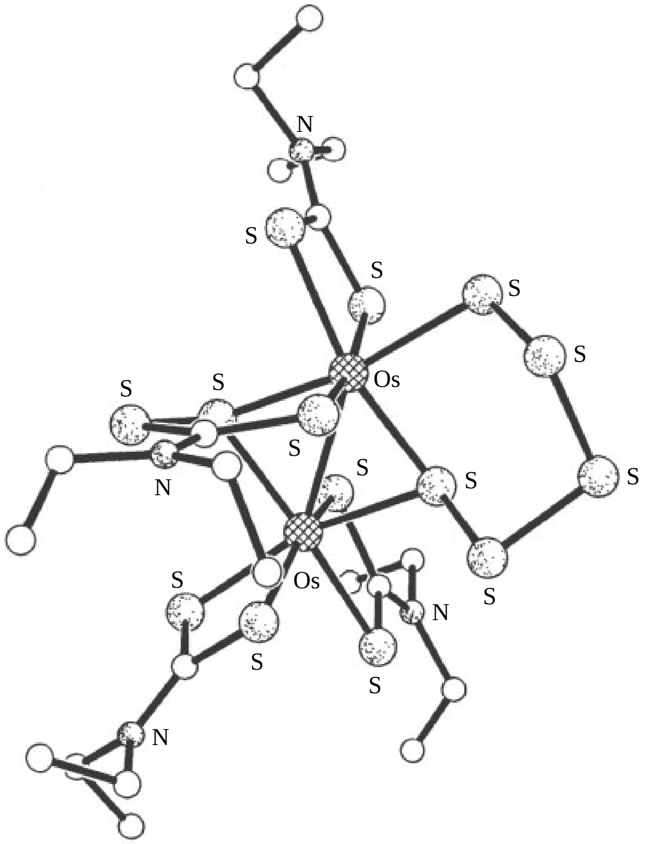


Scheme 13

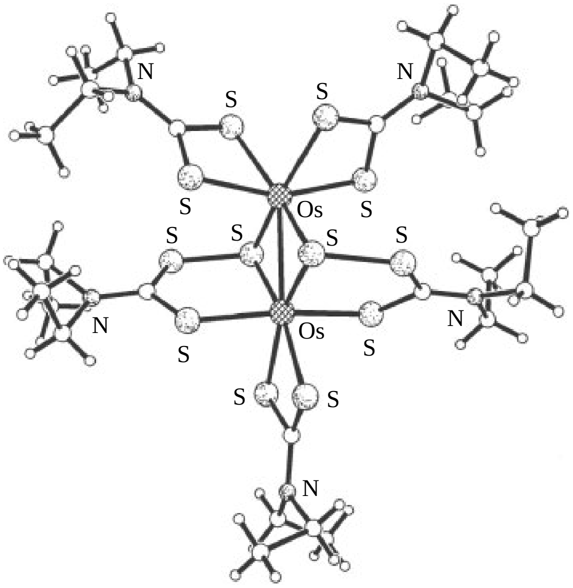
Reaction of [Os(PMe$_3$)$_3$(H)(CH$_2$PMe$_2$)] with elemental S affords two products [Os(PMe$_3$)$_3$(S$_6$)] and [Os(PMe$_3$)$_3$(S$_7$)] (**22**), the latter incorporating a tridentate S_7^{2-} ligand.[23] Likewise, reaction of [Os(S$_2$CNR$_2$)$_3$] with elemental S affords [Os$_2$(S$_5$)(S$_3$CNR$_2$)(S$_2$CNR$_2$)$_5$] (**23**; R = Et) in which an S_5^{2-} chelate has been formed, and an S has been incorporated into one of the dithiocarbamate, S$_2$CNR$_2$, ligands to give coordinated S$_3$CNR$_2$.[23] The dinuclear species [Os$_2$(S$_3$CNEt$_2$)$_2$(S$_2$CNEt$_2$)$_3$]$^+$ (**24**) has been isolated from the reaction of [OsCl$_6$]$^{2-}$ with NaS$_2$CNEt$_2$.



(**22**)



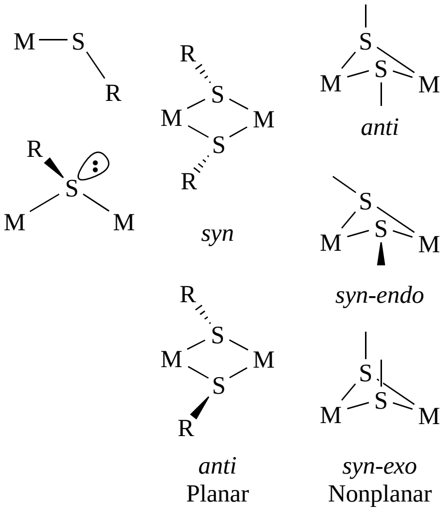
(**23**)



(**24**)

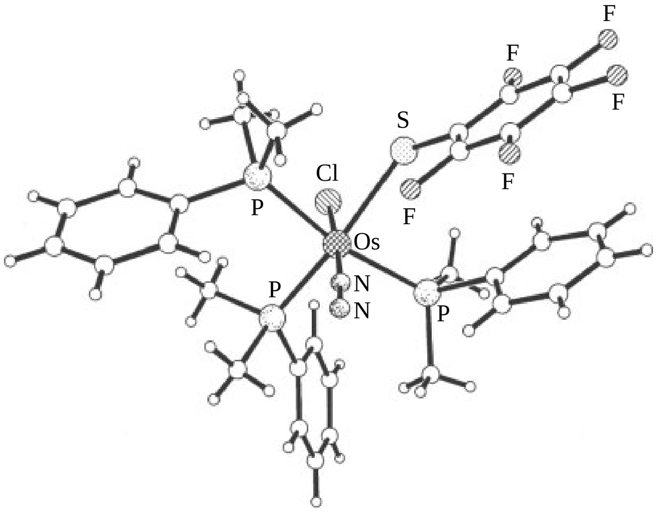
4 THIOLATES: RS$^-$

Comprehensive reviews on the coordination chemistry of thiolates and hindered thiolates have appeared.[24,25] One of the major problems in preparing complexes is oxidation of the thiolate to the corresponding disulfide. This can be more readily controlled with hindered thiolates, which can stabilize highly reactive, coordinatively unsaturated complexes. An important feature of thiolates is their ability to level charge within metal complexes. Thus, both π-acceptor (d-orbital on S, or S–C σ^*-orbital) and π-donor (lone pair on S) properties of thiolates have been discussed in relation to the degree of electron density at the metal center(s). The tendency for S···S interactions and the polarizability of S-donors contrasts with the chemistry of the corresponding O-donor alkoxides. Scheme 14 illustrates the bonding modes of thiolates, RS$^-$, to transition metal centers.

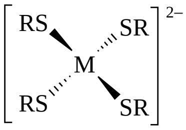


Scheme 14

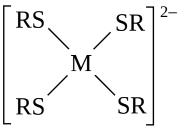
Thiolates, RS$^-$, can bind terminally in octahedral [$OsCl(PPhMe_2)_3(N_2)(SC_6F_5)$] (**25**), tetrahedral [$M(SR)_4$]$^{2-}$ (**26**) (M = Fe, Co, Ni, Zn, Cd, Hg), square-planar [$Pd(SR)_4$]$^{2-}$ (**27**), trigonal planar [$M(SPh)_3$]$^-$ (**28**) (M = Cu, Hg), and linear structures [$Hg(SR)_2$] (**29**) (R = for example, Ph, SC_6F_5, SC_6Cl_5, SEt_3).



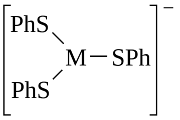
(**25**)



(**26**)



(**27**)



(**28**)

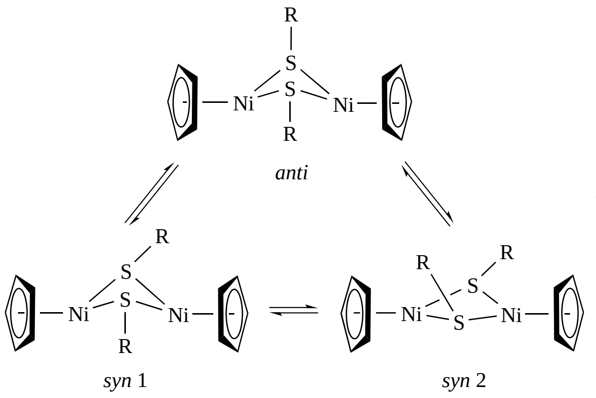
RS—Hg—SR

(**29**)

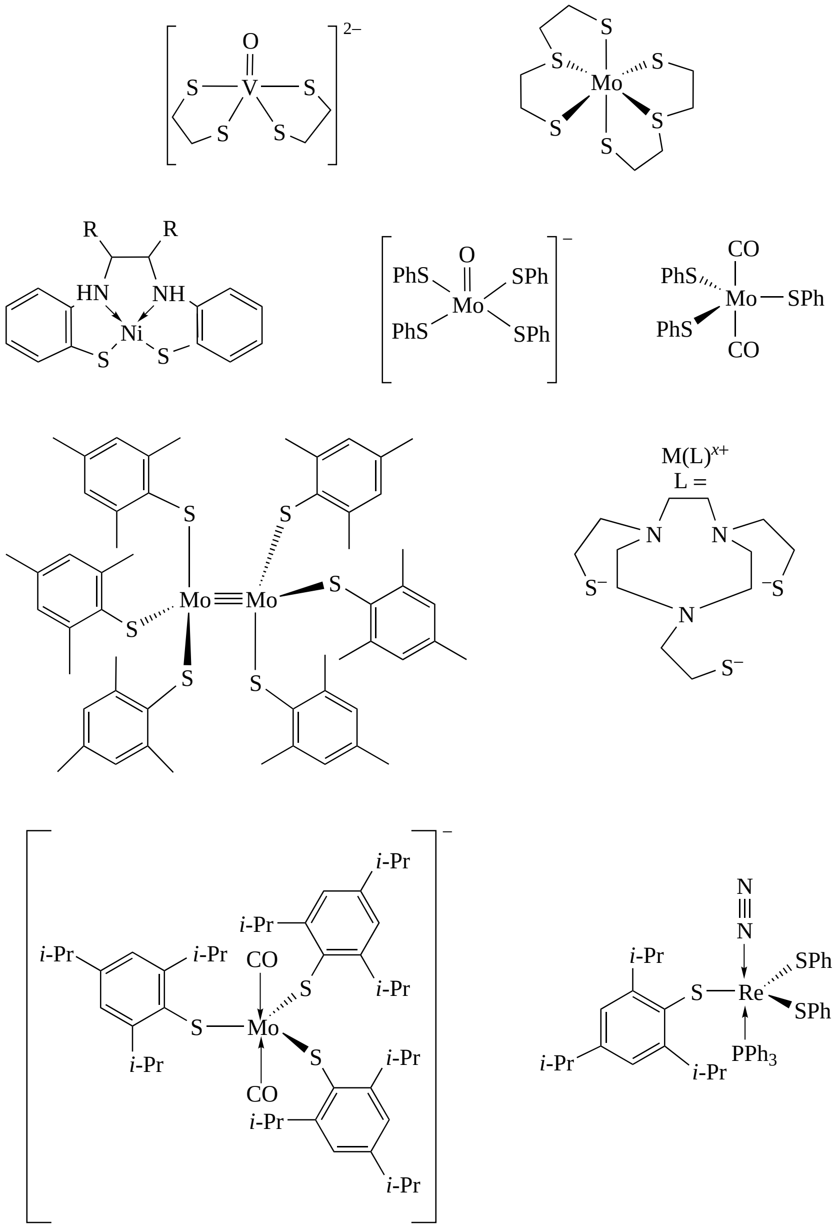
The synthesis, structures, and reactivities of metal thiolates with group 4 and 5 metals,[26] and the synthesis and study of copper-thiolates[27] have been reviewed. Hg^{II} thiolate chemistry has been reviewed and related to the binding of Hg^{II} in vivo by metalloregulatory proteins.[28] A range of two-, three-, and four-coordinate Hg^{II} thiolate complexes has been prepared, and comparisons with the metalloregulatory protein, Hg-MerR,

suggest that the latter involves a trigonal planar $[Hg(SCys)_3]^-$ model. A ligand composed of *p-tert*-butylcalix[4]arene backbone bearing two thiol and two dodecyloxy- groups displays selective extraction of Hg^{II} from aqueous solution over Cd^{II} and Pb^{II}.[29] Scheme 15 illustrates some terminally bound thiolate complexes. Au^I thiosugar complexes and thiomalate complexes are used for the treatment of rheumatoid arthritis. Bridging thiolate ligands have been also observed and some complexes are given in Scheme 16.

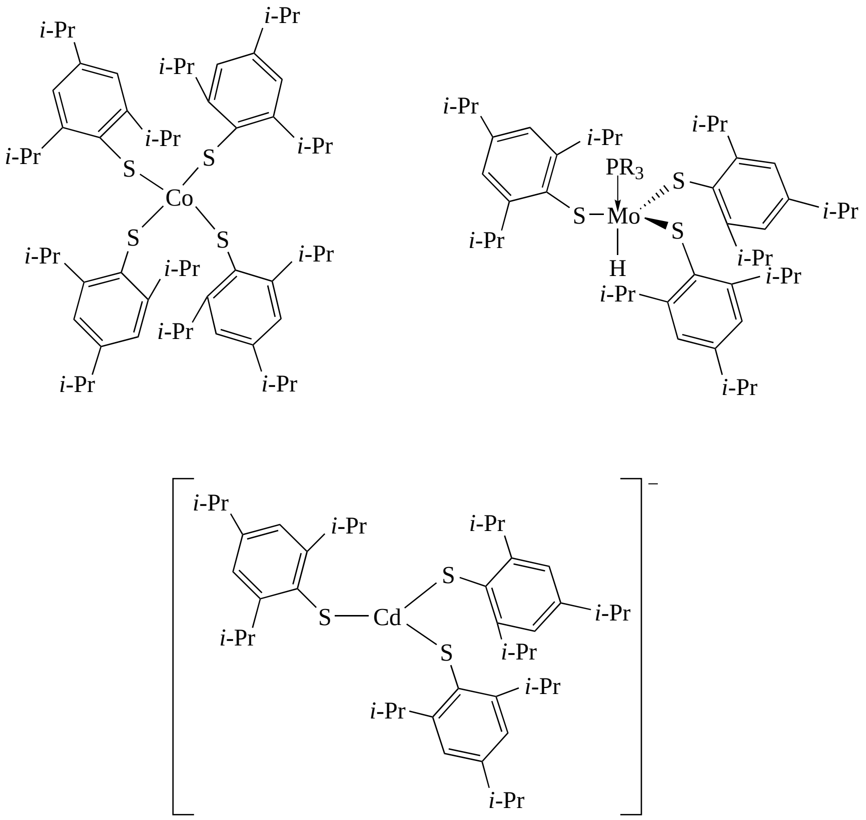
Inversion at the S-donors of thiolates (Scheme 17) can be monitored by NMR spectroscopy and the activation energies for these fluxional processes have been assessed for a range of complexes (equation 5).[30]



(5)



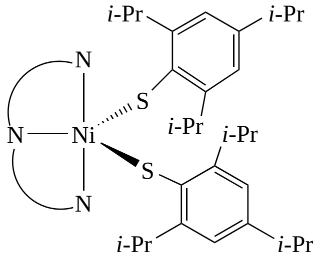
Scheme 15



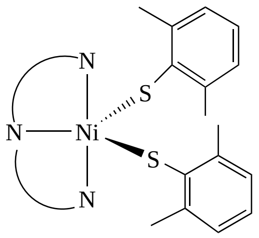
Scheme 15 cont'd

Pendant arm macrocycles with thiolate arms have been synthesized and shown to encapsulate Ga^{III} and In^{III} octahedrally.[31]

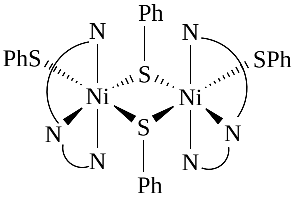
A recent major impetus for the study of S-donor complexes has been provided by the discovery of paramagnetic Ni centers in several biological systems (see Section 9). Several mixed N/S-donor complexes have been prepared and characterized, including $[Ni(terpy)(SPh)_2]_2$ (**30**), $[Ni(terpy)(SC_6F_5)_2(NCMe)]$ (**31**), $[Ni(terpy)(SR)_2]$ [R = 2,4,6-i-$Pr_3C_6H_2$ (**32**); 2,6-$Me_2C_6H_3$ (**33**)], and their chemical and redox properties have been related to the in vivo systems.[32]



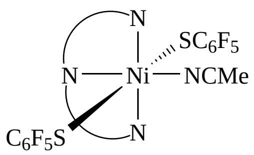
(**32**)



(**33**)

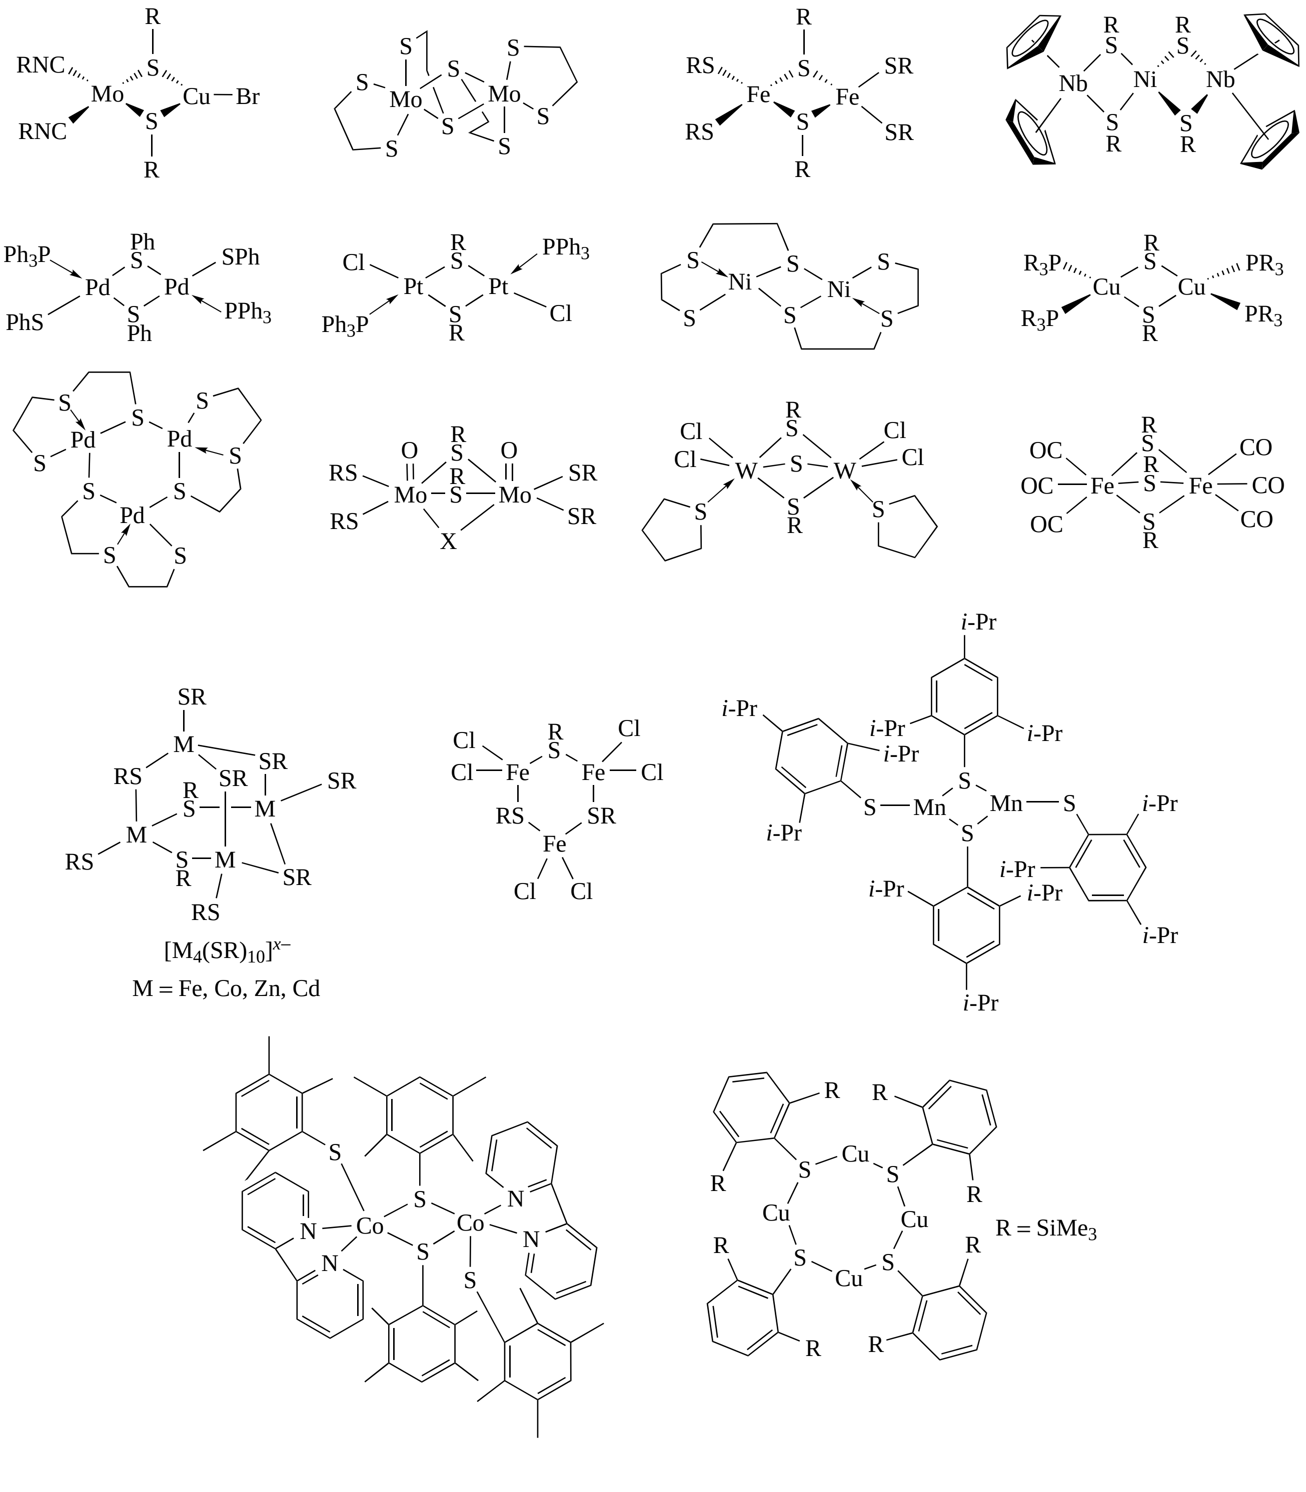


(**30**)



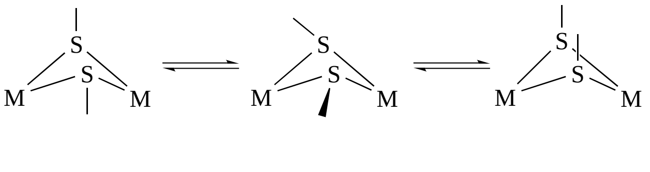
(**31**)

Holm and coworkers have investigated the structural and redox properties of a related series of mixed N/S-donor Ni^{II} complexes, for example (**34**) and (**35**), and have generated and studied the corresponding Ni^{III} species.[33] The binuclear nickel-thiolate macrocyclic complex (**36**) displays a one-electron oxidation to yield a $Ni^{III}.Ni^{II}$ species with significant delocalization of the unpaired electron density onto the bridging thiolate ligands but not onto the second nickel ion. Thus, the charge delocalization in this complex lies between the two redox extremes of nickel(III)-thiolate and nickel(II)-thiyl radical.[34] Redox studies on a series of metal bound thiolates such as (**37**) demonstrate their oxidation to sulfones and then to the sulfoxides. All the complexes display a reversible Ni^{II}-Ni^{I} reductive couple with the thiolate complexes also showing an irreversible ligand-based oxidation presumably to an unstable thiyl radical species. The

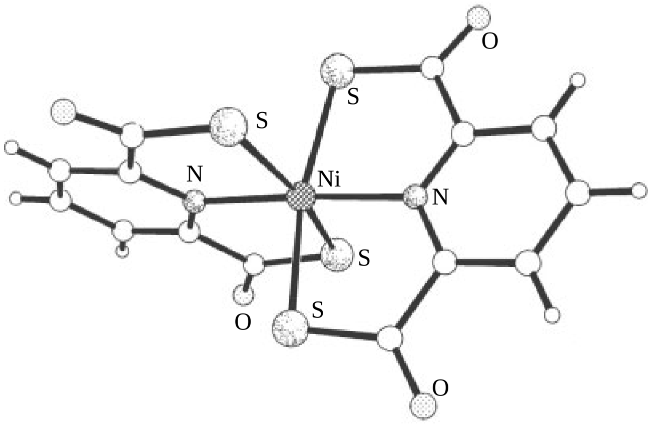


Scheme 16

bis(sulfone) complexes additionally show a reversible Ni^{II}-Ni^{III} oxidative process as do the analogous complexes where the sulfur has been alkylated. The possibility for a two centred Ni-SR site to function in oxidative-addition reactions was suggested as an intriguing solution by Nature to achieve this type of reactivity.[35]

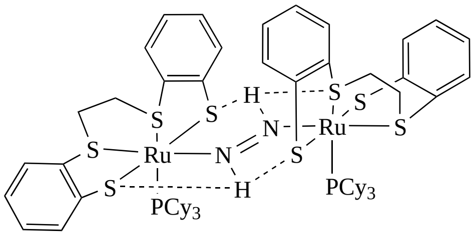


Scheme 17

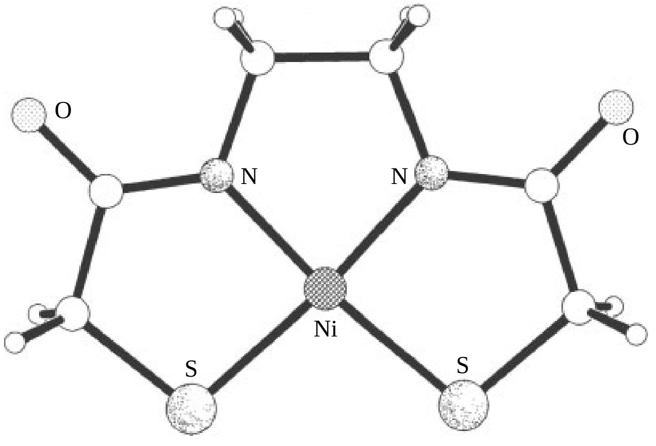


(**34**)

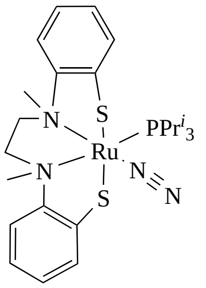
The Ru diazene binuclear complex (**38**) represents an important model for the activation of N_2 with N–H···(S-thiolate)$_2$ interactions being vital to stabilisation of the diazene ligand.[36] Furthermore, the amino-thiolate Ru complex (**39**) incorporating bound dinitrogen can be prepared under mild conditions by exchange of a bound MeCN ligand.[37] Related Fe amino-thiolate complexes have also been shown to stabilize diazene fragments and the observed strong coupling of the H^+/e^- flux in these systems has been related to the mechanism of the nitrogenase FeMo cofactor.[38]



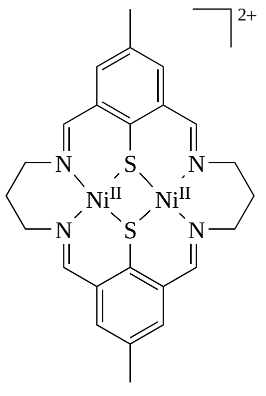
(**38**)



(**35**)



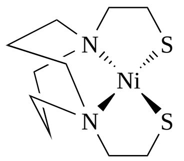
(**39**)



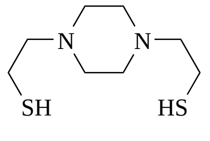
(**36**)

The Fe^{II} complex of 4,6-di-*tert*-butyl-2-aminothiophenol has been characterized crystallographically with the ligand in *o*-aminothiophenolate(1-), aromatic *o*-iminothiophenolate dianionic (2-) and open-shell *o*-iminothionebenzosemiquinonate (1-) forms. Zero-field Mossbauer spectroscopy unambiguously confirms the presence of high-spin ferrous ions throughout.[39]

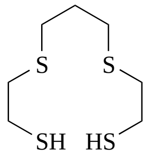
The aggregation of Ni^{II} thiolate complexes yields homohexanuclear and heteropentanuclear complexes.[40,41] Fascinating pinwheel motifs have been observed with ligands such as (**40**) and (**41**) in which two Ni^{II} ions bridge four Ni^{II} amino-thiolate complexes. Alternatively, heteropentanuclear or heterohexanuclear complexes are realized where two Cu^I



(**37**)



(**40**)



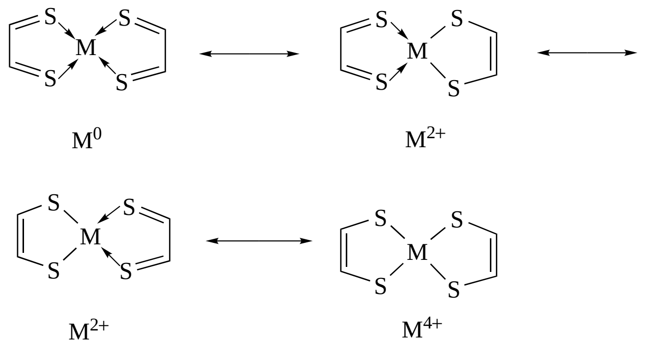
(**41**)

ions or two Pd^{II} ions bridge three or four Ni^{II} amino-thiolate complexes, respectively. Both the bite angle of the S^--Ni-S^- unit and the choice of bridging metal ion influence whether a simple trinuclear aggregate or a higher motif is favored.

The isomers of [Co(L-cys)(en)$_2$](NO$_3$)·AgNO$_3$ have been structurally characterized. Significantly, the structure derived from Δ_L-[Co(L-cys)(en)$_2$]$^+$ leads to a two-dimensional sheetlike structure, while Δ_L-[Co(L-cys)(en)$_2$]$^+$ affords a one-dimensional left-handed helix, where the left-handed helicity is predetermined by the chiral configuration in the starting Co^{III} complex.[42]

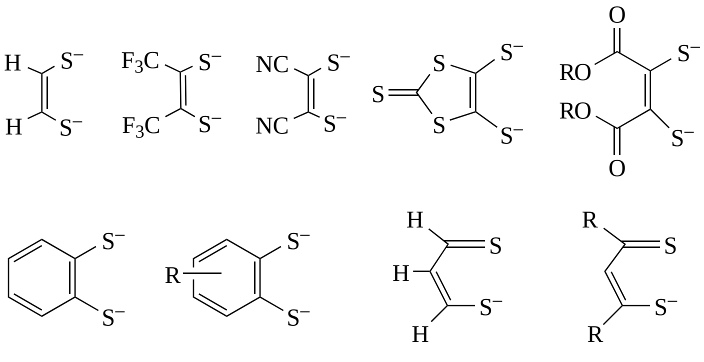
5 DITHIOLENES

The coordination chemistry of 1,2-dithiolenes and related ligands has been reviewed.[25,43] 1,2-Dithiolenes are bidentate, redox-active ligands which can coordinate in the limit as dithiodiketones or dithiolates (Scheme 18). Scheme 19 illustrates the more common dithiolene ligands that have been investigated. Syntheses of these ligands are well established and are usually based upon derivatization of dihalo and ketonic starting materials (Scheme 20).

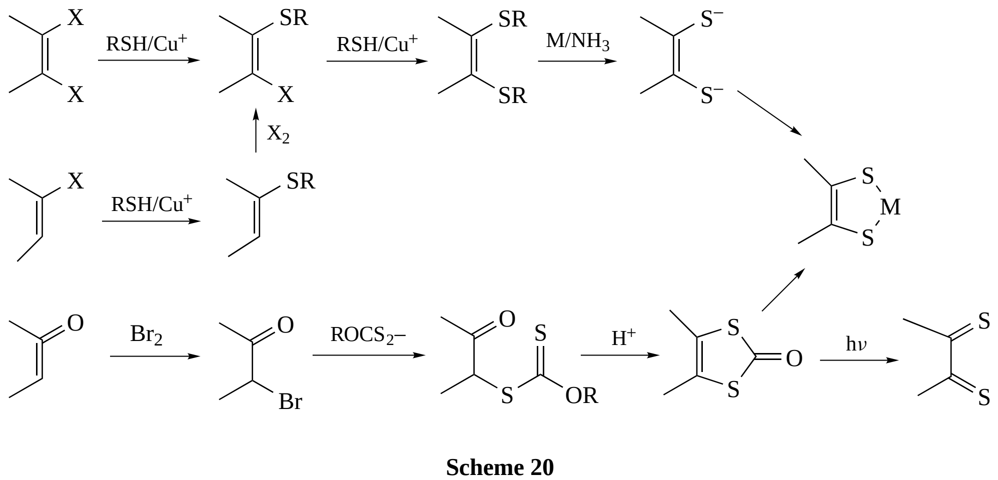


Scheme 18

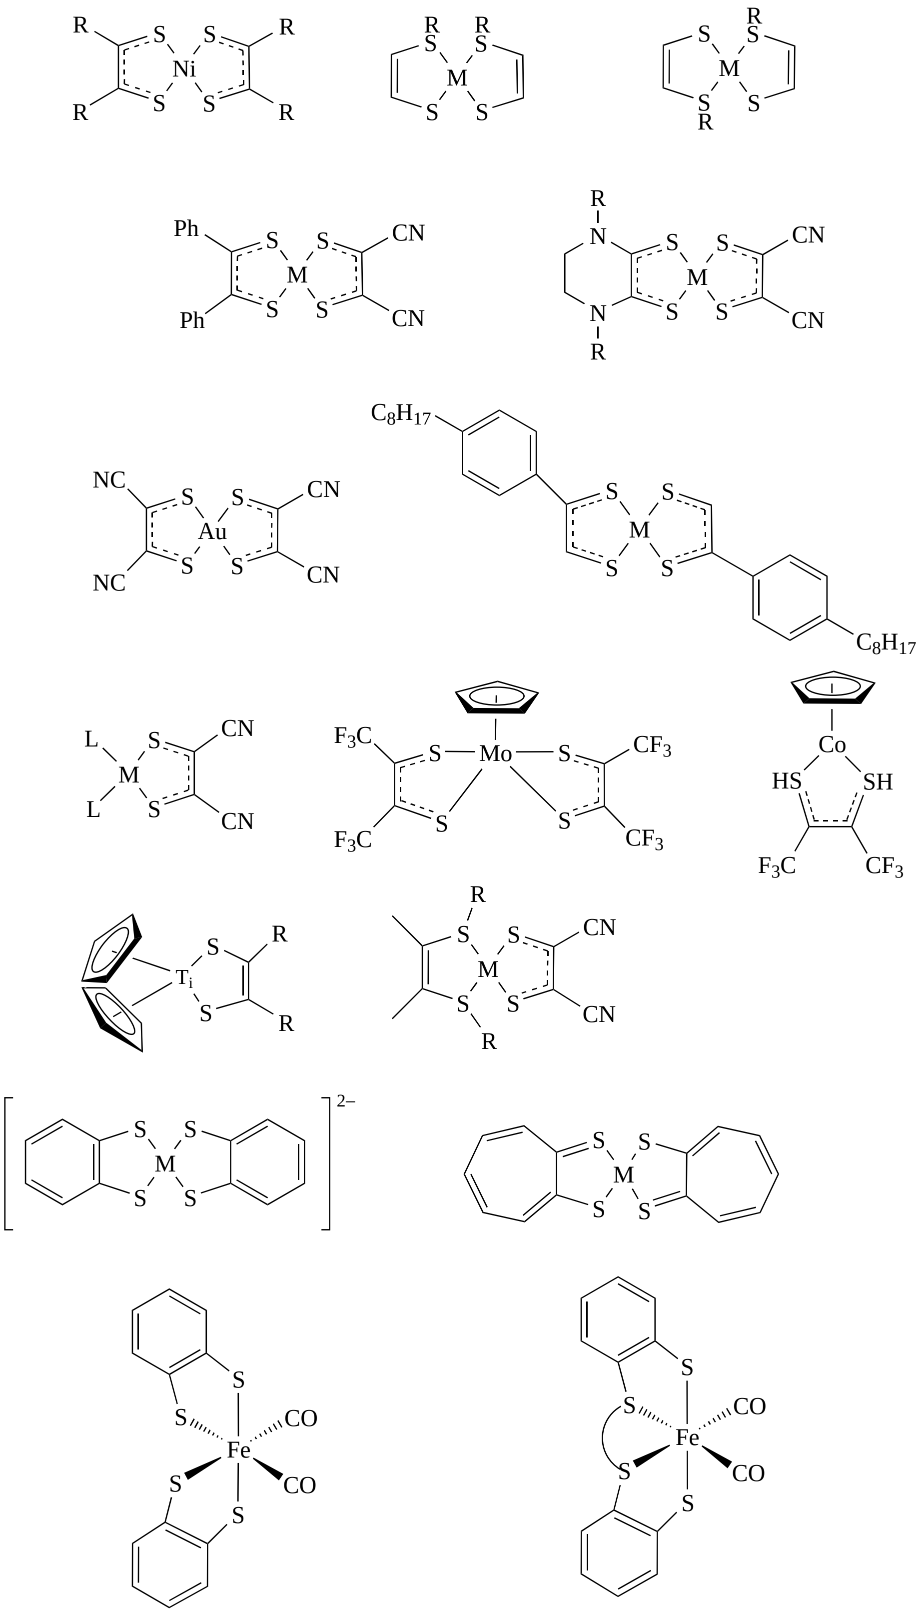
The coordination chemistry of dithiolenes is extensive with square-planar $[M(L)_2]^{x+}$ (**42**) and tris-chelate complexes $[M(L)_3]^{x+}$ (**43**) being prevalent. The latter are interesting since they tend to adopt trigonal prismatic rather than the much more common octahedral geometry, the driving force being thought to be attractive intraligand S–S interactions. The square-planar complexes $[M(L)_2]^{x+}$ can form five-coordinate adducts or oligomers via M–S bridges (equations 6 and 7). The formation of redox oligomers and related



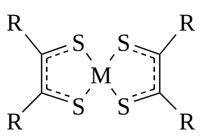
Scheme 19



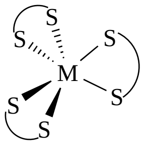
Scheme 20



Scheme 21

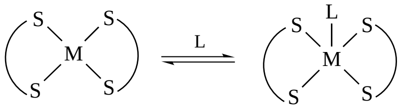


(42)

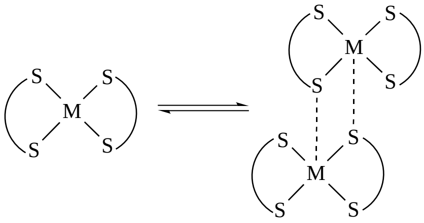


(43)

complexes showing stacked structures in the solid state has led to the formation of one-dimensional conductors, partially oxidized/reduced conducting polymers, and charge-transfer salts. Liquid crystal dithiolenes have also been prepared. Many dithiolene complexes are redox active, and the interpretation of these electron-transfer processes as being metal or ligand based has been controversial. The problems of assignment stem from the facile electron transfer of dithiolene ligands themselves, and delocalization of charge density across the ligand and metal centers.



(6)

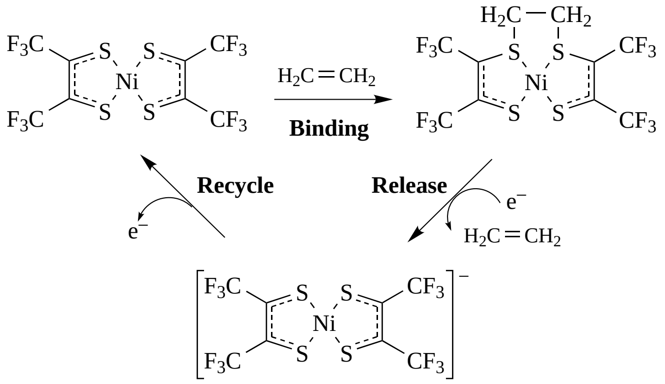


(7)

Scheme 21 illustrates some of the diothiolene complexes that have been prepared. The coordination chemistry of ligands derived from benzene-1,2-dithiolate has been investigated with Fe and Ru centers for the potential binding of N_2 and N_2H_4 as models for nitrogenase (*see* ***Nitrogenase: Metal Cluster Models***).[36,44]

Ni^{II} dithiolenes have been shown to be effective for the electrochemical separation of alkenes from complex streams. No poisoning was observed in the presence of H_2, CO, acetylene, or H_2S with binding of alkene to the sulfur ligands rather than to Ni (Scheme 22). This reflects the radical nature of dithiolenes in these complexes.[45] Metal bis-1,2-dithiolene complexes may also act as conducting or magnetic assemblies.[46]

A general route to asymmetric dithiolenes has been developed and has been used for the generation of the dithiolene complexes $[MO(dithiolene)_2]^{2-}$ (M = Mo or W).[47] These complexes have been developed to explore the chemistry of Mo and W when bound to pterin ligands in biology, for example in the molybdenum cofactor of DMSO reductase or in aldehyde oxidoreductase. A comprehensive study of 25 complexes $[W^{IV}(OC_6H_4\text{-}p\text{-}X')(S_2C_2(C_6H_4\text{-}p\text{-}X)_2)_2]^{1-}$ (X = Br, F, H, Me, OMe and X′ = CN, Br, H, NH_2) has been reported and their relevence to the mechanism of oxygen atom transfer in the DMSO reductase isoenzyme



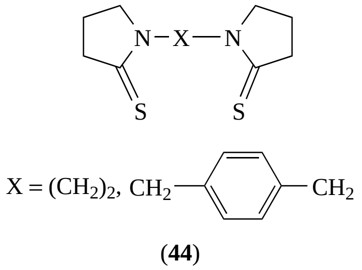
Scheme 22

described. A stepwise oxo-transfer reaction is proposed in an early transition state in which primary W^{IV}-O(substrate) bond-making is rate-limiting. This is followed by a six-coordinate structure with another transition state involving both atom and electron transfer to yield an $W^{VI} = O$ group.[48] Monodithiolene complexes of Mo^V and Mo^{VI} have been synthesized as structural analogs of the oxidized form of the sulfite oxidase enzyme family.[49]

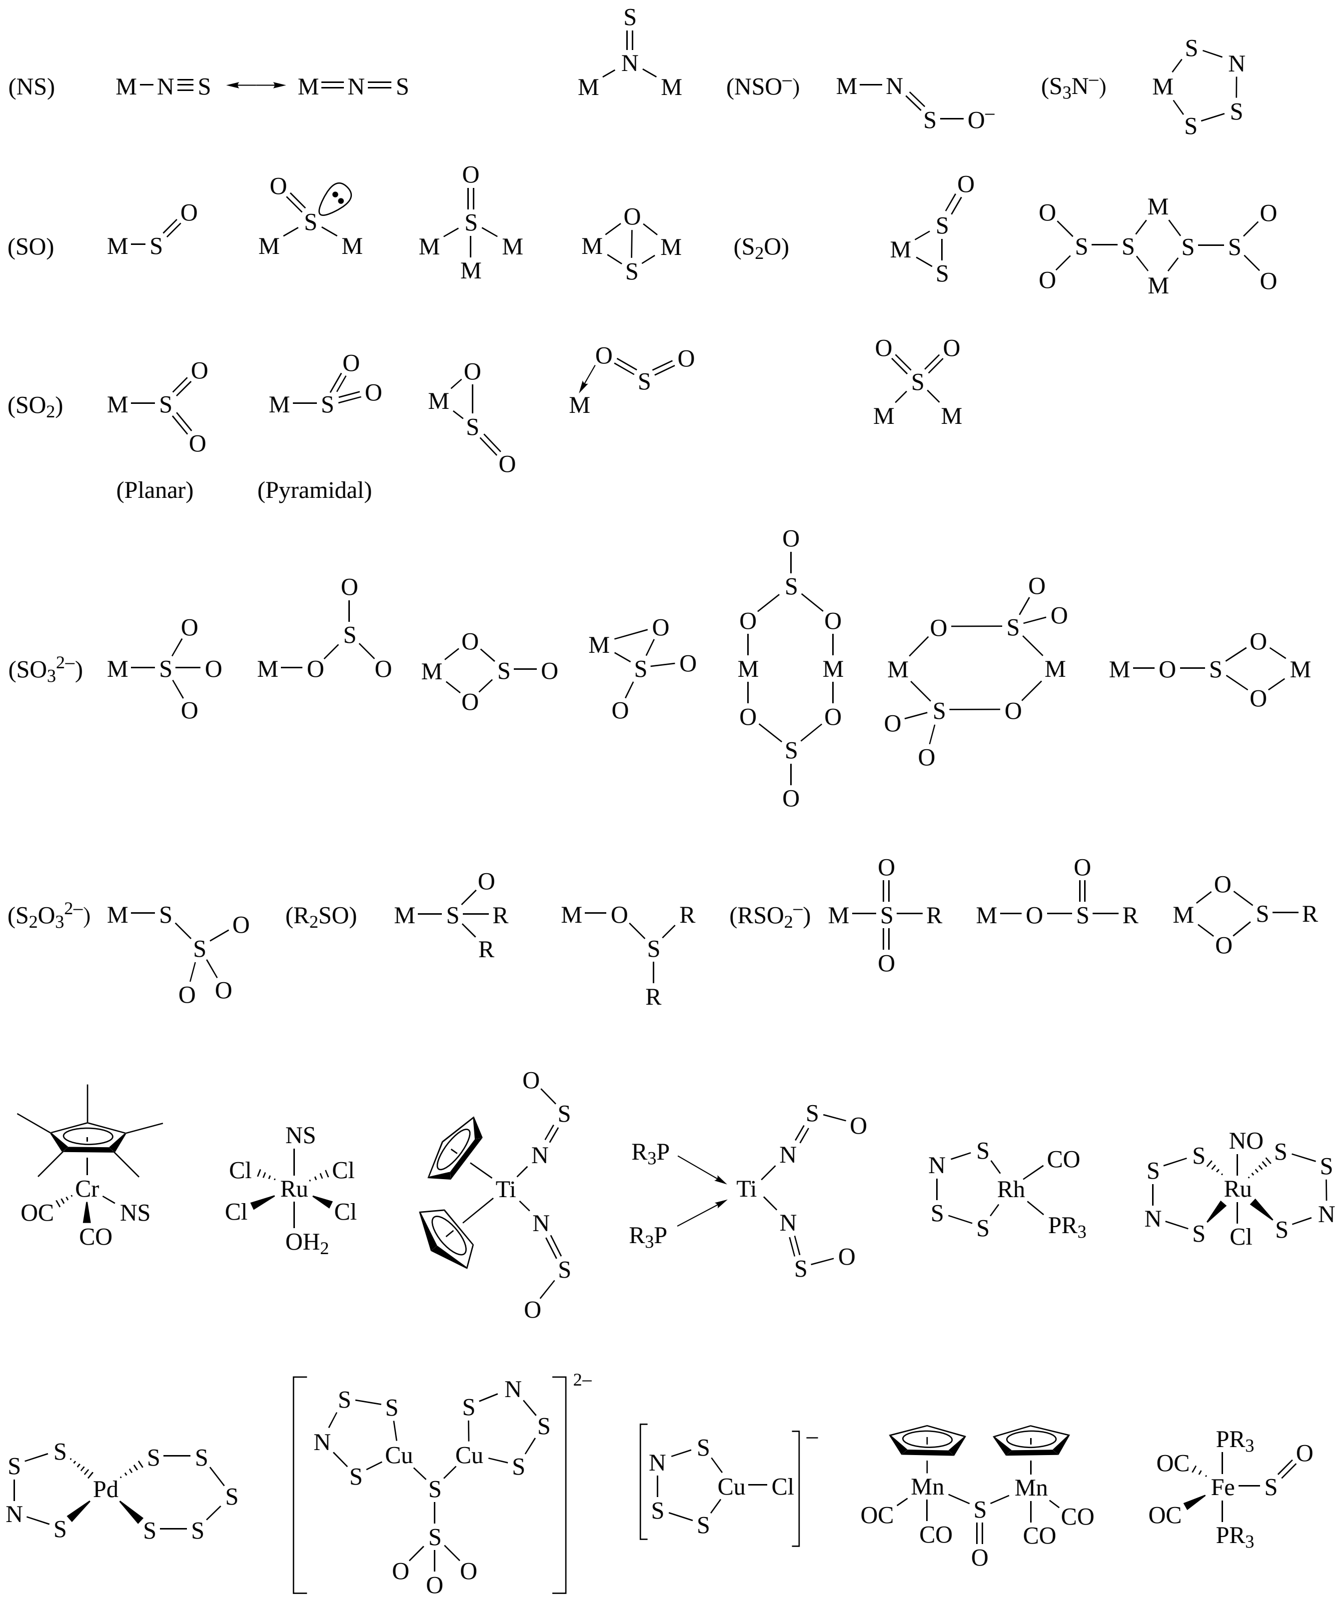
6 MIXED S/O, S/N AND P/S LIGANDS

The coordination chemistry of NS (thionitrosyl), thiazate (NSO^-), disulfidothionitrate (S_3N^-), sulfur monoxide (SO), disulfur monoxide (S_2O), SO_2, DMSO, thiosulfate, sulfite, and thiourea ligands is extensive.[50–52] Scheme 23 illustrates their coordination modes and some of the complexes that can be generated.

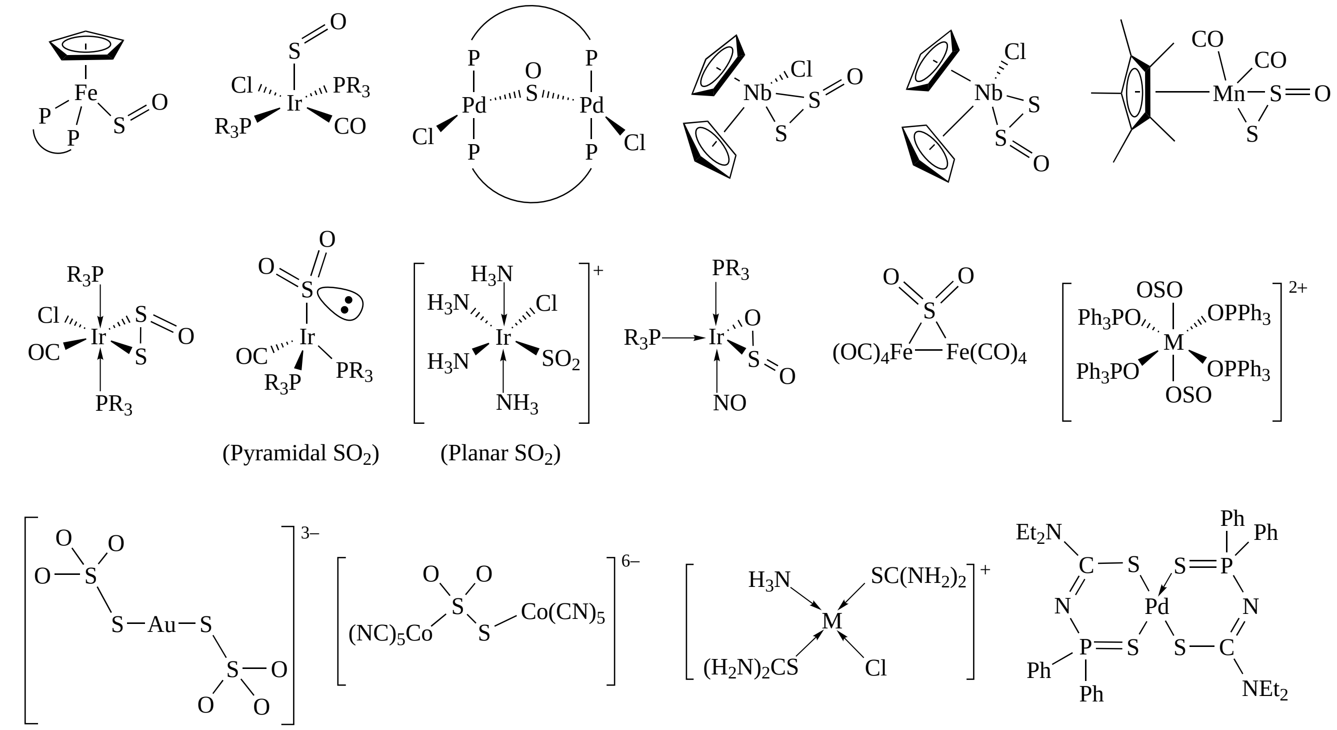
The transition metal coordination chemistry of P/S ligands[53] and of thiophosphorus and thio arsenic ligands bound to transition metals and main group elements[54] have been summarized. An interpenetrating diamond-type framework has been prepared from the high-temperature solid-state reaction of U, P_2S_5, and S to yield UP_4S_{12}. This material contains U^{IV} ions linked by S,S′-bidentate $P_2S_6^{2-}$ molecular rods.[55] Extended S-donor ligand such as (**44**) can generate novel polymeric network materials.[56]



(**44**)



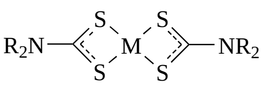
Scheme 23



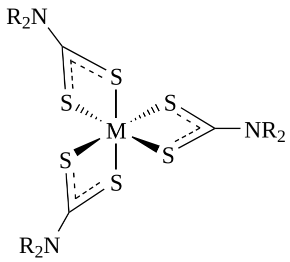
Scheme 23 cont'd

7 DITHIOCARBAMATES AND RELATED LIGANDS

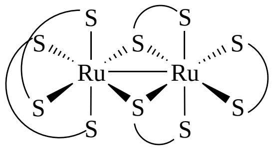
The chemistry of dithiocarbamates, thioacids, and related ligands,[57] dithiolium and dithio-β-diketonate ligands,[58] thiooxalates,[59] and CS_2[60] has been reviewed. Scheme 24 illustrates the dithiocarbamate ligands that have been studied; complexes of monothio derivatives have also been investigated. The ligands are generally prepared by reaction of CS_2 or COS with the corresponding amine. A range of dithiocarbamate complexes, including $[M(S_2CNR_2)_2]$ (**45**) (M = Ni, Pd, Pt) and $[M(S_2CNR_2)_3]$ (**46**) (M = Fe, Ru, Os), have been prepared. Dithiocarbamates can also bridge between two metal ions, as in $[Ru_2(S_2CNR_2)_5]^+$, which exists as two isomers, the α form (**47**) and β form (**48**). The complexes $[Zn(S_2CNMe_2)_2]$ and $[Fe(S_2CNMe_2)_3]$ and the disodium salt $Na_2[S_2CNHCH_2CH_2NHCS_2]$ have been marketed as fungicides under the names Ziram, Ferbam, and Nabam, respectively.



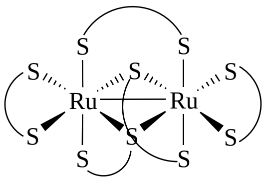
(**45**)



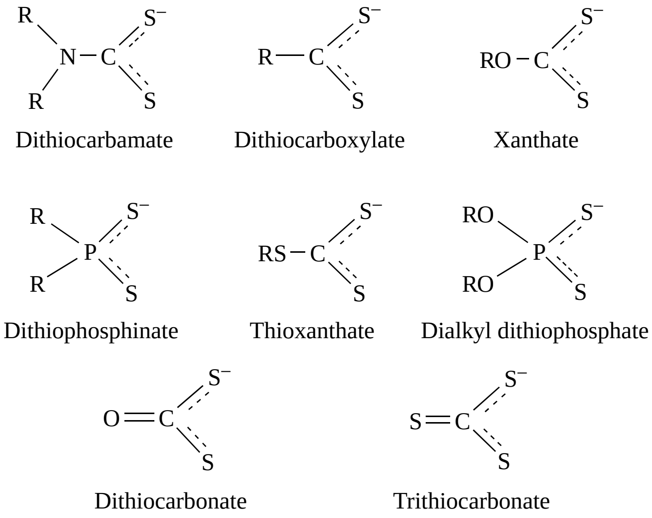
(**46**)



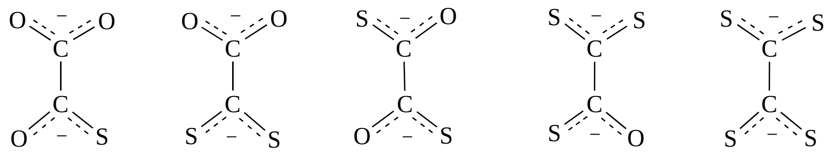
(**47**)



(**48**)



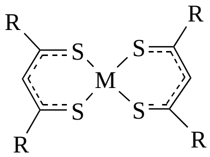
Scheme 24



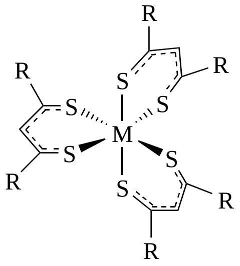
Scheme 25

Fe dithiocarbamates are enjoying a resurgence of interest in their chemistry following their application in the detection and analysis of biological NO produced endogenously from NO synthase.[61] Diothiocarbamates have been found to form complexes with Au^{II} ions as in binuclear complexes, $[Au_2(S_2CNR_2)_2X_2]$ and $[Au_2(S_2CNR_2)(CH_2PPh_2CH_2)X_2]$.[62]

Mono-, dithio-β-diketonate, and related ligands are effective chelates for a wide range of metal ions, forming complexes of the type $[M(L)_2]$ (**49**) (M = Co, Ni, Pd, Pt, Zn, Cd, Hg) and $[M(L)_3]$ (**50**) (M = Cr, Fe, Ru, Os, Co, Rh, Ir). The complexes are often redox active, and like those of dithiolenes, the location of redox activity in terms of metal- or ligand-based radicals has been the subject of much interest.



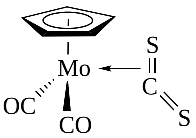
(**49**)



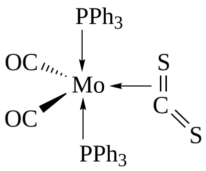
(**50**)

A wide range of mono-, di-, tri-, and tetrathiooxalate complexes have been prepared. These species can act as mono-, bi-, tri-, and tetradentate ligands and can also bridge between metal centers (Scheme 25).

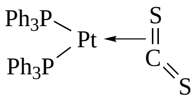
CS_2 can bind in monodentate end-on, bidentate chelate, bridging, or η^2 forms (Scheme 26). Most complexes of CS_2 are low-valent electron-rich species, for example $[Mo(Cp)(CO)_2(\eta^2\text{-}CS_2)]$ (**51**), $[Ru(CO)_2(PPh_3)_2(\eta^2\text{-}CS_2)]$ (**52**), and $[Pt(PPh_3)_2(\eta^2\text{-}CS_2)]$ (**53**). Conversion of coordinated CS_2 to CS and CS_3 fragments can occur on coordination. The coordination chemistry of phosphine-carbon disulfide adducts (S_2CPR_3) has been reviewed; these versatile ligands can act as 2 to 8 electron donors to metal centres.[63]



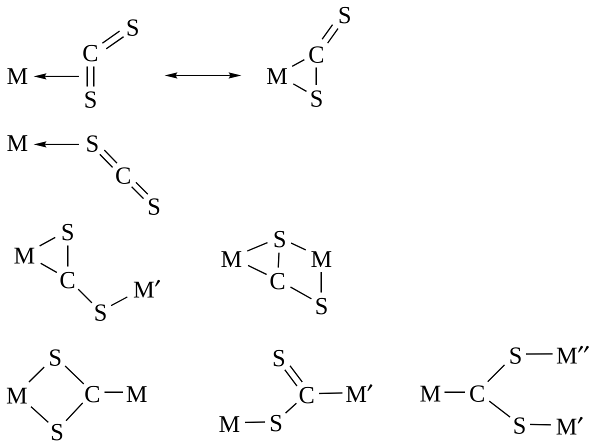
(**51**)



(**52**)



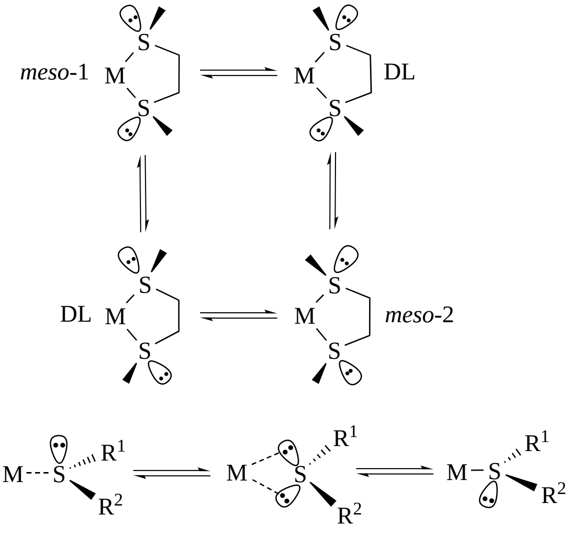
(**53**)



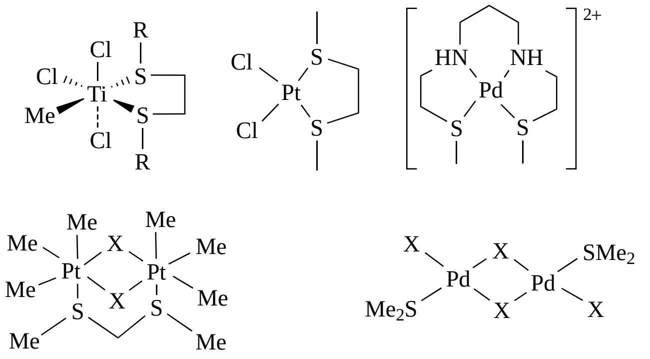
Scheme 26

8 THIOETHERS: R_2S

The coordination chemistry of thioethers has been reviewed.[2–4] They are generally poor ligands and highly labile, and so can be used as leaving groups for metal complex syntheses. For example, $[Au(tht)_2]^+$ (**54**; tht = tetrahydrothiophene) is an effective starting material

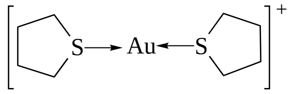


Scheme 27



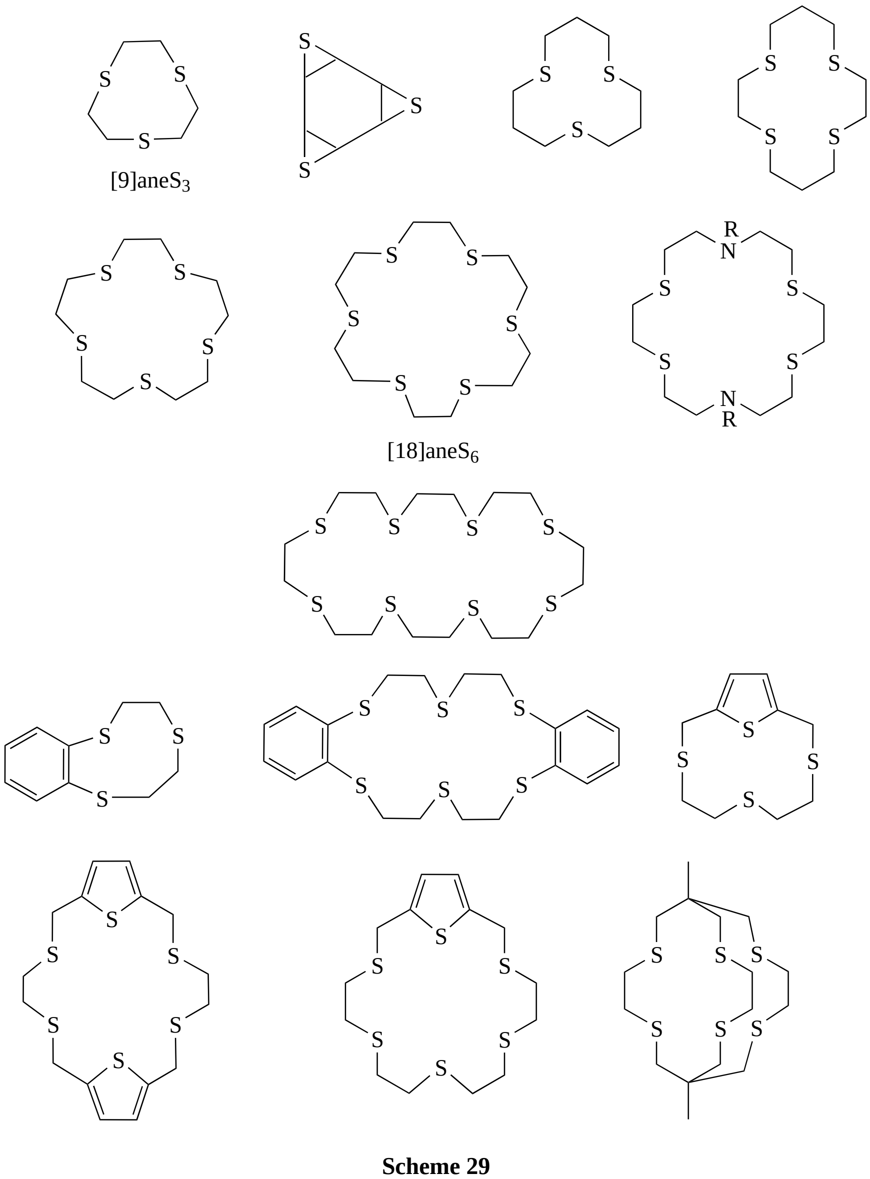
Scheme 28

for substitution reactions. Many thioether complexes are fluxional with inversion at the coordinated thioether S-center (Scheme 27). Scheme 28 illustrates some of the thioether complexes that have been prepared. The fluxionality of thioether and mixed thiolate/thioether ligands has been reviewed.[30] Reviews of complexes of groups 3–6 covering oxidation states greater than 3,[64] and of complexes of the p-block (groups 13–15)[65] with acyclic and macrocyclic thioethers have appeared.



(**54**)

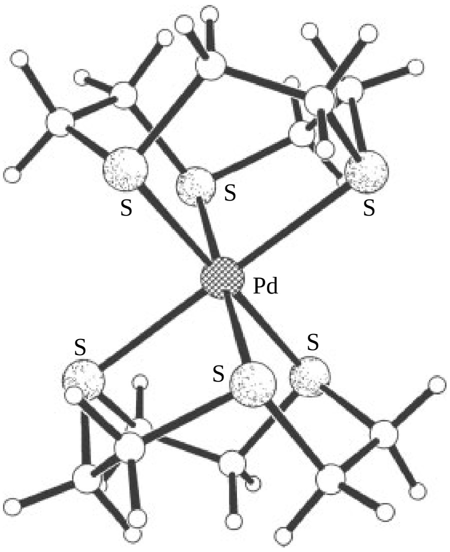
Thioether coordination chemistry has undergone a renaissance with the development of general syntheses of polythioether macrocyclic ligands. Scheme 29 illustrates some of the ligands that have been reported. The tridentate ligand



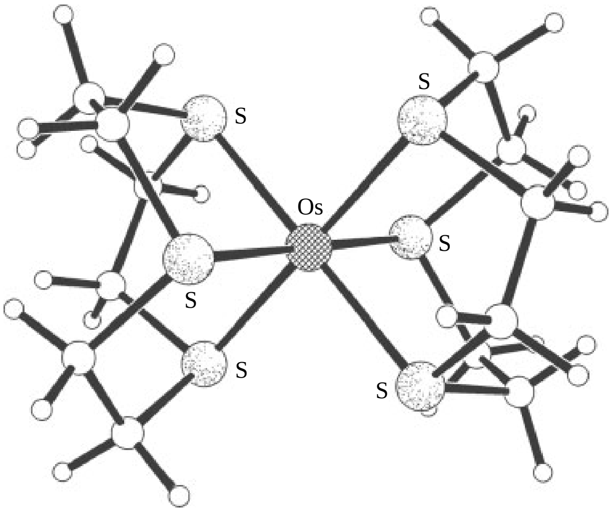
Scheme 29

[9]aneS_3 is unique in that it can be regarded as 'preorganized' for facial coordination, and indeed, this ligand forms a range of low-spin, bis-sandwich complexes $[M([9]aneS_3)_2]^{n+}$ (M = Cr, Fe, Ru, Os (**55**; $n = 2$), Co, Rh, Ir, Ni, Pd (**56**; $n = 2$), Pt, Zn, Ag, Au, Tl, In). Many of these complexes are redox active, and a series of mononuclear radical species of unusual metal oxidation states can be characterized and isolated, including the Pd^{III} radical complex $[Pd([9]aneS_3)_2]^{3+}$ (**57**).[66] The redox interconversion of Au^{I}, Au^{II}, and Au^{III} centers in $[Au([9]aneS_3)_2]^{+/2+/3+}$, (**58**), (**59**), (**60**), respectively, has been reported and illustrates the high coordinative flexibility of thioether crowns.[67]

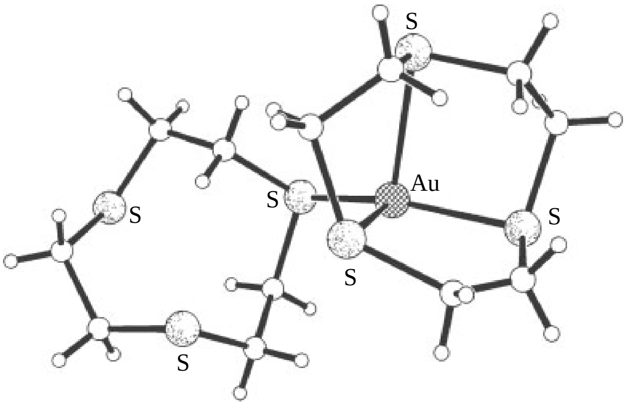
The hexathioether ligand [18]aneS_6, the S-analog of 18-crown-6 ([18]aneO_6), can encapsulate M^{II} ions to form highly stable complexes $[M([18]aneS_6)]^{2+}$ (M = Fe; Co, Ni, Cu (**61**); Pd (**62**); Pt). The complexes of these ligands with d^8 metal ions such as Pd^{II}, Pt^{II}, and Au^{III} tend to show long-range M· · ·S interactions in the range 2.8–3.1 Å. This is reminiscent of the coordination at Cu sites in blue copper proteins such



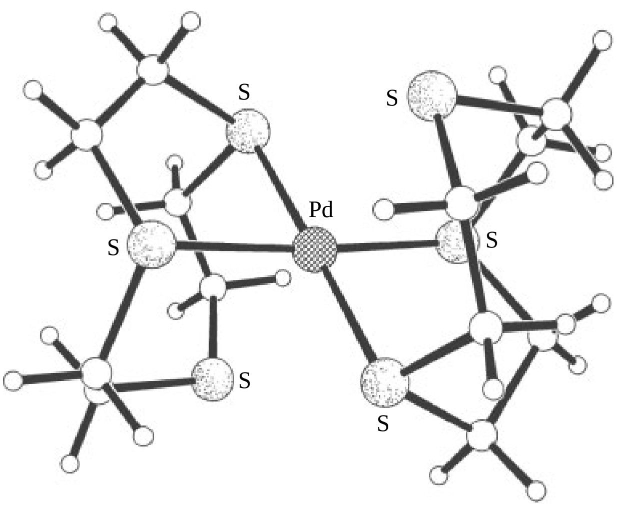
(**57**)



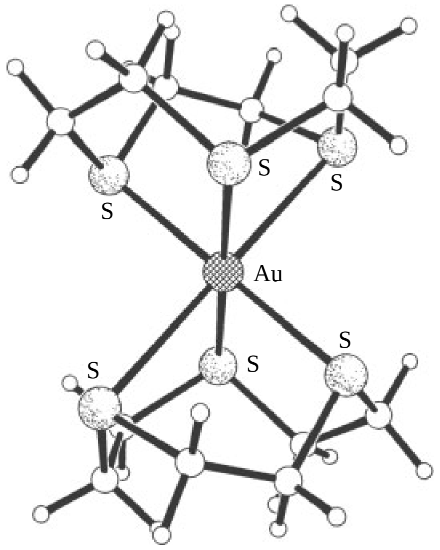
(**55**)



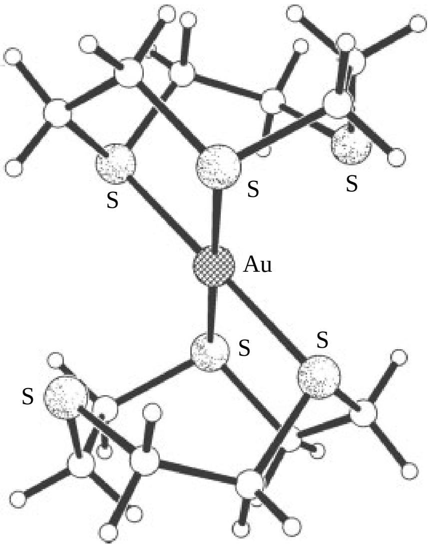
(**58**)



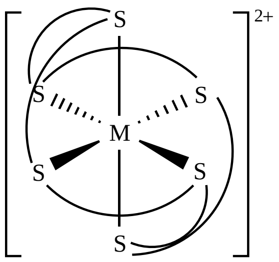
(**56**)



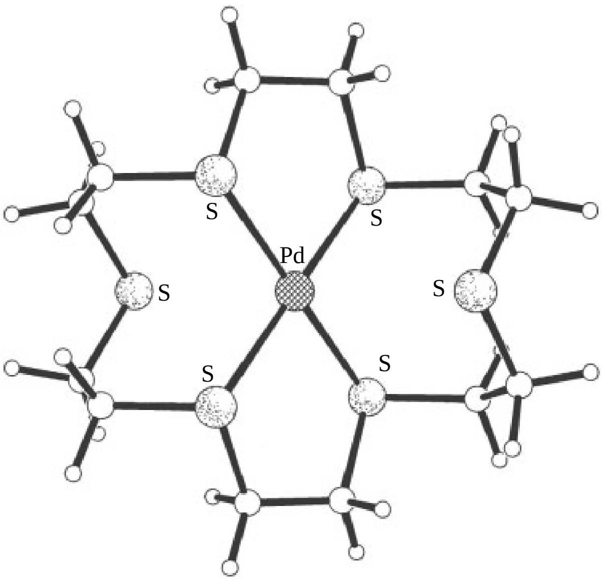
(**59**)



(**60**)

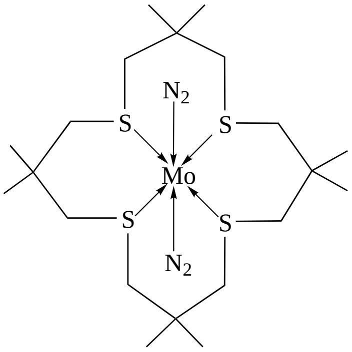


(**61**)



(**62**)

as azurin and plastocyanin, in which long-range thioether S to Cu distances of some 2.9 Å are observed. The binding of N_2 in the thioether complex *trans*-[$Mo(N_2)_2(Me_8$[16]aneS_4)] (**63**) has been reported and the ability of homoleptic thioether coordination at Mo^0 to stabilize N_2 binding has been discussed.[68]



(**63**)

A range of half-sandwich complexes [Pd([9]aneS_3)Cl(L)](PF_6) (L = $2PPh_3$, $Ph_2PCH_2PPh_2$, $Ph_2PCH_2CH_2PPh_2$, $(Ph_2PCH_2)_3CMe$, 2,2′-bipyridine or 1,10-phenanthroline) show an approximately square-planar geometry at Pd^{II} with two sulfur donors and the ligand L; additionally, there is a weaker interaction to the other apical sulfur.[69]

The chemistry of tridentate mixed azathioether macrocyclic transition metal complexes has recently been reviewed in particular, focusing upon structural and redox properties,[70] and a series of acylurea pendant arm azathioether macrocycles have been developed as heteroditopic receptors for transition metal salts.[71] The first examples of mixed thio- and telluro-ethers [11]aneS_2Te, [12]aneS_2Te and [14]aneS_3Te, have been prepared. The complex [Ag([11]aneS_2Te)]BF_4 shows a one-dimensional polymeric chain adopted by the cation, in which the Ag^I ions are coordinated by three macrocyclic ligands.[72] The transition metal chemistry of alkylcycloarsathianes, in particular, of chain and macrocyclic As-S ligands has been reviewed.[73]

Thiacalixarenes have been observed to form complexes Cu_4L_2 (L = p-*tert*-butyltetrathiacalix[4]arene) with both S- and O-binding to Cu. This represents the first example of an intentionally synthesized paramagnetic koiland, that is hollow molecular building block.[74] Chiral thioether ligands have found applications in asymmetric catalysis of allylic substitution, hydrogenation, transfer hydrogenation, hydrosilation, Michael addition, 1,4-conjugate additions, and copolymerisations.[75]

9 METALLOENZYMES

Separate sections in this series are devoted to biological and bioinorganic chemistry (*see* ***Copper: Hemocyanin/Tyrosinase Models***; ***Copper Proteins with Dinuclear***

Active Sites; ***Copper Proteins: Oxidases***; ***Copper Proteins with Type 1 Sites***; ***Copper Proteins with Type 2 Sites***; ***Copper Enzymes in Denitrification***; ***Iron–Sulfur Models of Protein Active Sites***; ***Iron–Sulfur Proteins***; ***Nickel Enzymes & Cofactors***; and ***Nickel: Models of Protein Active Sites***). However, since many metalloenzymes have been found or postulated to incorporate metal–sulfur bonding, it is appropriate that a very short summary be included here.

The structural, electronic, biological, and magnetic properties of iron–sulfur clusters in metalloproteins has been reviewed focussing particularly on $[4Fe\text{-}4S^{*}]^{n+}$ $(n = 1-3)$ centres,[76] and on synthetic $[Fe_3S_4]$ and heterometallic $[MFe_3S_4]$ clusters.[77] The chemistry and properties of aconitase have been reviewed in the context of its spectroscopic properties, structure, mechanistic function, and its relationship to the iron-regulatory protein.[78,79]

Metallothioneins are cysteine-rich proteins capable of binding a range of metal ions, such as Zn, Cu, Cd, and Hg, via thiolate coordination. The structure of a Zn/Cd metallothionein shows a triangular array of metals, each coordinated tetrahedrally to thiolate cysteines.

The blue copper proteins azurin, plastocyanin, stellacyanin, and umecyanin incorporate Cu bound to a combination of N/thiolate/thioether ligands. An important feature of these metalloenzymes is the facile copper(II)/(I) couple that these species exhibit, which is linked to the highly strained, asymmetric coordination geometry at the metal center. The synthesis of model complexes for these so-called Type 1 copper proteins has been reviewed.[80]

Cytochrome P_{450} catalyzes the oxidation of external substrates and particularly the incorporation of O from O_2 into C–H bonds. The active site involves an Fe-haem, with thiol ligation at an apical site from a S-donor cysteine residue being implicated in the mechanism of action. A short review of synthetic models for the active site of cytochrome P_{450} has appeared and discusses two kinds of iron porphyrins each with an axial thiolate ligand and hydroxyl groups inside the molecular cavity. A hydrogen bond to bound dioxygen has been observed in the oxy-form of a thiolate heme model system.[81] The electron-transfer metalloenzyme cytochrome *c* involves methionine S-coordination.

Rubredoxins are enzymes are found in anaerobic bacteria and are involved in redox reactions. They contain one Fe center bound to thiolate cysteine ligands, and are modeled by tetrahedral Fe^{II} $[Fe(SR)_4]^{2-}$ and Fe^{III} $[Fe(SR)_4]^{-}$ complexes.

Ferredoxins and high-potential iron proteins (HiPIPs) involve clusters of two, three, and four tetrahedral Fe centers bridged by sulfido S^{2-} donors. The coordination sphere at Fe is completed by thiolate cysteine ligands.

Nitrogenase converts N_2 to NH_3 in leguminous plants. Much work has been reported on the synthesis of model coordination compounds and clusters for nitrogenase. This complicated metalloenzyme contains an FeMo cofactor consisting of $[Fe_4S_3]$ and $[Fe_3MoS_3]$ cubanes linked together by two S^{2-} linkages and one O- or N-donor.[82] In addition, Fe_4S_4 cubes (so-called *P* clusters) are present and act as an electron-transfer agents.[83] The chemistry of Mo-sulfur complexes and clusters have been reviewed in relation to the nitrogenase FeMo cofactor.[84]

A range of chemical analogs of the catalytic centers of Mo and W dithiolene-containing enzymes (pterins) have been prepared.[85,86] In particular, the rich chemistry of multisulfur transition metal systems allows ligand redox, internal electron transfer, and intermediate redox states. Such redox flexibility may facilitate coupled proton/electron transfer and/or oxo-transfer mechanisms, which are employed by Mo and W enzymes.

Hydrogenase enzymes interconvert H_2 to $2H^+$ and involve thiolate binding at FeFe or NiFe active sites. The structure of [NiFe] hydrogenase comprises a heterobimetallic NiFe centre, with the Ni ligated by four cysteines, two of which are terminal and two of which bridge to Fe. The Fe centre is ligated further by two cyanide and one carbonyl ligands.[87] Activation of the enzyme is believed to involve loss of a bridging oxo-ligand and contraction of the nickel–iron separation to some 2.5–2.6 Å.[88] The application of hydrogenase for in vitro photoinduced H_2 evolution has been discussed.[89] A range of structural models for [NiFe] hydrogenase has been prepared,[90] and the reversible reduction of protons to dihydrogen in models for hydrogenase has been the subject of a recent review.[91]

The X-ray structure of methyl-coenzyme M reductase shows an octahedral Ni^{II} ion bound in a tetrapyrrole hydrocorphin ring and the oxygen from a glutamine residue at the fifth site. The sixth site is occupied by a thiol group of coenzyme M in the methyl-coenzyme M $reductase_{ox1-silent}$ structure and a sulfonate oxygen of coenzyme M in the methyl-coenzyme M $reductase_{silent}$ structure.[92]

The active site of carbon monoxide dehydrogenase has been shown to contain an asymmetric [Ni-4Fe-5S] cluster.[93] There have been two recent independent reports of X-ray structures for the bifunctional enzyme carbon monoxide dehydrogenase/acetyl-coenzyme A synthase. In both structures, Ni^{II} is also bound in the acetyl-coenzyme A synthase within a N_2S_2 environment originating from amide N- and thiolate S-donors. The latter donors bridge to either a Cu, Zn, or Ni, which in turn is connected to a 4Fe4S cluster.[94,95]

Zinc fingers are protein DNA-binding motifs have a finger structure, which is held together by Zn^{II} chelated by four cysteine S-donors. The binding and selectivity of Zn in proteins has been the subject of a short review.[96]

Compounds with S-centers such as sodium diethyldithiocarbamate and sodium thiosulfate have found use as protecting groups when used in combination with cisplatin in order to limit the toxicity associated with this

anticancer drug. The mode of action remains a subject of debate.[97]

Abbreviations

$bipyO_2$ = 2,2′-bipyridyl *N*,*N*′-dioxide; 12-crown-4 = 1,4,7,10-tetraoxacyclododecane; 15-crown-5 = 1,4,7,10,13-pentaoxacyclopentadecane; 18-crown-6 = 1,4,7,10,13,16-hexaoxacyclododecane; dbm = Dibenzoylmethane; diglyme = Bis(2-methoxyethyl)ether; dipic = 2,6-pyridinedicarboxylate; dme = 1,2-dimethoxyethane; dmi = 1,3-dimethyl-2-imidazolidione; DMP = 2,6-dimethyl-4-pyrone; DOTA = 1,4,7,10-tetraaza-cyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetate; dpm = Dipivaloylmethane (= tmhd); dmpu = Dimethylpropylene urea; DTPA = Diethylenetriaminepentaacetate; DTPA-BMA = Dimethylamide of diethylenetriaminepentaacetic acid; EO2 = Diethylene glycol; EO3 = Triethylene glycol; EO4 = Tetraethylene glycol; EO5 = Pentaethylene glycol; facam = 3-trifluoroacetyl-d-camphor; fod = 2,2-dimethyl-6,6,7,7,8,8,8-heptafluorooctane-2,4-dione; hfac = 1,1,1,5,5,5-hexafluoropentane-2,4-dionate; Hhfip = Hexafluoroisopropanol; naph = 1,8-naphthyridine; pc = Phthalocyaninato; pmdien = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine; pmhd = 1-phenyl-5-methylhexane-1,3-dionate; pu = Tetrahydro-2-pyrimidone; pyO = Pyridine N-oxide; terpy = 2,2′:6′,2″-terpyridyl; tetraglyme = $Me(OCH_2CH_2)_4OMe$; tmen = *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine; tmhd = 2,2,6,6-tetramethylheptane-3,5-dionato; tmu = -Tetramethylurea; Tp = Tris(pyrazolyl)borate; $Tp^{Bu^t,Me}$ = Hydrotris(3-*t*-butyl-5-methylpyrazolyl)borate; Tp^{Me2} = Tris(3,5-dimethylpyrazolyl)borate; tpa = Tris[(2-pyridyl)methyl]amine; tpza = Tris[(2-pyrazinyl)methyl]amine; tptz = 1,3,5-tri(2-pyridyl)-2,4,6-triazine; ttfa = Thenoyltrifluoroacetonato.

1 INTRODUCTION

These elements are generally grouped together in group 3 of the Periodic Table.[1–10] Scandium has considerably smaller atomic and ionic radii than the other metals and significantly different chemical properties, so it is treated separately in this article; the *Lanthanide Contraction* (*see Lanthanide Contraction*)means, however, that the later lanthanides are of similar size to yttrium, to which they bear a close chemical resemblance, and are thus often grouped together as the *Rare Earth Elements* (*see Rare Earth Elements*). The lanthanides resemble the group II metals, rather than the transition metals, in many respects – they have similar reactivities to Mg; the bonding in their complexes is essentially ionic in nature; coordination numbers are generally driven by steric considerations (and are usually high); most of the chemistry is in one oxidation state (+3). There is essentially no low oxidation-state organometallic chemistry, and they are not involved in multiple bonds, so there are no species like UO_2^{2+} or MnO_4^-. On the other hand, because of the gradual filling of the 4f subshell across the series, there are nuances in lanthanide chemistry owing to the gradual change in ionic radius – the partly filled 4f subshell leads most ions to be paramagnetic, and sometimes have visible colors; certain lanthanides (Ce, Eu, Sm, Yb in particular) have a significant chemistry in more than one oxidation state; and the complexes exhibit an exceptionally wide range in coordination numbers, often with subtle changes on passing from one lanthanide to another.

Lanthanide chemistry has its beginnings in Scandinavia.[3,11] In 1794, Johann Gadolin succeeded in obtaining an ‘earth’ (oxide) from a black mineral subsequently known as gadolinite, naming the earth yttria. Soon afterwards, M. H. Klaproth, J. J. Berzelius, and W. Hisinger obtained ceria, another earth, from cerite, but it was not until 1839–1843 that the Swede C. G. Mosander first separated these earths into their component oxides; thus ceria was resolved into the oxides of cerium and lanthanum and a mixed oxide ‘didymia’ (a mixture of the oxides of the metals from Pr through Gd), and likewise ‘yttria’ was separated into erbia, terbia, and yttria (though some 40 years later, the first two names were to be reversed!). Spectroscopic analysis aided the identification of further elements but also complicated matters with the erroneous identification of mixtures as over 70 ‘new’ elements. With the report of lutetium in 1907 by Urbain and von Welsbach, all the stable lanthanide elements had been discovered (von Welsbach’s alternative name of cassiopeium did not finally pass out of use until the 1950s), but Moseley showed (1913) the existence of an undiscovered element between Nd and Sm, leading to futile searches for the missing element. Counterclaims by both American and Italian researchers for element 61 (‘illinium’, ‘florentium’) were made in 1926. It was subsequently realized that element 61 would not have any stable isotopes and it was not until 1947 that it was identified in uranium fission products (and later named promethium).

Useful sources of information on these elements and their compounds include the 'Gmelin Handbook',[1] with extensive up-to-date coverage, and regular comprehensive reviews in the 'Handbook on the Physics and Chemistry of the Rare Earths'.[2] General accounts of the elements, their inorganic chemistry,[3] and coordination chemistry exist,[4,5] the latter being the most up-to-date. There are also recent monographs,[6–8] and compilations of in-depth and informed articles on different aspects of lanthanide chemistry and spectroscopy.[9,10]

When Mendeleev first published his Periodic Table in 1869, of these elements he included only lanthanum, cerium, didymium (now known to have been a mixture of Pr and Nd), another mixture in the form of erbia, and yttrium; unreliable information about atomic mass made correct positioning of these elements in the table difficult. Subsequently, it was not until the work of Bohr and of Moseley that it was known precisely how many of these elements there were. Most current versions of the Periodic Table place lanthanum under scandium and yttrium in group 3, though study of the periodic properties shows that lutetium bears a more compelling resemblance to Sc and Y, so that it has been cogently argued that these metals should appear in the same group, with lutetium preceded by the sequence La through Yb.[11]

In the traditional view, lanthanum is classed as a transition element; cerium, which has a 4f electron, is considered to be the first lanthanide, rather than lanthanum, which does not possess an electron in a 4f orbital (Table 1).

2 SCANDIUM

There are comprehensive accounts, covering the literature through 2002,[3–5,12,13] of the chemistry of scandium. References to it frequently occur in the context of the chemistry of the 4f metals.

In 1869, Mendeleev predicted the existence and certain properties of an element with atomic mass 45, terming it 'ekaboron'; within a decade, the Swede L. F. Nilsson and Frenchman P. T. Cleve independently isolated scandium oxide, subsequently preparing various other compounds. There are few ores where scandium is the main element (e.g. thortveitite, a silicate, $Sc_2Si_2O_7$, and sterrite, $ScPO_4{\cdot}2H_2O$) so that it is mainly obtained as a by-product from uranium extraction.

Scandium, a soft and silvery metal, was first isolated (1937) electrolytically, but it is generally obtained metallothermically, typically by reduction of the trifluoride with calcium. It is electropositive, tarnishing rapidly in air and reacting with water. It forms a wide range of binary compounds.

The ionic radius of Sc^{3+} is, at 0.745 Å (for six coordination) the largest of the 3d metals, so that high coordination numbers are frequently met with in its chemistry; examples between three and nine are known.

2.1 Binary Compounds of Scandium

2.1.1 Halides

All four scandium(III) halides are known, all but the fluoride (WO_3 structure) having the $FeCl_3$ structure. They can be obtained as white solids directly from the elements and in some cases by dehydration of the hydrated salts, as well as by thermal decomposition of $(NH_4)_3ScX_6$ (X = Cl, Br), a method also used for the lanthanides. Gas-phase studies have identified isolated planar ScF_3 molecules at 1750 K; $ScCl_3$ molecules with a very slight pyramidal distortion; and both monomers and dimers in ScI_3 vapour at 1050 K.

Table 1 Properties of scandium, yttrium, and the lanthanides

Element	Electronic configuration	Mp; bp (K)	Atomic radius (Å)	$E(M/M^{3+})$ (V)	EC M^{3+}	Ionic radius (Å)	Ground state	Magnetic moment (μ_B)	Color
Sc	$[Ar]3d^14s^2$	1814; 3104	1.606	2.03	[Ar]	0.745	$^1S_0$	0	
Y	$[Kr]4d^15s^2$	1795; 3611	1.81	2.37	[Kr]	0.901	$^1S_0$	0

Scandium forms a number of well-defined lower halides,[14] especially chlorides. These are synthesized by high-temperature reaction of Sc with $ScCl_3$. Phases synthesized and characterized by diffraction methods are ScCl, Sc_2Cl_3 (‘mouse fur’), Sc_5Cl_8, Sc_7Cl_{10}, and Sc_7Cl_{12}. They typically have chain structures with metal–metal bonding and octahedral clusters of scandiums (Figure 1). ScCl is isostructural with ZrBr, Sc_5Cl_8 contains infinite chains of Sc_6 octahedra sharing trans edges, while Sc_7Cl_{10} has two parallel chains of octahedra sharing a common edge. Sc_7Cl_{12} is regarded as made of Sc_6Cl_{12} octahedra with isolated scandium atoms in octahedral interstices. Sc_2Br_3 is also known.

2.1.2 Other Binary Compounds

Scandium oxide is a refractory white solid (mp 3100 °C) formed on ignition of either the metal or appropriate compounds such as the nitrate, sulfate, and hydroxide. It has amphoteric tendencies denoted by its solubility in excess alkali from which compounds like $K_3[Sc(OH)_6]$, containing octahedrally coordinated scandium, have been isolated. In the solid state it has six-coordinate scandium in the Mn_2O_3 structure.

Other significant binary compounds include the fcc dihydride ScH_2; unlike most of the lanthanides, scandium does not form a trihydride. This compound is conducting and is probably a scandium(III) compound of the type $Sc^{3+}(H^-)_2(e^-)$. The carbide ScC is cubic (NaCl structure) and other carbides Sc_3C, Sc_2C, Sc_4C_3, $Sc_{13}C_{10}$, and $Sc_{15}C_{19}$ are reported. Fullerene complexes (*see* ***Carbon: Fullerenes***) have been made: laser vaporization of scandium oxide–graphite mixtures followed by extraction of the resulting soot gives scandium–fullerene clusters, identified by MS to contain 1–3 scandiums, particularly paramagnetic $Sc_n@C_{82}$ ($n = 1,3$). The three pnictides ScQ (Q = N, P, As) exist with the nitride in particular being very high-melting (2600 °C), while there are two borides, ScB_2 and ScB_{12}.

2.2 The Aqua Ion and Hydrated Salts[15]

Although there was no real evidence for the coordination number of scandium in aqueous solution, it was been generally assumed for many years that the scandium aqua ion was $[Sc(H_2O)_6]^{3+}$, probably by analogy with the ions of the succeeding transition metals, all of which form $[M(H_2O)_6]^{3+}$ (M = Ti–Co). Against this was the fact that Sc^{3+} has an ionic radius much larger than that of the succeeding 3d metals (0.745 Å in six-coordination), intermediate between Ti^{3+} (0.670 Å) and the lanthanides ($La^{3+} = 1.032$ Å; $Lu^{3+} = 0.861$ Å). Since the lanthanides form $[Ln(H_2O)_9]^{3+}$ and $[Ln(H_2O)_8]^{3+}$ aqua ions, a coordination number intermediate between 6 and 8 could have been expected for scandium on steric grounds. Study of the Raman spectra of glasses of $ScCl_3$ and $Sc(ClO_4)_3$ led to the suggestion that the aqua ion was not a hexaaqua species. X-ray diffraction data[16] from scandium perchlorate solutions gave a sharp peak (suggesting that the Sc–O distances were all very similar) having a Sc–O distance of 2.180(7) Å with a coordination number of 7.4(4). X-ray absorption fine structure (XAFS) data from scandium triflate solutions also indicate a Sc–O distance of 2.18(2) Å, but no coordination number could be unambiguously obtained from the XAFS measurements. This Sc–O distance of 2.18 Å, nearly 0.1 Å longer than that found for six-coordination, fits

well with the Sc-water distances found in the seven-coordinate $[Sc(H_2O)_7]^{3+}$ ions in the solid state. Considering all the data, it seems most likely that the predominant species present in rather acidic aqueous solution is a pentagonal bipyramidal $[Sc(H_2O)_7]^{3+}$ ion, with an average Sc–O distance around 2.18 Å. Study of the scandium aqua ion is handicapped by its ready hydrolysis and ability to complex with anions like chloride, nitrate, and even perchlorate. ^{45}Sc NMR studies on aqueous solutions of the chloride, nitrate, and formate were been interpreted in terms of the presence of both the aqua ion and mixed aqua/hydroxy species.

Among hydrated salts, scandium forms perchlorates $Sc(ClO_4)_3{\cdot}nH_2O$ ($n = 6$, 7); the hexahydrate is isostructural with the lanthanide analogues, thus containing octahedral $[Sc(H_2O)_6]^{3+}$ ions. The very soluble scandium triflate is isostructural with the lanthanide analogues $Ln(O_3SCF_3)_3{\cdot}9H_2O$, though there is evidence that the cation present is actually $[Sc(H_2O)_8]^{3+}$, rather than the nonaaqua species. When scandium halides (except the fluoride) are recrystallised from slightly acidified aqueous solution (to prevent the hydrolysis that could otherwise result in the hydroxy-bridged dimers discussed below), hydrated salts $ScX_3{\cdot}7H_2O$ (X = Cl, Br) and $ScI_3{\cdot}8H_2O$ are obtained. X-ray diffraction studies[17] show them all to contain $[Sc(H_2O)_7]^{3+}$ ions; in the chloride and iodide, the coordination geometry is essentially pentagonal bipyramidal, whilst in the iodide there is a substantial distortion (in view of the tendency of many of the hydrated lanthanide halides to contain coordinated halide ions, the chlorides in particular, the absence of halide from the coordination sphere of scandium in these compounds is remarkable). Reaction of refluxing aqueous $HC(SO_2CF_3)_3$ with scandium oxide yields the triflide salt $[Sc(H_2O)_7]$ $(C(SO_2CF_3)_3)_3$. Though complicated by disorder, the structure shows two scandium-containing sites, with Sc–O distances falling in the range 2.113 (13)–2.222 (10) Å, averaging 2.17 Å. In contrast, the ytterbium analogue contains eight-coordinate $[Yb(H_2O)_8]^{3+}$ ions.

Overall, then, the existence of the three scandium-containing ions $[Sc(H_2O)_x]^{3+}$ ($x = 6,7,8$) in five different solid salts indicates that in itself X-ray diffraction data on solids cannot be relied upon to indicate the coordination number in aqueous solution. Ultimately, it is the solubility of a particular salt that determines which compound crystallises out from aqueous solution.

Other hydrated salts include $Sc_2(C_2O_4)_3{\cdot}6H_2O$, $Sc(NO_3)_3{\cdot}4H_2O$, and $Sc_2(SO_4)_3{\cdot}5H_2O$; the structure of the oxalate shows approximately dodecahedral coordination of scandium by two water molecules and six oxygens from bridging oxalates. The oxalate is, unlike lanthanide oxalates, slightly soluble in water and also dissolves in excess oxalate as $Sc(C_2O_4)_2^-$. No structural data are available for the nitrate, although it should be noted that eight-coordinate $Sc(NO_3)_3(H_2O)_2$ and nine-coordinate $Sc(NO_3)_3(H_2O)_3$ molecules are present in crown ether complexes, while the sulfate $Sc_2(SO_4)_3{\cdot}5H_2O$ has six-coordinate scandium. Both the nitrate and sulfate dehydrate on heating above 100 °C; at higher temperatures they change to the oxide. Structures are known of two other salts where water shares the coordination sphere of scandium with anions. Freshly precipitated $Sc(OH)_3$ reacts with picric acid (Hpic) forming a 1:1 adduct with picric acid, *trans*-$[Sc(H_2O)_4(pic)_2](pic)(HPic){\cdot}8.2\ H_2O$; scandium is present as part of a six-coordinate cation. In contrast to the benzenesulfonate, the p-toluenesulfonate salt $Sc(tosylate)_3{\cdot}6H_2O$ has coordinated anions in six-coordinate $[Sc(H_2O)_4(tosylate)_2]^+$ ions (the tosylates of the heavier lanthanides have six bound water molecules and two coordinated tosylates in eight-coordinate cations).

An important dimeric species is the $[(H_2O)_5Sc(OH)_2Sc(H_2O)_5]^{4+}$ ion (Figure 2), a cationic species with two hydroxy bridges, with approximately pentagonal bipyramidal coordination of scandium. It has been characterized as a benzene sulfonate salt,[18] and also as chlorides and bromides $[(H_2O)_5Sc(\mu\text{-}OH)_2Sc(H_2O)_5]\ X_4{\cdot}2H_2O$ (X = Cl, Br). The Sc–OH_2 and the Sc–OH bond lengths are similar in all three of these dimeric cations. These $[(H_2O)_5Sc(\mu\text{-}OH)_2Sc(H_2O)_5]^{4+}$ ions are significant in that they are believed to be formed in the first stage of the hydrolysis of the scandium aqua ion, and the coordination geometry involving scandium bound to seven water molecules and hydroxide ions can clearly derive from a $[Sc(H_2O)_7]^{3+}$ ion.

Among the carboxylates, scandium formate has a 2-D polymeric structure, whilst in the acetate, chains of Sc^{3+} ions are bridged by acetate groups (Figure 3) with essentially octahedral coordination of scandium. Similar bridging is found in the chloroacetate, where the six-coordination is in contrast with the nine-coordinate trimeric structure adopted by the heavier lanthanide ions. Scandium propynoate has

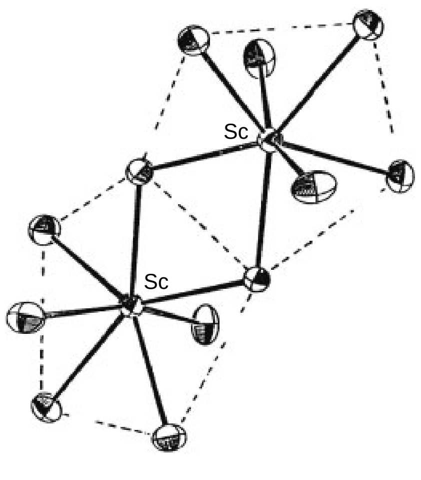

Figure 2 Structure of the dimeric cation $[(H_2O)_5Sc(OH)_2Sc(H_2O)_5]^{4+}$

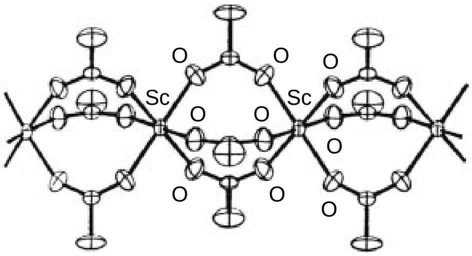

Figure 3 Chain structure in scandium acetate

an unusual three-dimensional polymeric structure (featuring six-coordinate scandium) that undergoes polymerization on γ-irradiation (probably with formation of a poly(propynoate)).[19]

2.3 Complexes[4,5]

A range of O-donor ligands (e.g. pyO, Me_2SO, HMPA, R_3PO) forms complexes with scandium, with two main series, ScL_3X_3 (where X is a coordinating anion such as chloride) and ScL_6X_3 (with anions such as perchlorate). With nitrate, higher coordination numbers are possible (because of the small 'bite' angle of bidentate nitrate).

A large number of complexes of phosphine and arsine oxides have been examined. $Sc(OTf)_3(Ph_3PO)_4$ has the structure *trans*-$[Sc(OTf)_2(Ph_3PO)_4]$ OTf, featuring octahedrally coordinated scandium (monodentate triflates), whilst $[Sc(NO_3)_3(Ph_3PO)_2]$ is eight-coordinate with symmetrically bidentate nitrates. Both $Sc(NO_3)_3(Ph_2MePO)_3$ and $Sc(NO_3)_3(Ph_2MePO)_4$ exist; the latter is $[Sc(NO_3)_2(Ph_2MePO)_4](NO_3)$ (bidentate nitrates). With Me_3PO, $[Sc(Me_3PO)_6](NO_3)_3$ is formed; similarly $[Sc(Me_3AsO)_6](NO_3)_3$ has octahedrally coordinated scandium. $Sc(NO_3)_3(Ph_3AsO)_3$ is seven-coordinate $[Sc(NO_3)_2(Ph_3AsO)_3]NO_3$. Among halide complexes, *trans*-$[ScBr_2(Ph_3PO)_4]Br$, *trans*-$[ScCl_2(Ph_3AsO)_4]Cl$ and $[Sc(Me_3AsO)_6]Br_3$ have all had structures confirmed by X-ray diffraction. Six-coordination is likewise found in *trans*-$[Sc(HMPA)_4(CF_3SO_3)_2]CF_3SO_3$ and the tetrahydro-2-pyrimidone complex $[Sc(pu)_6](CF_3SO_3)_3$, the latter unexpectedly having trigonal antiprismatic coordination of scandium, possibly partly induced by side-on interactions between pairs of pu ligands. Various complexes of *N*-oxide ligands $ScL_6(CF_3SO_3)_3$ (L = pyridine *N*-oxide, 2-picoline *N*-oxide, 3-picoline *N*-oxide, 4-picoline *N*-oxide) have been described, and all presumably contain octahedrally coordinated scandium, confirmed in $[ScCl_3(dme)(MeCN)]$ and $[ScCl_3(diglyme)]$.

$(NO^+)_2$ $[Sc(NO_3)_5]^{2-}$ contains a nine-coordinate pentakis(nitrato)scandate ion, one nitrate being monodentate, but in Rb_2 $[Sc(NO_3)_5]$ there are three bidentate and two monodentate nitrates, resulting in eight-coordinate scandium. These contrast with the lanthanide analogs which are ten-coordinate (the lanthanides also form 12-coordinate hexa(nitrato) complexes, see Section 3.7.7).

There are a number of complexes with diketonates, all probably octahedral like $Sc(acac)_3$ (X-ray); $Sc(tropolonate)_3$ also has six-coordinate scandium but eight-coordination also exists in $HSc(tropolonate)_4$ and probably in similar $Sc(diketonate)_4^-$ species. A number of crown ether complexes[20] like $Sc(NO_3)_3(H_2O)_2\cdot$crown (crown = 15-crown-5, benzo-15-crown-5) do not involve direct crown ether–scandium bonding; instead they have hydrated scandium nitrate molecules linked to the crown ether by hydrogen bonds to the ether oxygens, However, reaction of $ScCl_3$ with halogen-extractor $SbCl_5$ and 18-crown-6 in acetonitrile gives $[ScCl_2(18\text{-crown-}6)](SbCl_6)$, in which the scandium is bound (Figure 4) to five ether oxygens and two chlorines in roughly pentagonal bipyramidal coordination.

Other $[ScCl_2(crown)]^+$ $[SbCl_6]^-$ species (crown = 15-crown-5, benzo-15-crown-5, and dibenzo-18-crown-6) complexes have been isolated, all believed to have a pentagonal bipyramidal coordination geometry, confirmed crystallographically for the benzo-15-crown-5 complex. Reaction of $ScCl_3(thf)_3$ and 1 mol of $SbCl_5$ with 1 mol of a larger crown ether yields the complexes $[ScCl_2(\text{dibenzo-24-crown-}8)(H_2O)]^+SbCl_6^-\cdot 2$ MeCN and $[ScCl_2(\text{dibenzo-30-crown-}10)(H_2O)_2]^+SbCl_6^-\cdot MeCN\cdot H_2O$. The cavity in the smaller tetradentate 12-crown-4 ring is too small for a $[ScCl_2]^+$ ion to fit, so $[ScCl_2(12\text{-crown-}4)(MeCN)]^+SbCl_6^-$ is believed to have an 'extra-cavity' (half-sandwich) structure.

Use of excess $SbCl_5$ permits the extraction of further chlorides from the crown ether complexes. Thus reaction of $[ScCl_3(thf)_3]$ in MeCN with 3 mols of $SbCl_5$ and dibenzo-18-crown-6 leads to the complex $[ScCl(\text{dibenzo-18-crown-}6)(MeCN)]^{2+}$ $(SbCl_6^-)_2$. If $SbCl_5$ and $SbCl_3$ are used together, $[Sc(12\text{-crown-}4)_2]^{3+}$ $(Sb_2C_8)(SbCl_6)_2(MeCN)_2$ is obtained, with eight-coordinate Sc.

Few scandium alkoxides have been studied in detail, but monomeric three coordination is known in $[(2,6\text{-}(t\text{-}Bu)_2\text{-}4\text{-}MeC_6H_2O)_3Sc]$, where the bulky ligand enforces steric

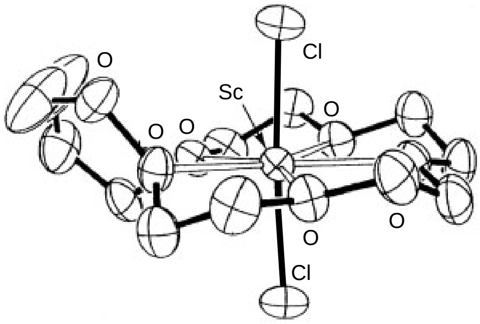

Figure 4 Seven-coordinate scandium in $[ScCl_2(18\text{-crown-}6)]$ $(SbCl_6)$

crowding. It will, however, expand its coordination sphere to form four-coordinate adducts with Ph_3PO and thf, unlike the corresponding three-coordinate silylamide. $Sc(OSi(t\text{-Bu})_3)_3{\cdot}L$ ($L = $ thf, py, NH_3) have also been prepared (the Lewis base cannot, however, be removed to afford the homoleptic siloxide; *see Homoleptic Compound*). The isopropoxide is pentanuclear $[Sc_5O(OPr^i)_{13}]$, similar to those formed by Y, Yb, and In, with the structure $[Sc_5(\mu_5\text{-O})(\mu_3\text{-OPr}^i)_4(\mu_2\text{-OPr}^i)_4(OPr^i)_5]$. Anodic oxidation of scandium in aliphatic alcohols has been used as a pathway to scandium alkoxides $[Sc(OR)_3]$ (R = Me, Et) and $[Sc_5O(OPr^i)_{13}]$. The elusive structure of the methoxide $[Sc(OMe)_3]$ is still not known; it appears not to contain an oxo ligand, and to be a polymer. Alcoholysis of $[Sc_5O(OPr^i)_{13}]$ leads to $[Sc(OR)_3]$ (R = Me, Et, Bu^n), $[Sc_5O(OBu^s)_{13}]$ and $[Sc_5O(OPr^i)_8(OBu^t)_5]$.

Scandium complexes with ammonia have only been made by dry methods.[21] In $(NH_4)_2\,[Sc(NH_3)I_5]$, obtained from reaction of NH_4I and metallic scandium in a sealed tube at 500 °C, scandium has octahedral coordination with Sc–N = 2.29 (2) Å and Sc–I = 2.856(5) − 2.899(5) Å. Reaction of Sc with NH_4Br in a sealed Ta vessel gives $[Sc(NH_3)_2Br_3]$ (isotypic with $Sc(NH_3)_2Cl_3$) having isolated dimers of bromide edge-connected $[mer\text{-}Sc\text{-}(NH_3)_3Br_3]$ and $[Sc(NH_3)Br_5]$ octahedra. $[Sc(NH_3)Br_3]$, isotypic with $Sc(NH_3)Cl_3$, has zigzag chains of edge-connected $[Sc(NH_3)Br_5]$ octahedra as $[Sc(NH_3)_{1/1}Br_{1/1}Br_{4/2}]$.

Reaction of the anhydrous ScX_3 (X = Cl, Br) with pyridine yields $Sc(py)_4X_3$, which possibly have one molecule of pyridine in the lattice, as it is lost in vacuo. $Sc(py)_3(NCS)_3$ also exists. Using bidentate ligands, ScL_2X_3 (L = phen, bipy) have been made, sometimes in two forms; they are believed to be $[ScL_2X_2]^+X^-$ and it is possible that cis and trans-isomers may exist, but there is no structural confirmation. Similar ethylenediamine complexes have been made by removal of a ligand molecule in vacuo from $Sc(en)_3X_3$ (X = Cl, Br). Of the complexes of tridentate N-donors, the best characterized is $Sc(terpy)(NO_3)_3$, which has nine-coordinate scandium, but with one rather long Sc–O bond.

A range of porphyrins and phthalocyanines exist; syntheses often involve the high-temperature routes typical of the transition metals but recently a high-yield low-temperature route has been utilized:

$$Li(OEP)^- + ScCl_3(THF)_3 \longrightarrow Sc(OEP)Cl + 2Cl^- + 3THF \quad (1)$$

The chloride can be replaced by alkoxy, alkylamide, alkyl, and cyclopentadienyl groups. Similar compounds with other porphyrins and with phthalocyanine have been made, as well as the oxo-bridged dimer $(OEP)Sc(\mu\text{-O})Sc(OEP)$.

Scandium resembles the other 3d transition metals from titanium through cobalt in forming an unusual three-coordinate silylamide, $Sc[N(SiMe_3)_2]_3$, but unlike them its solid-state structure is pyramidal, not planar, in which respect it resembles the lanthanides and uranium. It does not form adducts with Lewis bases, presumably on steric grounds, the resemblance here being to the 3d metals. The less congested amide $[Sc\{N(SiHMe_2)_2\}_3]$ forms a thf adduct $[Sc\{N(SiHMe_2)_2\}_3(thf)]$, which has distorted tetrahedral coordination of scandium, with short solid-state Sc···Si contacts (this is in contrast to 5-coordinate $[Ln\{N(SiHMe_2)_2\}_3(thf)_2]$ (Ln = La–Lu).

Like other M^{3+} ions, scandium forms strong complexes with EDTA and DTPA. In $NH_4\,[Sc(EDTA)(H_2O)_2]{\cdot}3H_2O$, scandium is eight-coordinate with hexadentate EDTA and two coordinated water molecules), as expected in comparison with the smaller Fe^{3+} ion (forming seven-coordinate $[Fe(EDTA)(H_2O)]^-$) or larger La^{3+} ion (which forms nine-coordinate $[La(EDTA)(H_2O)_3]^-$). Again, scandium is eight-coordinate in $Mn[Sc(DTPA)]{\cdot}4H_2O$, in which DTPA is octadentate but there are no coordinated water molecules, unlike the complex of the larger Gd^{3+} ion, $[Gd(DTPA)(H_2O)]^{2-}$, familiar as a magnetic resonance imaging (MRI) contrast agent (see Section 'Magnetic Resonance Imaging and MRI Agents'), also in the $[Sc(DOTA)]^-$ ion found in $[[NaSc(DOTA)]_3{\cdot}NaOH{\cdot}18H_2O]$, where the coordination geometry is twisted square antiprismatic. These compounds nicely illustrate the tendency of Sc^{3+} to adopt coordination numbers intermediate between those of the M^{3+} ions in the first transition series and those found for the lanthanides.

The best-defined halide complexes are the hexafluoroscandates, M_3ScF_6, which clearly contain $ScF_6{}^{3-}$ anions; Na_3ScF_6 adopts the cryolite structure, K_2NaScF_6 also has the cubic elpasolite structure, as does the high-temperature phase of Rb_2KScF_6; Sr_2ScF_7 has seven-coordinate scandium however. $KScF_4$ has a layered structure in which scandium acquires six-coordination by edge-sharing alternate cis- and trans-corners, whilst $(enH_2)_{0.5}ScF_4$ has corner-linked octahedral. Ba_2ScCl_7 is $Ba_2[ScCl_6]Cl$, whilst Na_3ScCl_6 again has the cryolite structure. $NaScCl_4$, is isostructural with $NaLuCl_4$, the structure being made up of *cis*- edge-sharing $ScCl_6$ octahedra. Na_3ScBr_6 has the Na_3CrCl_6 structure.

3 YTTRIUM AND THE LANTHANIDES[22]

The lanthanides exhibit a number of features in their chemistry that differentiate them from the d-block metals.

1. Reactivity significantly greater than the transition metals, akin to group 2 elements.
2. A wide range of coordination numbers (generally 6–12, but 2–5 are also known).
3. Coordination geometries determined by ligand steric factors rather than crystal-field effects.
4. The formation of labile 'ionic' complexes that undergo facile exchange of ligand.
5. The inability of the 4f orbitals (*see f-Orbitals*) in the Ln^{3+} ion to participate directly in bonding.[23] Their

spectroscopic and magnetic properties are thus largely uninfluenced by the ligand.

6. Small crystal-field splittings (*see Crystal Field Theory*) and very sharp electronic spectra in comparison with the d-block metals.
7. The preference for anionic ligands with donor atoms of rather high *Electronegativity* (e.g. O, F, *see Electronegativity*).
8. The ready formation of hydrated complexes (on account of the high hydration energy of the small Ln^{3+} ion) and this can cause uncertainty in assigning coordination numbers.
9. The insolubility of hydroxides which precipitate at neutral pH unless complexing agents are present.
10. The dominance of one (3+) oxidation state.
11. Their inability to form Ln=O or Ln≡N multiple bonds of the type known for many transition metals and certain actinides.
12. Unlike the transition metals, they do not form stable carbonyls, and have virtually no chemistry in the 0 oxidation state.

3.1 Ores and Extraction of the Metals[1,3,6]

In general, Y and the heavier lanthanides, Gd to Lu, are less abundant than the lighter lanthanides, La to Eu. However, there are two further complicating factors: one is that the elements with even atomic number are more abundant than those of odd atomic number, reflecting the greater stability of such nuclei. Secondly, some ores (e.g. bastnasite, monazite) are richer in the lighter metals while others (e.g. xenotime) have more of the heavier metals. The abundance of yttrium in the Earth's crust is 31 ppm while the total abundance of the lanthanides is some 180 ppm; cerium is the most abundant (66 ppm), while thulium and lutetium are the rarest (0.5 and 0.8 ppm, respectively).

Although over 150 minerals are known to contain lanthanides, the three most important (outside of China) are bastnasite ($LnFCO_3$), monazite ($LnPO_4$), and xenotime ($LnPO_4$). The main western source of bastnasite is California, USA, with some coming from Baiyunebo (inner Mongolia) where it is present as part of an iron ore. Monazite mainly comes from China and Australia (with important contributions from Malaysia, India, and Brazil), where the monazite contains 5–10% of ThO_2 (whose radioactivity presents an additional processing problem). Xenotime is likewise a phosphate containing rather more of the heavier metals and also containing thorium oxide with some U_3O_8 (main exporters are Australia, China, and Malaysia). Chinese rare earth reserves amount to over 70% of the known world total. Much of this is in the form of the ionic ores from southern provinces, of which the Longnan mineral contains a remarkable quantity of yttrium oxide (over 60%). These Chinese ion-absorption ores, weathered granites with lanthanides adsorbed on to the surface of aluminum silicates, are in some cases low in cerium and rich in the heavier lanthanides (Longnan), while the Xunwu deposits are rich in the lighter metals; the small particle size makes them easy to mine.

3.2 Extraction of the Lanthanides

As mined, Californian bastnasite contains around 8% lanthanide oxides. Flotation followed by dissolution of the calcite content in 10% HCl concentrates this to around 70%. The resulting concentrate is treated to oxidize Ce^{III} to Ce^{IV}, followed by reaction with hydrochloric acid to dissolve the oxides of the metals La and Pr through Gd, separating them from cerium (which is recovered as CeO_2). Solvent extraction of the resulting solution affords the individual lanthanides (europium can be separated from the mixture by zinc reduction to Eu^{II}, followed by precipitation as $EuSO_4$). Monazite is generally first treated with NaOH at 150 °C to remove phosphate as Na_3PO_4, leaving a mixture of the hydroxides of lanthanum and thorium. These can be separated either by selective precipitation of $Th(OH)_4$ while the Ln^{3+} ions remain in solution, or by selectively dissolving the lanthanides out of the hydroxide mixture. The resulting solution of Ln^{3+} ions is separated into the individual metal ions by solvent extraction.

Various other separation methods have been described, one recent one involving the use of supercritical carbon dioxide at 40 °C and 100 atm to convert the lanthanides into their carbonates, while the quadrivalent metals (e.g. Th and Ce) remain as their oxides.

For many years up to and immediately following the Second World War, isolation of the individual lanthanide compounds in a pure state was a problem that required innumerable fractional crystallizations of salts such as the bromates or magnesium double nitrates, exploiting slight solubility differences. As radioactive lanthanide isotopes are among the important fission products of uranium and because it was expected that the elements beyond plutonium would resemble the lanthanides, the development of ion-exchange chromatography was a highly important spin off from the Manhattan project and commercial separation processes based on cation exchange rapidly came into being. The later lanthanides with their smaller ionic radii conversely have the larger hydrated radii because of their greater tendency to attract water molecules. The separation relies on the use of complexing agents such as EDTA and HEDTA (hydroxyethylethylenediaminetriacetate), which form stronger complexes with the heavier lanthanides and elute them first (the original eluent was ammonium citrate).

The major disadvantage of ion exchange is that it is a slow process for large-scale separations. Solvent extraction has therefore come to be the process of choice, at least for the initial separation (up to the 99.9% purity level); it employs an automated continuous counter-current process using a two-solvent mixture, an acid (HCl or HNO_3) aqueous phase, and an organic phase, for which tributyl phosphate or similar compound with a P=O group is the usual complexing ligand.

This process is capable of giving individual lanthanides of sufficient purity for chemical use (99.9%), but for electronic or spectroscopic use ('phosphor grade') 99.999% purity is necessary, and further ion exchange is used for final purification to these levels.[24]

3.3 Preparation and Properties of the Metals[25]

Most of the elements are usually made by metallothermic reduction of the trifluoride, generally with calcium in excess of 1000 °C.

$$2MF_3 + 3Ca \longrightarrow 2M + 3CaF_2 \qquad (2)$$

The fluoride is chosen as it is both nonhygroscopic and also oxide-free. This method is not applicable to Sm, Eu, or Yb, which are only reduced to the difluorides; these metals are instead made by heating their oxides with lanthanum at 1000–1300 °C, the more volatile metal being removed by distillation at low pressure:

$$3La + M_2O_3 \longrightarrow 2M + La_2O_3 \qquad (3)$$

A third method, electrolysis of the mixed molten chlorides of the lighter lanthanides, is used to make the lanthanide mixture known as mischmetal. For some research applications, ultrapure metals are needed as even small quantities of light nonmetals such as carbon and hydrogen can have a marked effect on the properties of the metal. Thus if the LnF_3–Ca method is used the molten fluoride has to be treated with HF to ensure the absence of the oxyfluoride, while the calcium is twice redistilled under an ultrapure argon atmosphere before use. Further purification of the lanthanide can be achieved by methods including vacuum remelting, zone melting, and distillation.

These elements are silvery white reactive metals. The reactivity order is europium followed by lanthanum through lutetium, the exception being ytterbium, placed between Sm and Gd. Yttrium resembles terbium and dysprosium. Europium is quickly oxidized by air and the powdered metal can be pyrophoric; it reacts with water like calcium. Lighter lanthanides are oxidized readily at room temperature, especially in moist air, but the metals in the second half of the series tend to be fairly stable in dry air. All the metals dissolve rapidly in dilute acid and react slowly with the halogens at room temperature, rapidly on warming. Similar reactions occur with other nonmetals (S, C, N_2, Si, B, H_2) on heating. In their reactivity the metals resemble the alkaline earth metals; in the case of Eu and Yb the resemblance extends to forming dark blue solutions in liquid ammonia. The physical properties of the lanthanide metals follow a smooth pattern, with the exception of the metals with a tendency to divalency. The atomic radii of Eu and Yb are ca. 0.2 Å greater (and the densities correspondingly lower) than the other metals; samarium, ytterbium, and europium are considerably more volatile than the other lanthanides, implying that while most lanthanide metals can be represented as Ln^{3+} $(e^-)_3$, Eu and Yb should be regarded as Ln^{2+} $(e^-)_2$.

The lanthanides form a wide range of alloys, several of considerable importance. $LaNi_5$ readily absorbs hydrogen gas up to a composition $LaNi_5H_6$ and has been extensively studied for its potential for hydrogen removal and storage (as H_2 is desorbed on heating to about 140 °C), rechargeable batteries (as used in notebook PCs), electrode and fuel-cell materials, and in catalytic hydrogenation. Samarium–cobalt alloys have been widely used as $SmCo_5$ and Sm_2Co_{17} in permanent magnets. A ferrocerium alloy containing 25% iron and 75% mixed light lanthanides, mainly cerium (mischmetal), is used to make lighter flints; another use of mischmetal is for deoxidation and desulfurization of steels.

3.4 Oxidation States and Coordination Numbers[10]

The adoption of the (+3) oxidation state by the lanthanides in most of their chemistry is a consequence of the balance of a number of factors,[6,26,27] although many divalent and tetravalent compounds also exist. Nevertheless, in aqueous solution, only the lanthanide(III) ions are stable; Ce^{4+} is metastable whilst Eu^{2+} has a life of a few hours.

The ionic radius of the smallest lanthanide(III) ion, Lu^{III} is 0.861 Å (for six coordination), considerably greater than that of scandium and the 3d metals (corresponding values for lanthanum and yttrium are 1.032 and 0.900 Å, respectively). Purely on steric grounds, high coordination numbers would therefore be expected for Ln^{3+}, and in fact a range of values between 3 and 12 is known. The observed geometries are discussed in more detail in Section Magnetic Resonance Imaging and MRI Agents.

The lack of directional character of the essentially ionic bonding is a result of crystal-field effects being absent. The decreasing size of the lanthanide atoms and ions across the series, the *Lanthanide Contraction* (*see Lanthanide Contraction*), is due to the contraction of the ($5s^25p^6$) configuration due to their penetration inside the 4f orbitals (a similar contraction is noted for the transition metals, although for a different reason).[28] Consequently a decrease in coordination number in a series of related compounds is often observed.

3.5 Magnetic and Spectroscopic Properties of the Ln^{3+} Ions[29,30]

These may be accounted for in terms of the Russell–Saunders coupling scheme in which the electron spins are coupled together separately from the coupling of the orbital angular momenta of the electrons and the orbital moment is unquenched. The ground state for a given lanthanide ion is unaffected by the ligands (and thus crystal-field splittings are weak) because of the shielding of the 4f electrons by the

filled 5s and 5p orbitals. The strength of spin–orbit coupling means that the ground state is well separated from excited states, except for Sm^{3+} and Eu^{3+}, where contributions from low-lying paramagnetic excited states contribute to the magnetic moment. Thus, if the magnetic properties of the Eu^{3+} ion were solely determined by the $^7F_0$ ground state, its compounds would be diamagnetic, whereas contributions from thermally accessible levels such as $^7F_1$ and $^7F_2$ lead to the observed magnetic moments in the region of 3.5 μ_B. The magnetic moments in the second half of the series are greater than those in the first half, as $J = L + S$ for a shell greater than half-filled and $J = L - S$ for a less than half-filled shell. (Table 1 lists the magnetic moments for the tripositive lanthanide ions.) The magnetic moment of the Ln^{3+} ions are essentially independent of environment, from the practical viewpoint of the coordination chemist measuring bulk powder samples at around room temperature. The moments are given by the equation

$$\mu_{\text{eff}} = g_J\sqrt{J(J+1)} \tag{4}$$

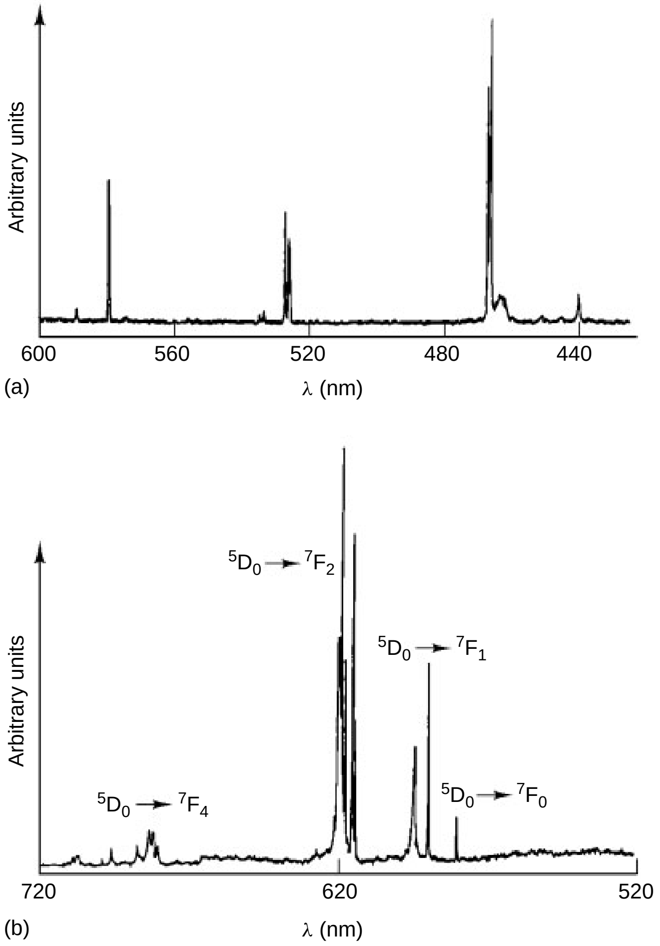

Figure 5 (a) Excitation spectrum at 77 K of $Eu(NO_3)_3\cdot$15-crown-5 (λ_{anal} = 618 nm) (b) Fluorescence spectrum at 77 K (λ_{exc} = 397.7 nm). (Reprinted with permission from J.-C.G. Bunzli, B. Klein, G. Chapuis, and K.J. Schenk, *Inorg. Chem.*, 1982, **21**, 808. © 1982 American Chemical Society)

where the Landé g factor is defined by

$$g_J = \frac{[S(S+1) - L(L+1) + 3J(J+1)]}{2J(J+1)} \tag{5}$$

The electronic spectra of lanthanide compounds resemble those of the free ions, in contrast to the norm in transition metal chemistry; the crystal-field (CF) splittings can be treated as a perturbation on the unsplit $^{2S+1}L_J$ levels. A further consequence of the weak CF splittings is the sharpness of the f–f transitions. The spectrum of the complex $Eu(NO_3)_3$(15-crown-5) shown in (Figure 5) displays this.

Certain transitions in the electronic spectra of some tripositive lanthanide ions (notably Nd, Ho, Er) exhibit 'hypersensitivity' to the environment, which can sometimes be used to indicate geometry, as in the case of the neodymium(III) aqua ion shown in Figure 6.

Study of the intensity and splitting pattern of certain transitions in the fluorescence spectra of compounds of Eu^{3+} and Tb^{3+} in particular can give a good deal of information about the environment of the lanthanide ion.[31,32] The $^7F_0$ ground state is unsplit, so that transitions to it give straightforward information about the excited state. Thus, since the $^5D_0$ state is also unsplit, if more than one component

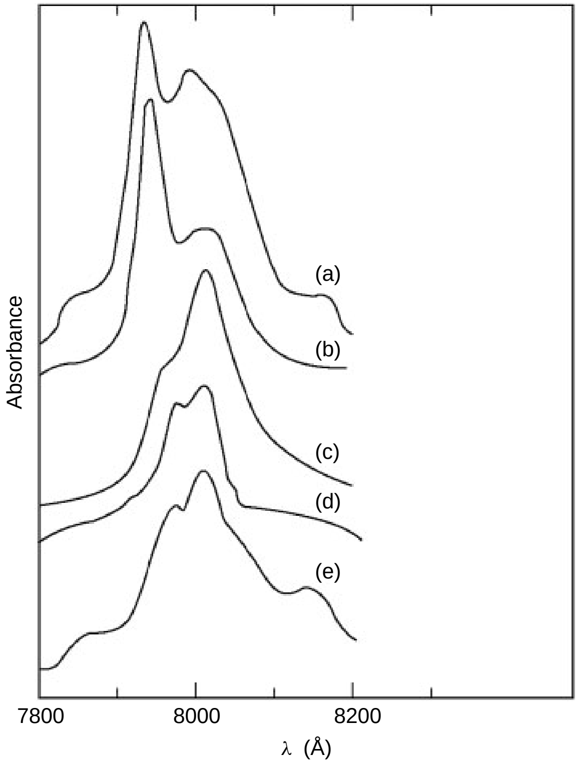

Figure 6 Spectra of the $Nd^{3+}\,^4I_{9/2} \rightarrow {}^2H_{9/2}, {}^4F_{5/2}$ transitions: (a) solid $Nd(BrO_3)_3\cdot 9H_2O$; (b) 5.35 × 10^{-2} M Nd^{3+} (aq); (c) 5.35 × 10^{-2} M Nd^{3+} in 11.4 M HCl; (d) solid $NdCl_3\cdot 6H_2O$; (e) $Nd_2(SO_4)_3\cdot 8H_2O$. is seen for this transition, it shows more than one europium site; only one line is observed for the crown ether complex shown in Figure 5 so the sites are identical. This transition is electric-dipole allowed and only observed in low-symmetry environments (it is not seen in the emission spectrum of the $[EuCl_6]^{3-}$ ions in $Cs_2Li[EuCl_6]$ where they occupy sites with cubic symmetry) whereas the intensity of the magnetic-dipole transition from $^5D_0$ to $^7F_1$ is relatively insensitive to this; in the spectrum of the crown ether complex this transition appears as a doublet and singlet, a splitting consistent with the approximately pentagonal pseudosymmetry seen in its crystal structure (in a lower-symmetry environment, the doublet would be further split).

Study of these and other transitions can thus yield valuable information. Crystals of the nine-coordinate complex $[Eu(tmhd)_3(terpy)]$ contain two slightly different molecules present in the crystal, its luminescence spectrum showing a broad but unresolved $^5D_0 \rightarrow {}^7F_0$ transition. In solid $[Eu(tmhd)_3(Me_2phen)]$ (Ln = La, Eu, Tb, Ho), there are two different square-antiprismatic isomers in the unit cell, and in this case emissions from both isomers can be distinguished in the fluorescence spectrum of the europium complex, which shows an unusually high splitting of the $^5D_0 \rightarrow {}^7F_0$ transition.[33]

The paramagnetism of many lanthanide ions finds practical application in NMR shift reagents and, increasingly, in MRI contrast agents. EPR (*see Electron Paramagnetic Resonance*) spectra are only readily obtained from Gd^{3+}, with its ^8S ground state,[34] as yet there has been little study of the effects of environment upon the spectra.

The electronic spectra and magnetic susceptibility of lanthanide complexes thus cannot be used to give diagnostic information on the stereochemistry of lanthanide compounds as for the 3d transition metals. Ultimately, reliable stereochemical information can only be obtained from diffraction measurements.

The lanthanides form a series of ions of closely related size and bonding characteristics and in many respects resemble Ca^{2+}, for which they often substitute isomorphously in biological systems; since different Ln^{3+} ions can be probed with particular spectroscopic techniques (e.g. Eu^{3+} and Tb^{3+} fluorescence, Gd^{3+} ESR, Nd^{3+} electronic spectra), in favorable circumstances it should be possible to obtain information about the binding site of spectroscopically inactive Ca^{2+} in several ways.[35]

3.6 Binary Compounds of Yttrium and the Lanthanides

3.6.1 Halides[36,37]

These are the best characterized binary compounds of these metals; all the halides of the trivalent metals are well defined except EuI_3, whose existence is extremely uncertain. The insoluble fluorides are conveniently prepared by precipitation, followed by dehydration of the hydrate; this route is not generally open for the other anhydrous halides, as attempted dehydration of the hydrated halides tends to lead to oxyhalides. Reaction of the elements with the halogens or HX is often possible although a more convenient route involves heating the lanthanide oxide with the appropriate ammonium salt to afford $(NH_4)_3LnX_6$, followed by thermal decomposition. The halides may be purified by vacuum sublimation, with the caveat that the hot halides attack glass, forming the oxyhalide. The lanthanide trihalides very clearly demonstrate the effect of varying the cation and anion radii upon the structure type adopted (Table 2). As the radius of the lanthanide ion decreases on crossing the series from left to right, the coordination number of the metal in a given halide decreases; a similar effect is seen on descending group 17, as the radius of the halide ion increases.

The early fluorides feature the tysonite (LaF_3; Figure 7) structure in which the lanthanide has nine nearest-neighbor fluorides in a tricapped trigonal prismatic array (like the aqua ions), with two rather more distant neighbors capping the trigonal faces. From SmF_3 onwards the stable form is the

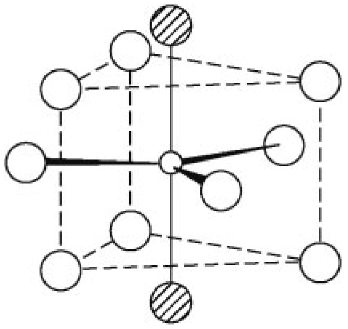

Figure 7 The LaF_3 structure

Table 2 Structures of the trihalides of yttrium and the lanthanides[a]

Halide	La	Ce	Pr	Nd	Pm	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	Lu	Y
F	1	1	1	1	1	2	2	2	2	2	2	2	2	2	2	2
Cl	3	3	3	3	3	3	3	3	4	5	5	5	5	5	5	5

I	4	4	4	4	4	6	?	6	6	6	6	6	6	6	6	6

[a]Abbreviations for structure types: 1 = LaF_3 (CN9 + 2); 2 = YF_3 (CN 9); 3 = UCl_3 (CN 9); 4 = $PuBr_3$ (CN 8); 5 = $AlCl_3$ (CN 6); 6 = $FeCl_3$ (CN 6).

'YF_3' structure in which there is a distorted tricapped trigonal prismatic array of fluorines round the metal. The trichlorides adopt successively the UCl_3 (nine-coordinate), $PuBr_3$ (eight-coordinate), and $AlCl_3$ (six-coordinate) structures. A similar sequence is found in the bromides, while nine-coordination is not found at all in the iodides; eight-coordination is the rule for the early metals as far as promethium with six-coordination for the later metals.

3.6.2 Lower Halides[14,38]

Whether an individual lanthanide forms a dihalide depends upon a number of factors, particularly the value of I_3, the third ionization energy.[39] There are three main types of lower halides.

1. The salt-like dihalides form the widest range. All MX_2 ($X = F$, Cl, Br, I) are formed by Eu, Sm, and Yb, the metals with the most stable divalent states; in addition, all except the difluoride are known for Nd, Dy, and Tm. They may typically be formed by reproportionation (comproportionation; see *Disproportionation*):

$$Nd + 2NdCl_3 \longrightarrow 3NdCl_2 \quad (6)$$

   although hydrogen reduction is available for all the europium halides and all YbX_2 except YbF_2. They are nonconductors and have magnetic and spectroscopic properties consistent with the presence of M^{2+} ions. Only EuX_2 are stable for any length of time in aqueous solution. A range of solid-state structures is adopted; for example, all the difluorides have the fluorite structure.
2. Metallic diiodides are formed by La, Ce, Pr, and Gd, even though none of these lanthanides are well known in the divalent state. These have high conductivity, a metallic lustre, and are good reducing agents, reacting immediately with air and water. All the evidence supports the formulation Ln^{3+} $(I^-)_2(e^-)$ with the free electron in a conduction band. A high-pressure form of NdI_2 is also believed to be of this type. The 'reduced' halide Pr_2Br_5 is a Pr^{3+} compound with the extra electron in a d-band. Extra Pr can be incorporated into $PrCl_3$ to give a black solid, $Pr_{2.6}Cl_6$, whose electronic structure is uncertain.
3. Cluster compounds are exemplified by Gd_2Cl_3, which has a structure (Figure 8) based on Gd_6Cl_8 clusters sharing common edges in infinite chains. This, too, may be made by comproportionation; it is a semiconductor. Y_2Cl_3, Tb_2Cl_3, and Gd_2Br_3 have also been described. Many compounds hitherto thought to be reduced binary halides are now known to be clusters containing a third, interstitial, element as in YClH. An extensive range of mixed metal halides based on chain structures exist. Thus, La_4I_5Ru has metal octahedra linked into chains with edge-bridging iodines; parallel chains are also linked by iodine bridges, the whole structure having been described as a heterometal wire sheathed by iodine. Pr_3I_3Ru has a structure in which there are double chains of condensed, Ru-centered octahedra.

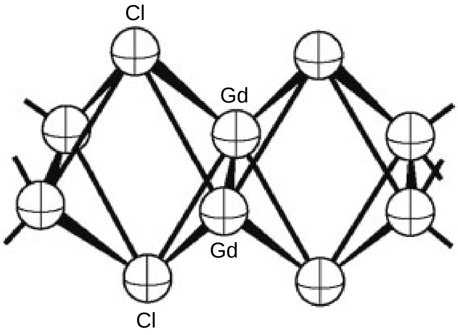

Figure 8 The Gd_2Cl_3 structure

3.6.3 M^{IV} *Halides*

The only tetrahalides isolated are the fluorides of Ce, Pr, and Tb. Only CeF_4 is made by direct fluorination of the metal (as well as CeX_3 ($X = Cl$, F)); the terbium compound is made by fluorination of TbF_3 while the more unstable PrF_4 is made by the reaction of Na_2PrF_6 with dry HF (it decomposes around 70 °C). $CeCl_4$, expected to be the most stable tetrachloride, has never been isolated (though Lewis base adducts have, cf. $PuCl_4$).

3.6.4 Oxides[40]

The most important of these compounds are the basic sesquioxides M_2O_3, readily prepared by heating oxysalts such as the carbonate or nitrate:

$$4Ln(NO_3)_3 \longrightarrow 2Ln_2O_3 + 12NO_2 + 3O_2 \quad (7)$$

though metals with an accessible (+4) state need a reducing atmosphere. They adopt three types of structures; in the A-type structure (La to Sm) they have capped-octahedral seven-coordination, while in the B-type (Pr to Dy) face-capped trigonal prismatic seven-coordination and a distorted capped-octahedral structure coexist. Distorted octahedral coordination is found in the C-type structure, the most stable phase for most lanthanides.

Reduction of Eu_2O_3 with lanthanum or europium, as well as carbon, affords the stablest M^{II} oxide:

$$Eu + Eu_2O_3 \longrightarrow 3EuO \quad (8)$$

Similar comproportionation has yielded NdO, SmO, and YbO, although in these cases it is necessary to work at high

pressure. Europium and samarium also give mixed-valence oxides M_3O_4.

Of the Ln^{IV} compounds, CeO_2 is the most important. It is obtained as the product (white when pure, but usually yellow) of thermal decomposition of Ce^{III} oxy salts in air or by burning cerium metal. It has the fluorite structure. Additional phases, Ce_nO_{2n-2} ($n = 7, 9, 10, 11$), have been characterized. A hydrated yellow form is precipitated from aqueous solution. CeO_2 can be persuaded to dissolve in acid to afford Ce^{4+}, generally as a complex ion. Praseodymium and terbium usually form Pr_6O_{11} and Tb_4O_7 when corresponding aerial ignition is employed, but can be produced as stoichiometric dioxides by heating with atomic oxygen. They dissolve in acid but no Ln^{IV} aqua ion can be made.

Several mixed metal oxides involving lanthanides have been found to exhibit *Superconductivity* (*see Superconductivity in Solids*) since the 1986 report of a superconducting transition temperature of 30 K in $La_{2-x}Ba_xCuO_4$, the highest found at that date. Shortly afterwards, a T_c of 93 K, above the boiling point of liquid nitrogen, was determined for $YBa_2Cu_3O_7$. Another class of superconductors, though with lower T_c values (20 K), are of the type $Nd_{2-x}Ce_xCuO_4$. These superconductors are believed to function by the so-called *Cooper Pair* mechanism in which electron pairs move unhindered by lattice vibrations and impurities. The conduction electrons probably reside primarily on the oxygen atoms. The cuprate superconductors have a common feature of two-dimensional copper oxide planes along which the superconductivity occurs; inserted between these layers are planes of metal atoms (or metal/oxygen atoms) which fulfil the function of acting as charge reservoirs.

The $YBa_2Cu_3O_7$ compounds have been most extensively studied (Figure 9). Other, paramagnetic, lanthanide ions can be introduced in place of yttrium with little effect upon the conducting properties, arguing that the yttrium site has little involvement with the coppers but probably plays a supporting role. On the other hand, the presence of copper(II) is shown to be vital by other doping experiments. Above the superconducting region these compounds exhibit pronounced anisotropy in their resistance, it being greatest perpendicular to the CuO_2 planes.

The commercial implications of ‘warm’ superconductors have led to intense study of the magnetic properties of these materials and the investigation of reliable synthetic routes, including the preparation of thin films.

3.6.5 *Other Binary Compounds*

Hydrides are readily formed by union of these metals with hydrogen on gentle warming.[41] Apart from europium, which only forms EuH_2, both LnH_2 and LnH_3 exist, although the composition ranges can be considerable and the phase isolated is often nonstoichiometric (thus for yttrium the stability ranges are $YH_{1.90-2.23}$ and $YH_{2.77-3.0}$). Both types of hydride contain Ln^{3+} ions with the trihydrides as salt-like $Ln^{3+}(H^-)_3$ while

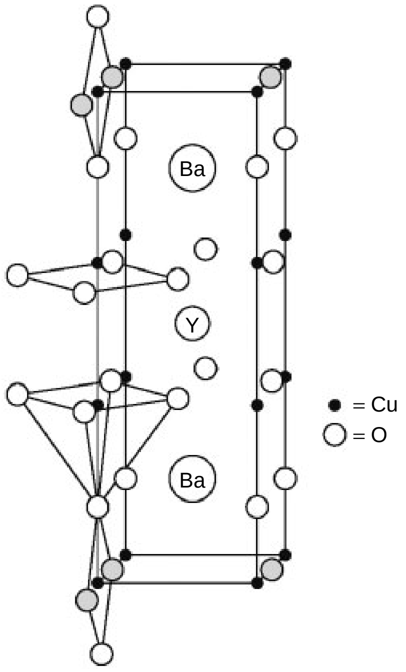

Figure 9 The structure of $YBa_2Cu_3O_7$; the shaded atoms are those removed to create oxygen-deficient phases up to $YBa_2Cu_3O_6$. (Ref. 6. Reproduced by permission of Palgrave Macmillan)

the conducting dihydrides are $Ln^{3+}(H^-)_2(e^-)$. The important alloy hydride $LaNi_5H_6$ is discussed in Section 3.3.

The lanthanides form a range of borides.[42] The most important of these is high-melting (2715 °C) LaB_6, widely used as a high-intensity thermal cathode in electron guns and in optical fibres. It has the CaB_6 structure and may be made by various routes, including La_2O_3 and B at 1500 °C. LaB_4(UB_4 type) and LaB_9 are also known. EuB_6 has been used as a neutron absorber in nuclear reactors; like YbB_6 it has Ln^{2+} ions, in contrast to the other hexaborides which contain Ln^{3+} ions, affording one electron from each lanthanide to provide a conduction band, and are metallic conductors. Many heavier lanthanides (above Gd) form MB_{12} (UB_{12} structure) and MB_{66} in which a B_{12} icosahedron is surrounded by 12 linked B_{12} icosahedra. A number of important ternary borides exist, particularly $Nd_2Fe_{14}B$, a high coercive-strength ferromagnet, while related compounds with other lanthanides are important in magnet technology. In addition to these, a number of $LnRh_4B_4$ compounds with the $CeCo_4B_4$ structure have been investigated for their superconducting properties.

An extensive array of sulfides has been obtained, and much research is still undertaken to clarify the picture.[43–45] The most important are sesquisulfides, M_2S_3, but other stoichiometries (MS, M_3S_4, and MS_2) also exist. A range of synthetic methods has been employed for the sesquisulfides (apart from the nonexistent Eu_2S_3); reaction of the lanthanide powders with sulfur in the presence of alkali-metal chlorides as a flux has found favor lately, as has reaction of the

sesquioxide or reduced chloride or chloride hydrides with sulfur. These compounds do contain the Ln^{3+} ions and often exist in several crystalline forms, sometimes obtained from high-pressure/temperature synthesis. The α-form (La–Dy) has seven- and eight-coordinate metals, the high-temperature γ-form (La–Dy) involves eight-coordination; the δ-form (Y, Ho–Tm) has six- and seven-coordination, while the ε-form (Yb, Lu) has six-coordination only. M_3S_4(Th_3P_4 structure) are generally found for the early lanthanides (La–Sm); most have Ln^{3+} but Eu_3S_4 contains both di- and trivalent europium. The monosulfides LnS are mainly golden yellow solids (NaCl structure) with a metallic luster whose metallic conductivity indicates a structure Ln^{3+} (S^{2-})(e^-), but the europium, ytterbium, and samarium compounds are insulators, $Ln^{2+}S^{2-}$.

Carbides are likewise formed in a number of stoichiometries.[46] LnC_2 are the most important; they can be made by direct synthesis from the elements as well as by heating the oxide or hydride with carbon. They have the CaC_2 structure with short C–C distances (around 1.28 Å) but have metallic conductivity and thus may be formulated Ln^{3+} ($C_2{}^{2-}$)(e^-). C_2 units are also found in Ln_2C_3 (Pu_2C_3 structure), while LnC, Ln_2C, and Ln_3C are also known. The carbides are readily hydrolyzed, affording a mixture of hydrocarbons whose composition depends on temperature.

Another kind of lanthanide–carbon binary compound recently discovered are the fullerenes (*see* ***Carbon: Fullerenes***); vaporization of graphite–Ln or graphite–Ln_2O_3 mixtures followed by toluene extraction of the resulting soot affords a number of clusters identifiable by mass spectroscopy, particularly Ln@C_{82}. ESR studies on the air-stable La@C_{82} and Y@C_{82} indicate the formulation Ln^{3+}@$(C_{82})^{3-}$; thus the spectrum of the lanthanum compound consists of eight lines of equal intensity due to hyperfine coupling to a single La ($I = 7/2$). An *Extended X-ray Absorption Fine Structure* (EXAFS) study on Y@C_{82} indicated that yttrium has seven carbon neighbors (2.35 Å) and one yttrium (at 4.05 Å), suggesting a dimeric formulation.

Pnictides LnQ (Q = Group 15 element) having the NaCl structure are made by direct synthesis, with other routes for the nitrides including the reaction of the lanthanide hydride with either nitrogen or ammonia; like the carbides, they are readily hydrolyzed to the hydride QH_3.

3.6.6 The Hydroxides

These metals form genuine hydroxides (not hydrous oxides) by alkaline precipitation from aqueous solution, obtainable in crystalline form by hydrothermal methods (crystallization from hot Ln_2O_3/NaOH under pressure). All have the nine-coordinate UCl_3 structure, except for $Lu(OH)_3$ which adopts the six-coordinate $In(OH)_3$ structure. Like the oxides, their basicity extends to reaction with atmospheric CO_2, affording the carbonates.

Table 3 Stability constants for complexes of Sc, Y, La, and Lu[49]

3.7 Coordination Chemistry of the +3 State[5,6,47,48]

Selected stability constants for scandium, yttrium, lanthanum, and lutetium are shown in (Table 3)[49] They show a preference for 'hard' donor atoms, as might be expected for the trivalent metals, but complexes with softer donor atoms like nitrogen can be isolated by operating in nonaqueous solvents.

3.7.1 Coordination Numbers and Geometries in Lanthanide Complexes[50]

As already noted, because of the large size of the lanthanide ion, it often occurs in high-coordination compounds (*see* ***Coordination Numbers & Geometries***). Application of a cone-packing model (*see Cone Angle*) to lanthanide complexes indicates that the coordination number adopted is a consequence of saturation in the coordination sphere. Analysis of the coordination numbers (*see* ***Coordination Numbers & Geometries***) for large numbers of coordination compounds of yttrium and the lanthanides indicates that coordination numbers of eight and nine are almost equally common, accounting for over 60% of the known structures. These are, of course, the coordination numbers associated with the aqua ions and related complexes.

Two coordination is known in the form of the monomeric (bent) alkyls $[Ln\{C(SiMe_3)_3\}_2]$ (Ln = Eu, Yb) which feature additional agostic interactions.[51] Coordination numbers of 3–5 are similarly associated with the use of bulky ligands, such as alkoxide (and related systems), bis(trimethylsilyl)amido, and the isolobal alkyl $CH(SiMe_3)_2$ (*see* ***Scandium, Yttrium & the Lanthanides: Organometallic Chemistry***). Several homoleptic three-coordinate LnX_3 systems are formed by these ligands, a few having the expected trigonal planar geometry, but usually they are pyramidal. The adoption of this geometry has, in the case of actinide trialkyls, been attributed to 6d involvement in the bonding; here it appears that weak agostic interactions are important in the solid state (the alkylamides have zero dipole moment in

solution and thus appear to be planar there, though pyramidal in the solid state). Tetrahedral geometry is, as expected, found in the four-coordinate $[Lu(2,6\text{-dimethylphenyl})_4]^-$ ion and in $Ln[(N(SiMe_3)_2]_3(Ph_3PO)$; in the latter complex the ligands have high second-order steric effects (*see Fan Angle*), generating crowding round the lanthanide even though there are only four atoms bound to the lanthanide. In contrast, the adoption of six-coordination in the $LnCl_6{}^{3-}$ anion is the result of first-order crowding among the six chlorides bound to the lanthanide. The six-coordinate complexes are usually octahedral, though with bidentate S-donors distortion towards trigonal prismatic may be the result of steric interactions between ligands. The first lanthanide thiocyanate complex to be characterised was the six-coordinate $[Er(NCS)_6]^{3-}$ ion, as the tetrabutylammonium salt; since then, crystallographic study of many lanthanide thiocyanate complexes has shown that seven and eight-coordination are also possible with the coordination number adopted being the result of a subtle balance of factors including the counterion and solvent used (Section 3.7.10).

Among seven-coordinate structures, many involve diketonate complexes $Ln(diket)_3{\cdot}L$; these generally have either capped-octahedral or capped trigonal prismatic geometry. A considerable number of complexes with neutral donors (e.g. thf) of the type LnX_3L_4 (X = halide, NCS), however, have structures closest to pentagonal bipyramidal, similarly found in the erbium perchlorate complex with 2,6-dimethyl-4-pyrone (Section 3.7.4).

Most eight-coordinate lanthanide complexes have dodecahedral or square-antiprismatic geometries; the energy difference between these is likely to be small. One exception is the $[La(bipyO_2)_4]^{3+}$ ion, which is cubic, possibly because of solid-state packing effects. Tricapped trigonal prismatic is the most familiar example of nine-coordinate geometry, adopted for the nonaqua ions of all lanthanides in a number of crystalline salts. This geometry is also often adopted where polydentate ligands are involved, such as the tris complexes with terpy and dipicolinate, even in $Eu(dpm)_3{\cdot}$ terpy.

Steric considerations (interdonor atom repulsions) make coordination numbers of 10 or more difficult, so fewer examples are known and, moreover, small differences between different types of polyhedra make assignment of a particular geometry difficult. Most examples involve nitrate, either alone (Section 3.7.7), or in combination with other polydentate ligands such as crown ethers (Section 3.7.8). Near-icosahedral geometries are found for regular 12-coordinate complexes such as $Pr(naph)_6{}^{3+}$ and $Ln(NO_3)_6{}^{3-}$.

Lanthanide complexes display a richness of coordination number and geometry unmatched by any other block of metals. It is becoming increasingly clear that in the absence of the strong ligand-field forces that often dictate coordination geometries in transition metal complexes, the coordination number adopted and the species formed in the solid state depends on the balance of a number of factors.

3.7.2 Aqua Ions and Simple Hydrated Salts[5,52]

Hydrated salts are readily prepared by reaction of the lanthanide oxide or carbonate with the acid. Salts of non coordinating anions most often crystallise as salts $[Ln(OH_2)_9]X_3$ (X e.g. bromate, triflate, ethylsulphate, tosylate). The tricapped trigonal prismatic structure was first established by X-ray diffraction in 1939 for the $[Nd(H_2O)_9]^{3+}$ ion in $[Nd(H_2O)_9]\ (BrO_3)_3$; this was an important structure historically, as it was the first clear indication that lanthanides could have high coordination numbers. It has since been verified for many other salts (Figure 10).

The crystals of the triflate contain columns of $[Ln(OH_2)_9]^{3+}$ cations and $CF_3SO_3{}^-$ ions, with a three-dimensional network of hydrogen bonds linking the columns. This presumably helps stabilise this structure favoring its isolation, even for the later lanthanides (Gd–Lu), where the eight-coordinate $[Ln(OH_2)_8]^{3+}$ ion predominates in solution (the $[Ln(OH_2)_8]^{3+}$ cation can be crystallised with certain other counter ions, for example, $[terpyH_2]_2[Tb(OH_2)_8]_7Cl_7{\cdot}8/3H_2O$, $[[Er(OH_2)_8](ClO_4)_3{\cdot}(dioxan){\cdot}2H_2O]$; $[[Eu(OH_2)_8]_2(V_{10}O_{28}){\cdot}8H_2O]$ and $[Lu(OH_2)_8]^{3+}$ in $[Lu(OH_2)_8]Cl_3{\cdot}1.5(12\text{-crown-4}){\cdot}2H_2O$, as well as in several hydrated iodides), and similar arguments are likely to apply to the ethylsulphates and bromates. The lanthanide–water distances for the positions capping the prism faces and at the vertices are different; as the lanthanide series is crossed, the Ln–O distance decreases from 2.62 to 2.50 Å for the three face-capping oxygens, but more steeply from ca. 2.52 to 2.29 Å for the six apical oxygens (data for the triflate salt[53]); the corresponding distances in the ethyl sulfates show a similar trend, with the Ln–O distances decreasing from 2.616 to 2.497 Å (face-capping) and from 2.517 to 2.318 Å (apical) on passing from La to Lu.

Octahedral six-coordination is, however, rather surprisingly found in the rather unstable perchlorates $[Ln(H_2O)_6]^{3+}(ClO_4{}^-)_3$ (X-ray, Ln = La, Tb, Er), although the dioxane complexes $Ln(ClO_4)_3{\cdot}9H_2O{\cdot}4$ dioxane may contain the nonaaqua ions. The isolation of $Ln(ClO_4)_3{\cdot}6H_2O$ in the solid state must

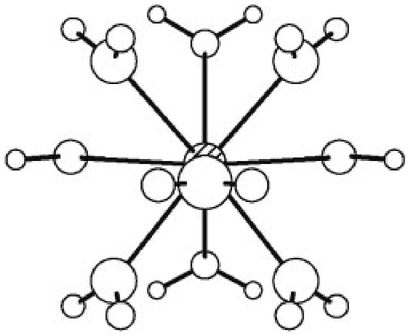

Figure 10 The structure of the nonaqualanthanide ion

reflect a balance of factors such as solubility and hydrogen-bonding in the solid state, as the close similarity between the EXAFS spectra of aqueous solutions of lanthanum perchlorate and the spectrum of solid $[Ln(H_2O)_9]$ $(CF_3SO_3)_3$, indicates a coordination number of 9 for La^{3+} (aq) in the perchlorate solutions. Similarly, the fact that erbium is eight-coordinate in $[[Er(OH_2)_8](ClO_4)_3{\cdot}(dioxan){\cdot}2H_2O]$ shows the fine balance here. Lower hydrates than the hexahydrates exist. Partial dehydration of $Ln(ClO_4)_3{\cdot}6H_2O$ (Ln = Er, Lu) gives $Lu(ClO_4)_3{\cdot}3H_2O$ and $Er(ClO_4)_3{\cdot}H_2O$, both of which have eightfold coordination of the lanthanide. Similarly, $Yb(ClO_4)_3{\cdot}H_2O$ has been shown to have bi and tridentate perchlorate groups giving eight-coordinate ytterbium.

When anions can coordinate, a wide variety of species is obtained. Thus, whilst early lanthanides (La–Nd) form $[Ln(OH_2)_9](p\text{-}MeC_6H_4SO_3)_3$ with the usual trigonal prismatic coordination, the later lanthanide ions form the tosylates $Ln(p\text{-}MeC_6H_4SO_3)_3{\cdot}9\ H_2O$, which contain $[Ln(OH_2)_6(p\text{-}MeC_6H_4SO_3)_2]^+$ ions (Ln = Sm, Gd, Dy, Ho, Er, Yb, Y) in distorted dodecahedral eight-coordination.

A considerable number of nitrates $Ln(NO_3)_3{\cdot}nH_2O$ have been examined; in general, the coordination number of the lanthanide decreases with decreasing ionic radius and all nitrate groups are coordinated as bidentate ligands in these compounds, but the number of waters of crystallisation is no guide to how many are actually bound to the metal. Thus $Ln(NO_3)_3{\cdot}6H_2O$ are known for La–Dy and Y. Of these, the lanthanum and cerium compounds are $[Ln(NO_3)_3{\cdot}(H_2O)_5]{\cdot}H_2O$ (Ln = La, Ce) with 11-coordinate lanthanides, whilst the others are $[Ln(NO_3)_3{\cdot}(H_2O)_4]{\cdot}2H_2O$ (Ln = Pr–Dy, Y) with 10-coordination for the metal. $[Ln(NO_3)_3{\cdot}(H_2O)_4]$ molecules are also present in the pentahydrates $Ln(NO_3)_3{\cdot}5\ H_2O$ (Ln = Eu, Dy–Yb). Lutetium forms $Lu(NO_3)_3{\cdot}4H_2O$ and $Lu(NO_3)_3{\cdot}3H_2O$, isolated under very similar conditions, both of which contain nine-coordinate $[Lu(NO_3)_3{\cdot}(H_2O)_3]$ molecules. Nine-coordinate $Yb(NO_3)_3(H_2O)_3$ has also been identified. Additionally, $Ln(NO_3)_3(H_2O)_3$ molecules (Ln = Gd, Ho, Y, Lu) have been found in adducts with noncoordinating crown ether and bipy ligands.[54]

Among the halides, the chlorides of La and Ce, $LnCl_3{\cdot}7H_2O$ are dimeric $[(H_2O)_7Ln(\mu\text{-}Cl)_2Ln(OH_2)_7]$ Cl_4 with what has been described as singly capped square-antiprismatic coordination of the metals (Figure 11) whilst $LnCl_3{\cdot}6H_2O$ (Ln = Ce–Lu) have antiprismatic $[LnCl_2(H_2O)_6]^+$ ions with the coordinated chlorides on opposite sides of the polyhedron. There are extensive hydrogen-bonding networks involving both coordinated and noncoordinated chlorides and water molecules.[55]

The hydrated bromides tend to resemble the chlorides; La and Ce form $LnBr_3{\cdot}7\ H_2O$, isomorphous with the corresponding chlorides and are dimeric $[(H_2O)_7Ln(\mu\text{-}Br)_2Ln(OH_2)_7]$ $Br_4{\cdot}LnBr_3{\cdot}6H_2O$ (Ln = Pr–Dy) are $[LnBr_2(H_2O)_6]Br$ whilst $LnBr_3{\cdot}8H_2O$ (Ln = Ho–Lu) which are $[Ln(H_2O)_8]$ Br_3, with no bromide coordinated, and which resemble the hydrated

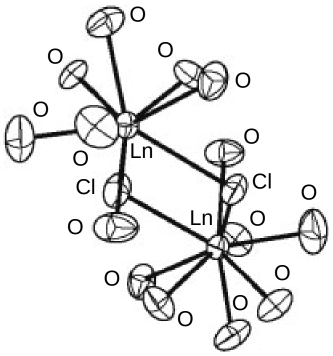

Figure 11 Structure of the dimeric cation $[(H_2O)_7LnCl_2Ln(H_2O)_7]^{4+}$

iodides of the heavier lanthanides. Study of the hydrated iodides has been difficult because of their deliquescence and their tendency to oxidation in air. Iodide does not coordinate to the metal in any of them. The iodides of the earlier lanthanides are $LnX_3{\cdot}9H_2O$ (Ln = La–Ho),[56] containing the familiar tricapped trigonal prismatic $[Ln(OH_2)_9]^{3+}$ ions, but the range of Ln–O distances is much smaller than in the triflates and ethylsulphates, falling in the range 2.552–2.576 Å for Ln = La and similarly between 2.403 and 2.405 Å for the Ho complex. Heavier lanthanides (Ln = Er–Lu) form $LnI_3{\cdot}10H_2O$, containing square-antiprismatic $[Ln(OH_2)_8]^{3+}$ ions. The little-known thiocyanates form hexa- and heptahydrates; heptahydrates contain $Ln(NCS)_3(H_2O)_6$ molecules (Ln = La–Dy) and hexahydrates have $Ln(NCS)_3(H_2O)_5$ (Ln = Sm–Eu) molecules, in each case the crystal containing one uncoordinated water molecule.

A number of hydrated sulfates exist. The nonahydrates of La and Ce have two distinct lanthanide sites, one nine-coordinate (six waters and three monodentatate sulfates) the other featuring 12-coordination (six waters and three bidentate sulfates). The other lanthanides form octahydrates with eight-coordination; the larger lanthanides also form pentahydrates such as $Nd_2(SO_4)_3{\cdot}5H_2O$ in which the metal is nine-coordinate (distorted trigonal prism) by seven sulfate oxygens and two water molecules.

The chloride, bromide, bromate, perchlorate, nitrate, acetate, and iodide salts are all soluble (the latter two types rather less than the others); the sulfates are sparingly soluble but the fluorides, carbonates, oxalates, and phosphates are insoluble.

3.7.3 *Aqua Ions*

The number of water molecules in the coordination sphere of the hydrated Ln^{3+} ion has been intensively studied for many years.[5] It now appears most probable that there is a change in coordination number from nine to eight for

$Ln(H_2O)_n^{3+}$ in mid-series, with the shape of the complex ion changing from tricapped trigonal prismatic nine-coordination for the lighter, larger, lanthanides to square-antiprismatic eight-coordination for the later metals, the changeover region (Sm to Tb) appearing to involve a mixture of eight- and nine-coordinate species. This view is based on information from a range of sources. A neutron-diffraction study of $Nd(ClO_4)_3$ and $Sm(ClO_4)_3$ in solution indicated coordination numbers of 9.0 and 8.5 respectively, with values of 7.9 for Dy and Lu, indicating that there are both eight- and nine-coordinate species present for samarium. EXAFS spectra (*see Extended X-ray Absorption Fine Structure*) of aqueous solutions of lanthanum perchlorate[57] are in close agreement with solid $[Ln(H_2O)_9]$ $(CF_3SO_3)_3$, suggesting a coordination number of 9 for La^{3+} (aq). In a study of chloride complexation by the lanthanides, EXAFS was used to determine hydration numbers of the aqua ions as 9.2 (La); 9.3 (Ce); 9.5 (Nd); 9.3 (Eu); 8.7 (Yb) and 9.7 (Y). Information from hydration studies of lanthanide ions by laser-induced fluorescence spectroscopy has been combined with other techniques to indicate a change in hydration number from 9 to 8 in the Eu–Tb region of the series. A luminescence study of lanthanide complexes reveals a linear correlation between the decay constant and the number of coordinated water molecules, used to calculate first coordination sphere hydration numbers of 9.0, 9.1, 8.3 and 8.4 for Sm^{3+}, Eu^{3+}, Tb^{3+}, and Dy^{3+}, respectively.

3.7.4 Complexes of Other O-Donor Ligands[4,5]

Complexes of ligands such as phosphine and arsine oxides were the first complexes of this type to be isolated from nonaqueous solvents. Among the studies of lanthanide halide complexes with these ligands, $[Ln(Ph_3PO)_5Cl]$ $(FeCl_4)_2$ (Ln = La–Nd, Sm–Er, Y) and $[Gd(Ph_3PO)_4Cl_2]$ $CuCl_3$ show that it is possible to pack several of these bulky ligands around a lanthanide. $YF_3{\cdot}0.5H_2O$ shows no signs of reaction with these ligands, but many complexes exist with other halides, most structurally confirmed examples involving yttrium, as in *trans*-$[YCl_2(Ph_3PO)_4]$ $Cl{\cdot}2.5EtOH{\cdot}H_2O$, *trans*-$[YBr_2(Ph_3PO)_4]$ $PF_6{\cdot}Et_2O$ and $[Y(Me_3PO)_6]$ Br_3, all with octahedrally coordinated yttrium. Other stoichiometries isolated include $[YX_3(Ph_2MePO)_3]$ (X = Cl, Br, I) and $[YCl(Ph_3PO)_5]$ $(SbCl_6)_2{\cdot}CeCl_3{\cdot}6H_2O$ reacts with Me_3PO in MeOH forming $[Ce(Me_3PO)_4Cl_3]{\cdot}4\ H_2O$; on slow crystallisation of a $MeNO_2$ solution in air, crystals of $[Ce(Me_3PO)_4(H_2O)_4]Cl_3{\cdot}3H_2O$ result, cerium having triangulated dodecahedral coordination.

A considerable number of nitrate complexes have been examined.[58] The precise experimental conditions can be very important in their synthesis; thus the reaction of $Y(NO_3)_3{\cdot}6H_2O$ with 1 or 2 mols of Ph_3PO in boiling EtOH gives $[Y(NO_3)_3(Ph_3PO)_2(EtOH)]$ whilst 4 of triphenylphosphine oxide gives $Y(NO_3)_3(Ph_3PO)_3$, and reaction with 6 mols of Ph_3PO in cold ethanol affords $Y(NO_3)_3(Ph_3PO)_4$, the latter being $[Y(NO_3)_2(Ph_3PO)_4]$ NO_3. Lanthanide nitrates react with excess Ph_3PO in acetone forming $[Ln(NO_3)_3(Ph_3PO)_4]$ (Ln = La–Nd) which are $[Ln(\eta^2\text{-}NO_3)_2(\eta^1\text{-}NO_3)(Ph_3PO)_4]$, but in solution ($Me_2CO$ or CH_2Cl_2) they dissociate into $[Ln(NO_3)_3(Ph_3PO)_3]$ (the only product of reaction in ethanol) and Ph_3PO. $[La(NO_3)_3(Ph_3PO)_3]{\cdot}CHCl_3{\cdot}EtOH$ has three bidentate nitrate groups. $[Ln(NO_3)_3(Ph_3PO)_3]$ are the only products for the nitrates of Sm–Gd. The later lanthanide nitrates (Tb–Lu) give crystals of $[Ln(NO_3)_3(Ph_3PO)_3]{\cdot}2\ Me_2CO$ in propanone, but $[Ln(NO_3)_2(Ph_3PO)_4]$ NO_3 in cold ethanol.

A number of $[Ln(NO_3)_3(Ph_3PO)_2(EtOH)]$ Ln = Ce, Nd, Sm, Eu) have also been confirmed. With the less bulky Ph_2MePO, $[Ln(\eta^2\text{-}NO_3)_3(Ph_2MePO)_3]$ are isolated for all lanthanides, and $[La(\eta^2\text{-}NO_3)_3(Ph_2MePO)_4]$, for La only. Ph_3AsO forms $[La(NO_3)_2(Ph_3AsO)_4]$ NO_3, $[La(NO_3)_3(Ph_3AsO)_3]$, and $[La(NO_3)_3(Ph_3AsO)_2(EtOH)]$. A range of complexes have been made for the even less demanding Me_3AsO, such as $[La(Me_3AsO)_6](NO_3)_3$, $[La(\eta^2\text{-}NO_3)_2(\eta^1\text{-}NO_3)(Me_3AsO)_4]$ and $[Eu(NO_3)_3(Ph_3AsO)_3]$.

Lanthanide triflates reacts with Ph_3PO in ethanol forming $[Ln(OTf)_2(Ph_3PO)_4]$ OTf (Ln = La, Nd, Er, Lu). The erbium and lutetium compounds have octahedral coordination, with monodentate triflates, but the complexes of the larger La and Nd have seven-coordination with one triflate being bidentate.

Using hexamethylphosphoramide ($(Me_2N)_3PO$) as a ligand, two series are obtained in which the stoichiometry is maintained across the series, $Ln(HMPA)_6(ClO_4)_3$ and $Ln(HMPA)_3Cl_3$; these are verified crystallographically for $[Nd(HMPA)_6](ClO_4)_3$ and *mer*-$[Ln(HMPA)_3Cl_3]$ (Ln = Pr, Yb). Apart from the direct reaction between the ligand and the appropriate metal salt, such complexes have been made by an unusual ‘one-pot’ synthesis[59] by heating the ligand, metal (e.g. La), and the appropriate ammonium salt together in toluene, leading to the isolation of nine-coordinate $La(HMPA)_3(NO_3)_3$, seven-coordinate $La(HMPA)_4(NCS)_3$ (Figure 12), and $La(HMPA)_4Br_3$. Isomorphous *fac*-$[LnCl_3(HMPA)_3]$ (Ln = La, Pr, Nd, Sm, Eu, Gd) have also been synthesised to set alongside the *mer*-isomers; the isomerisation can be followed in solution by NMR, and is believed to occur by an associative mechanism.[60]

The application of a solution of SmI_2 in hexamethylphosphoramide as a one-electron reductant in organic syntheses has led to numerous studies of samarium complexes of HMPA. $[SmI_3(HMPA)_4]$, prepared from Sm and CH_2I_2 in HMPA/thf, scavenges traces of water forming $[Sm(HMPA)_2(H_2O)_5]I_3{\cdot}2$ HMPA and $[Sm(H_2O)_4(HMPA)_3]I_3$, both with pentagonal bipyramidally coordinated samarium. Other such complexes reported are $[Sm(H_2O)_5(HMPA)_2]$ $I_3(HMPA)_2$, $[Sm(H_2O)_3(HMPA)_4]$ I_3, $[SmBr_3(HMPA)_2(thf)]$, $[SmBr_2(HMPA)_4]$ Br·thf, $[SmCl(H_2O)_4(HMPA)_2]$ Cl_2·thf, $[SmCl(HMPA)_5]$ $(BPh_4)_2$, $[Sm(O_3SCF_3)_2(HMPA)_4]$ (O_3SCF_3), $[Sm(O_3SCF_3)_3(H_2O)(HMPA)_3]$ and $[Sm(HMPA)_3(\eta^2\text{-}NO_3)_3]$.[61]

Seven-coordination (distorted pentagonal bipyramidal) is found in the complex of 2,6-dimethylpyrone, Er

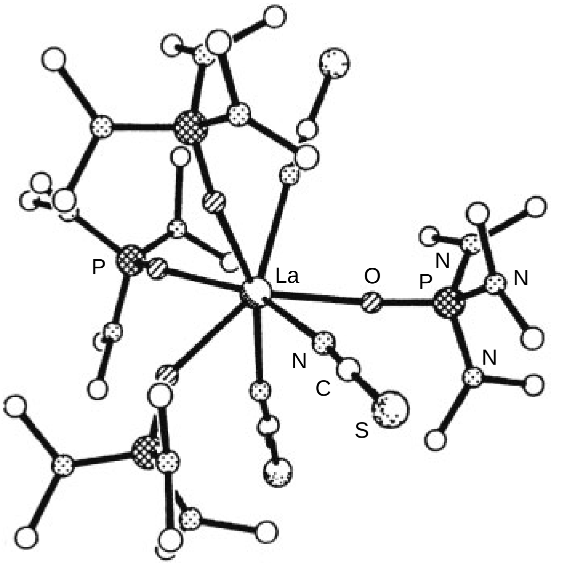

Figure 12 Structure of seven-coordinate $La(HMPA)_4(NCS)_3$

$(DMP)_7(ClO_4)_3$; with the earlier lanthanides this ligand forms $Ln(DMP)_8(ClO_4)_3$, presumably eight-coordinate.

Tetrahydrofuran complexes of the lanthanide chlorides are useful synthetic starting materials where a readily soluble form of the halide is needed, for example, in the synthesis of compounds such as alkoxides, aryloxides, alkylamides, and organometallics in general, though their stoichiometry can be uncertain owing to ready loss of the Lewis base. They are difficult to prepare from the hydrated chlorides; perhaps the best route is sonication of lanthanide powders and C_2Cl_6 in thf. There is a wide range of stoichiometry and structure,[59] with complexes $LnCl_3(thf)_x$ ($x = 2$, 2.5, 3, 3.5, 4) identified, and six different structure types confirmed. The compound actually isolated depends upon the reaction conditions, stoichiometry and the lanthanide concerned. Across the series, there is a decrease in coordination number from 8 (La) to 6 (Lu). Lanthanum is unique in forming $[LaCl_3(thf)_2]$ which is a single-stranded polymer ...$La(\mu\text{-}Cl)_3(thf)_2La(\mu\text{-}Cl)_3(thf)_2La$... with *cis*-thf molecules and square-antiprismatic eight-coordination of lanthanum. Compounds of the same stoichiometry, $[LnCl_3(thf)_2]$ are isolated for Ce–Nd, but have different structures, though again polymeric, in this case with seven-coordination ......$LnCl(thf)_2(\mu\text{-}Cl)_2LnCl(thf)_2(\mu\text{-}Cl)_2$ ...... chains. $[LnCl_3(thf)_4]$ have been isolated for Nd–Gd, and are monomeric seven-coordinate complexes, having pentagonal bipyramidal structures with two axial halides. Complexes with the nominal formula $[LnCl_3(thf)_{3.5}]$ are formed from Gd to Tm. These in fact have an ionic structure $[LnCl_2(thf)_5]^+$ $[LnCl_4(thf)_2]^-$, containing a seven-coordinate cation and octahedrally coordinated six-coordinate anion, both with trans-geometries. Ytterbium forms a dimeric $[Cl_2(thf)_2Yb(\mu\text{-}Cl)_2Yb(thf)_2Cl_2]$, whilst both ytterbium and lutetium form a monomeric octahedral *mer*-$[LnCl_3(thf)_3]$ (Ln = Yb, Lu) like scandium. Yttrium forms '$YCl_3(thf)_{3.5}$' and $YCl_3(thf)_2$, which has a chain structure with double chlorine bridges, having pentagonal bipyramidal coordination. Structures have been reported for many individual compounds and far-i.r. spectra of the complexes have been correlated with structural type.[62] Little is known about the bromides, though $Ln(THF)_4Br_3$ (Ln = La, Ce, Nd) are[63] seven-coordinate pentagonal bipyramidal like the corresponding chlorides and $YbBr_3(thf)_3$ has *mer*-octahedral coordination. Iodide complexes $LnI_3(thf)_4$ [Ln = La, Pr] and $LnI_3(thf)_{3.5}$ [Ln = Nd, Sm, Gd, Dy, Er, Tm, Y] are prepared by reaction of the powdered metal and I_2 in thf, followed by Soxhlet extraction. Only two structure types have been identified so far, $PrI_3(thf)_4$ again has a pentagonal bipyramidal structure, whilst $LnI_3(thf)_{3.5}$ [Ln = Nd, Sm, Gd, Y, Yb] have the 'ion pair' structure $[LnI_2(thf)_5][LnI_4(thf)_2]$ (pentagonal bipyramidal cation, octahedral anion) also familiar from the chlorides.[64]

Thiocyanate complexes have been synthesised by metathesis, from $LnCl_3$ and KNCS in thf, followed by filtering off the KCl. The formula, $Ln(NCS)_3(thf)_4$, applies across the series, but falling into two types. The ytterbium compound is a monomer, having a pentagonal bipyramidal structure with two axial thiocyanates. For earlier lanthanides, the same stoichiometry $Ln(NCS)_3(thf)_4$ obtains, but there is association by Ln···SNC-Ln bridges so lanthanides are in eight-coordinate square-antiprismatic coordination. Ln–S interactions are in region 3.10 Å (Nd) to 3.26 Å (Er), increasing in length as Ln gets smaller suggesting that the interaction weakens as steric crowding increases. These compounds have been obtained for all Ln from Pr to Er.[65] A few nitrate complexes, $[Pr(thf)_4(NO_3)_3]$ and $[Ln(thf)_3(NO_3)_3]$ (Ln = Ho, Yb) have been reported. Some complexes of multidentate ethers exist, such as $[LnCl_3(dme)_2]$, a series made of two families, $[LnCl_3(dme)_2]_2$, dimers with the structure $[Cl_2(dme)_2Ln(\mu\text{-}Cl)_2LnCl_2(dme)_2]$ (Ln = La–Nd), and monomeric $[LnCl_3(dme)_2]$ (Nd–Lu).[66]

Among dimethyl sulfoxide complexes of lanthanide nitrates; early lanthanide nitrates form 10-coordinate $Ln(DMSO)_4(NO_3)_3$ (Ln = La–Gd) while the heavier metals form $Ln(DMSO)_3(NO_3)_3$ (Ln = Tb–Lu, Y). Studies of these complexes in solution indicate that the coordination number depends on the size of the lanthanide, with coordination numbers of 10 for lanthanum, decreasing to eight for Yb–Lu and also upon the DMSO concentration. A similar decrease was found for perchlorate complexes in solution; solid $Ln(DMSO)_8(ClO_4)_3$ compounds, where the perchlorate does not coordinate, have been isolated.[67] The EXAFS spectra of $[Ln(dmso)_8]$ $(CF_3SO_3)_3$ in both the solid state and in dmso solution are very similar, indicating the same coordination geometry in both. Similar pyridine *N*-oxide complexes have been made; with $Ln(pyO)_8(ClO_4)_3$ there is a change in coordination geometry of the $Ln(pyO)_8$ moiety with increasing ionic

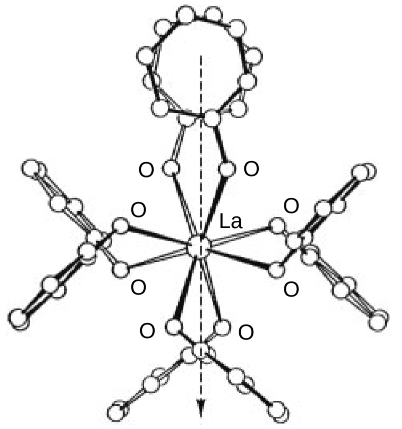

Figure 13 The structure of the $La(pyO)_8{}^{3+}$ ion

radius of the lanthanide, from square antiprismatic (Nd) to one intermediate between square antiprismatic and dodecahedral for the lanthanum compound (Figure 13).

3.7.5 Complexes of β-Diketones[68]

A wide variety of important complexes of *Diketones* (*see Diketones*), $Ln(R^1COCHCOR^2)_3$ has been synthesized and studied extensively. They came into prominence as *NMR Shift Reagents* in the early 1970s, but have subsequently found applications as precursors for high-temperature superconductors and chemical vapour deposition agents. The acetylacetonates (acac; R = Me) can be readily made from a lanthanide salt and the diketone with sodium hydroxide in a solvent such as methanol. They crystallize as hydrates, generally containing eight-coordinate $Ln(acac)_3(H_2O)_2$ (La–Ho, Y) (Figure 14) or seven-coordinate $Ln(acac)_3(H_2O)$ (e.g. Yb) molecules. The dihydrate of gadolinium is, however, reported to be a dimer. Some tri- and tetrahydrates are known, but these contain lattice water in addition to $Ln(acac)_3(H_2O)_2$ species (e.g. Eu, Ho). These water molecules can be hard to remove, and more sophisticated synthetic routes to β-diketonates in general begin with convenient starting materials like the oxides. The anhydrous acetylacetonates are not well defined, unlike the corresponding monomeric $M(acac)_3$ complexes formed by the d-block metals. The reasons for this are indicated in a careful study[69] of $Y(acac)_3$, which found that reaction of $[Y\{N(SiMe_3)_2\}_3]$ with Hacac gave hydrocarbon-soluble $[Y(acac)_3]_n$ (from NMR measurements, $n \sim 4$). Inadvertent hydrolysis on attempted slow crystallisation led to $[Y_4(OH)_2(acac)_{10}]$, a molecule with a diamond shaped Y_4 core, having μ_4-OH groups above and below the plane, and each acac terminal, affording eight-coordinate Y. Controlled vacuum thermolysis (85 °C)

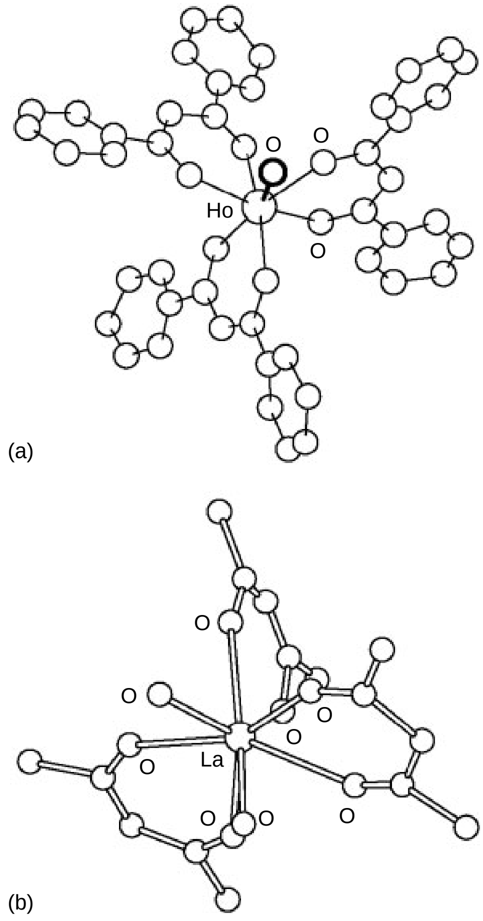

Figure 14 (a) The structure of $Ho(PhCOCHCOPh)_3(H_2O)$. (b) The structure of $La(acac)_3(H_2O)_2$

of $[Y(acac)_3(H_2O)_3]$ gives a product that can be crystallised from benzene to form $[Y_4(OH)_2(acac)_{10}]\cdot C_6H_6$. It is believed that hydrogen-bonding between water molecules and acac oxygens in $[Y(acac)_3(H_2O)_3]$ leads to the loss of acacH on thermolysis. In contrast, complexes of a bulkier ligand such as tmhd (dpm; R = t-Bu) readily form anhydrous $Ln(tmhd)_3$ which sublime in vacuo at 100–200 °C and are monomers in solution; they can be separated by gas chromatography. In the solid state they exist as dimers with seven-coordinate metals (La–Dy) and octahedral monomers (Dy–Lu, Y; trigonal prismatic coordination) which do hydrate readily (cf. capped trigonal prismatic $Dy(dpm)_3(H_2O)$).

A similar pattern of decreasing coordination number with decreasing ionic radius is found in complexes of 2,2-dimethyl-6,6,7,7,7,8,8,8-heptafluorooctane-2,4-dione (fod). Thus $Pr(fod)_3\cdot H_2O$ is in fact dimeric, $[Pr_2(fod)_6(H_2O)]\cdot H_2O$, with eight-coordination completed by a bridging water, whereas $Lu(fod)_3\cdot H_2O$ is a seven-coordinate monomer. As prepared, the complexes are hydrates but can be dehydrated in vacuo and are volatile at 180–260 °C (though they do

rehydrate avidly); trifluoro- and hexafluoroacetylacetonates are likewise generally obtained as hydrates which can be dehydrated in vacuo. Because the Ln(diketonate)$_3$ complexes are coordinatively unsaturated, they, as already noted, tend to complete their coordination sphere by forming adducts with Lewis bases, of which the hydrates have already been noted. For this reason, paramagnetic diketonates, especially some of the dpm and fod chelates, are of importance as NMR shift reagents (see Section 'β-Diketonates as NMR Shift Reagents[70–72]').

In addition to the neutral tris complexes, anionic [Ln(diketonate)$_4$]$^-$ species have been isolated for some of the less bulky ligands, such as antiprismatic [Eu(PhCOCHC OPh)$_4$]$^-$.

β-Diketonates as NMR Shift Reagents[70–72]. Paramagnetic lanthanide β-diketonate complexes produce shifts in the NMR spectra of Lewis base molecules capable of forming adducts with them and are thus often referred to as lanthanide shift reagents (LSR), although all paramagnetic lanthanide complexes can exhibit shifted resonances. The initial report (1969) concerned the ability of Eu(dpm)$_3$py$_2$ to induce considerable low-field shifts in the H spectrum of cholesterol; the magnitude of the proton shifts depended upon the distance of the proton from the site of coordination to the lanthanide ion. Subsequently it was realized that the diketonate complexes themselves were more effective than the pyridine adducts and that other lanthanide ions (e.g. Pr) could produce shifts in the opposite direction. Immense activity in this area resulted as the use of LSRs enabled simplification of the spectra of organic molecules (frequently to first order) without the use of high-frequency spectrometers. The spreading out of the spectrum and differential nature of the shifts removed degeneracies and overlaps while study of the shifts, particularly when more than one LSR was used, permitted spatial assignment of the protons (or other resonant nucleus) with concomitant structural information about the organic molecule.

Thus, to give but one example (Figure 15), the aromatic region of the proton NMR spectrum of benzyl alcohol is a singlet at 100 MHz, but on addition of Eu(dpm)$_3$, which coordinates at the OH group, the aromatic protons are shifted by amounts varying with their distance from the coordination site and become amenable to first-order analysis.

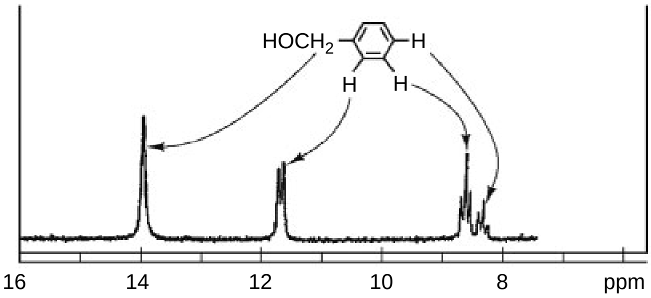

Figure 15 The proton NMR spectrum of benzyl alcohol in the presence of Eu(dpm)$_3$ (0.39 mol). (Reproduced by permission of The Royal Society of Chemistry from J.K.M. Sanders and D.H. Williams, *Chem. Commun.*, 1970, 422)

The lanthanide induced shifts (LIS) arise from the interaction of the magnetic nucleus with the magnetic field of the paramagnetic lanthanide ion. This could arise via two mechanisms: either a 'pseudocontact' (dipolar) through-space fashion involving a dipole–dipole interaction, or by a 'contact' mechanism with delocalization of unpaired spin density from the lanthanide f-orbitals via the lanthanide–substrate bond on to the organic molecule; the former is more important.

Adducts of Diketonates. Because of their involvement in NMR shift reagents, there has been considerable interest in the stoichiometry of the adducts formed between the diketonate complex and the Lewis base. Both 1:1 and 1:2 adducts are possible, the stoichiometry dependent upon the bulkiness of both the diketonate ligand and also upon that of the ligand. Since the species isolated in the solid state may not be the most abundant species in solution, complementary studies are necessary. Thus the M(fod)$_3$ chelates (Pr, Eu) have been found to form 1:1 and 1:2 adducts with a range of Lewis bases (even bulky ones like 2,4,6-Me$_3$py) in solution. The bulkier dpm chelates give isolable 2:1 adducts with pyridine and propylamine (Eu), but with the bulkier 3-picoline, only a 1:1 complex is isolated (Lu). Careful studies of Ho(dpm)$_3$ in solution have only given evidence for 1:1 adducts with bulky ligands such as triphenylphosphine oxide, camphor, and borneol. Some of the adducts vaporize unchanged; thus Ln(hfac)$_3$(Bu$_3$PO)$_2$ can be separated by gas chromatography. Adducts with polyethers have been studied as possible precursors for *Chemical Vapour Deposition* (*see Chemical Vapor Deposition*) as they often exhibit high volatility and good thermal stability. Thus La$_2$O$_3$ and Hhfac react together with tetraglyme in hexane forming [La(hfac)$_3$(tetraglyme)], an air-stable and volatile (95 °C, 10^{-4} mm Hg) substance.

Crystal structures have been determined for many of the adducts. Eu(acac)$_3$(phen) is antiprismatic, but Nd(ttfa)$_3$(Ph$_3$PO)$_2$, Eu(dpm)$_3$(py)$_2$, and Ho(dpm)$_3$(4-picoline)$_2$ are dodecahedral. Of the seven-coordinate adducts, Lu(dpm)$_3$(3-picoline) is a side-face capped trigonal prism and Eu(dpm)$_3$(quinuclidine) a capped octahedron. With the tridentate ligand terpyridyl, nine-coordination is possible as in Eu(dpm)$_3$(terpy); Pr(facam)$_3$(DMF)$_3$ is also nine-coordinate. What may be another case of nine-coordination are the acetylacetonate complexes Ln(acac)$_3$(Ph$_3$PO)$_3$ (Ln = Nd, Sm, Eu, Tb, Dy, Ho).

The geometric differences between one structure and another are often small, and a similar comment may also be made about the energy differences between one structure and another (e.g. square antiprismatic–dodecahedron). The structure adopted for an adduct in the solid state may be different to the one adopted in solution. The assumption of time-averaged axial symmetry for the monoadducts in solution

in the interpretation of shifted NMR spectra seems frequently to be justified; however, study of bis adducts of substituted pyridines with $Ln(dpm)_3$ indicate biaxial magnetic anisotropy.

3.7.6 Carboxylates[73]

Carboxylate complexes of the lanthanides differ from those of many trivalent transition metals in that they do not adopt oxo-centered structures with M_3O cores. The hydrated acetates have a long history, with the first examples reported by Cleve in 1874; they can be synthesized by dissolving the oxides in acetic acid and the anhydrous compounds obtained by azeotropic distillation.

Anhydrous $[La(OAc)_3]$ has 10-coordinate La, involving both chelating and bridging acetates (the latter having one oxygen bound to two different lanthanum ions and the second oxygen just bound to one); the Ce analogue is isostructural. Both 9 and 10-coordinate praseodymium are found in $Pr(OAc)_3$; like $La(OAc)_3$, this has a three-dimensional network structure, whereas for the later metals $Ln(CH_3COO)_3$ adopt chain structures. Holmium acetate adopts a structure shared with other $Ln(OAc)_3$ (Ln = Sm–Er, Y); Ho occupies two slightly different eight-coordinate sites, whilst $Ln(OAc)_3$ (Ln = Tm–Lu) have the structure exemplified by $Lu(CH_3COO)_3$, in which Lu is seven-coordinate. On heating, both these structures change to the six-coordinate $Sc(CH_3COO)_3$ structure, this drop in coordination number being accompanied by an acetate group switching to a symmetrical bridging mode.[74]

Among the hydrated lanthanide acetates, mono- and sesquihydrates are found for the early metals (La–Nd); the heavier metals (from Nd) tend towards tetrahydrates, but some trihydrates are known (e.g. Eu, Tm) though for any given lanthanide there may be two or more phases with nearly equal stabilities under ambient conditions. The sesquihydrates $[Ln(CH_3COO)_3{\cdot}1.5H_2O]$ (Ln = La–Pr) have structures with acetate-bridged chains cross-linked by further acetate bridges; the lanthanides being 9 and 10-coordinated by bridging and chelating acetates. Monohydrates $[Ln(CH_3COO)_3{\cdot}H_2O]$ (Ln = Ce–Nd) have one-dimensional polymeric structures with acetate bridges, the lanthanides being 9-coordinate in this case, whilst the tetrahydrates $[Ln(CH_3COO)_3{\cdot}4H_2O]$ (Ln = Sm–Lu) are acetate-bridged dimers, the lanthanides again being 9-coordinate. The bridging acetate groups in these compounds are often asymmetric, featuring one oxygen being bound to two lanthanide ions and the other oxygen bound to one lanthanide (this mode of bonding is common in lanthanide carboxylates). Among other carboxylates, $Pr(C_3H_7COO)_3{\cdot}3H_2O$ contains two distinctly different praseodymium sites. Each Pr is coordinated by four bidentate bridging carboxylates; additionally one is bound to three water molecules, the other is additionally bound to two bidentate propionates. $Nd(C_3H_7COO)_3(H_2O)$ has a zigzag chain structure containing 9-coordinate neodymium in capped square-antiprismatic coordination, there being two different neodymium sites. One neodymium is bound to four bridging tridentate carboxylates and one bridging bidentate group, as well as to two waters; the other neodymium is coordinated to four bridging tridentate carboxylates, one bridging bidentate carboxylate, and one chelating carboxylate. $[Ln(CF_3COO)_3{\cdot}3H_2O)]$ (Ln = La, Ce) are two-dimensional polymers containing eight-coordinate lanthanides, whilst $[Ln(CF_3COO)_3{\cdot}3H_2O]$ (Ln = Pr–Lu) have seven-coordinate lanthanides in dimeric units with four bridging carboxylates. $[La(CCl_3COO)_3{\cdot}5H_2O]$ and $[Ce(CCl_3COO)_3{\cdot}3H_2O]$ are linear one-dimensional polymers with nine and eight-coordinate lanthanides respectively. $[Ln(CCl_3COO)_3{\cdot}2H_2O]$ (Ln = Pr–Lu) are also linear polymers with a bridging water molecule rather than just carboxylate bridges. In these compounds the carboxylate groups act as bridging bidentate ligands or as terminal monodentate groups. Anhydrous europium methacrylate, $[Eu(H_2C{=}C(Me)CO_2)_3]$, has a chain structure in which Eu is eight-coordinate, one carboxylate acting as a bidentate bridging ligand and the other two also bridging, but with one oxygen bound to two europiums, the familiar chelate-bridging mode. Both this compound and the acrylates $[Ln(H_2C{=}CHCO_2)_3]$ (Ln = Eu, Tb) undergo radical-induced polymerisation.

Carbonate complexes are increasingly studied because of their importance in mobilising the actinides in the environment; lanthanide complexes are nonradioactive models for the later actinides. The first mononuclear lanthanide carbonate complex to be structurally characterised was $[N(CH_2)_3]_5[Nd(CO_3)_4]$. On the other hand, $[Co(NH_3)_6][Sm(CO_3)_3(H_2O)]{\cdot}4H_2O$ has anions linked in a zigzag chain structure with μ-η^2-η^1 carbonate bridges affording nine-coordinate samarium. Similar bridges are found in the one-dimensional chains in $[Co(NH_3)_6]_6$ $[K_2(H_2O)_{10}]$ $[Nd_2(CO_3)_8]_2{\cdot}20H_2O$, formed on mixing solutions of $[Co(NH_3)_6]Cl_3$, $Nd(NO_3)_3$ and K_2CO_3.

The oxalates are very insoluble, affording quantitative precipitation of the lanthanide, a fact made use of in traditional quantitative analysis; on ignition, they are obtained as the oxide, the weighing form. In the solid state, structures show eight-coordination in the hexahydrates and nine-coordination in the nonahydrates such as $Nd_2(C_2O_4)_3{\cdot}9H_2O$.

Structures of the dialkylcarbamates $[Ln_4(O_2CNPr^i_2)_{12}]$ (Ln = Nd, Gd, Ho, Yb) indicate a steady contraction in Ln–O distances, averaging 14%, across the lanthanide series.

3.7.7 Nitrate Complexes

Nitrate complexes are of historical importance for their role in separation of the early lanthanides by fractional crystallization, when magnesium double nitrates, $Mg_3Ln_2(NO_3)_{12}{\cdot}24H_2O$, were used. These complexes contain 12-coordinate $[Ln(NO_3)_6]^{3-}$ groups, also found in some crown ether complexes. Other nitrate complexes characterized include 10-coordinate $[Ln(NO_3)_5]^{2-}$, as salts with counterions

like Ph_4As and Me_4N. Both these types of complex are characterized across the lanthanide series.

3.7.8 *Complexes of Crown Ethers*[75,76]

Crown ether (*see Crown Ethers*) complexes represent a very important area of lanthanide coordination chemistry that has undergone considerable development in recent years (*see Crown Ethers*). In contrast to the alkali metals, the lanthanides do not form such complexes readily in aqueous media, owing to the considerable hydration energy of the lanthanide ion, but are readily synthesized by operating in nonaqueous solvents. Complexes are obtained both with and without direct lanthanide-crown ether bonds as when $[Ln(NO_3)_3(H_2O)_3]$ is encapsulated by 18-crown-6. The choice is determined by the match between the size of the central cavity in the crown ether ring and the size of the lanthanide ion. Many of the studies have been made with lanthanide nitrate complexes, with the concomitant consequence of high coordination numbers in the resulting complexes on account of the proclivity for bidentate nitrate coordination. Thus 12-coordination is found in $La(NO_3)_3$(18-crown-6) (Figure 16), 11-coordination in $Eu(NO_3)_3$(15-crown-5), and 10-coordination in $Eu(NO_3)_3$(12-crown-4).

In addition to the 1:1 complexes, some other stoichiometries have been obtained; thus Nd(18-crown-6)$_{0.75}$ $(NO_3)_3$ is actually [Nd(18-crown-6)$(NO_3)_2]_3[Nd(NO_3)_6]$ with 10-coordination in the cation and 12-coordination in the anion.

The first crown ether complexes to be made were usually with lanthanide nitrates; when crown ethers complex with lanthanide nitrates, the two ligands generally combine to saturate the coordination sphere, but since chloride is a monodentate ligand, coordinative saturation is not always achieved that way and indeed chlorides are frequently displaced from the coordination sphere by water. Thus 12-crown 4 tends to give complexes of the type $[Ln(H_2O)_5$(12-C-4)] $Cl_3 \cdot 2H_2O$ (Ln e.g. Er) and $[LnCl_2(H_2O)_2$(12-C-4)] $Cl \cdot 2H_2O$ (Ln e.g. Nd) but coordinating ability is affected by the presence of water and other solvents. The crown ether does not coordinate to the lanthanide at all in $[Lu(H_2O)_8]$ 1.5(12-C-4)$\cdot 2H_2O$, instead forming hydrogen bonds to coordinated water molecules. With the larger lanthanum ion, $[LaCl_3$(12-crown-4)(MeOH)] is eight-coordinate, owing to a molecule of solvent coordinating. 18-crown-6 forms two series of complexes with lanthanide chlorides $[LnCl(H_2O)_2$(18-crown-6)]$Cl_2 \cdot 2H_2O$ (Ln = Pr–Tb) and $[LnCl_2(H_2O)$ (18-crown-6)]$Cl \cdot 2H_2O$ (Ln = La, Ce) although, depending upon conditions, $[LnCl_3$(18-crown-6)] can also be made. Its inability to form complexes with the chlorides of the smaller lanthanides is ascribed to a lack of flexibility found in polyethylene glycols, which can. By modifying conditions, different complexes can be isolated; thus in MeCN/MeOH, neodymium chloride and 15-crown-5 react to afford complexes where $[Nd(H_2O)_9]^{3+}$ and $[NdCl_2(H_2O)_6]^+$ ions are hydrogen-bonded to the crown ether, without direct lanthanide–crown ether bonding. However, by electrocrystallization the anhydrous eight-coordinate complex Nd(15-crown-5)Cl_3 with neodymium–crown ether bonding is obtained (Figure 17).

Unusually, chloride is found in the first coordination sphere of lanthanum as well as nitrate in the serendipitously discovered mixed anion complexes $[LaCl_2(NO_3)$(12-crown-4)$]_2$ and $[LaCl_2(NO_3)$(18-crown-6)]. A few complexes have been reported with other halides, such as $[SmI_3$(dibenzo-18-crown-6)] (tricapped trigonal prismatic) and $[LaBr_3$(12-crown-4)(acetone)] (distorted square antiprismatic). Lanthanide thiocyanate complexes of crown ethers are now starting to be studied. Several thiocyanate complexes of the

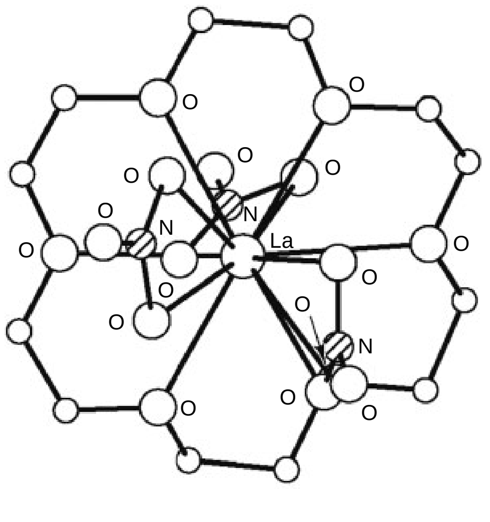

Figure 16 The structure of $La(NO_3)_3$(18-crown-6)

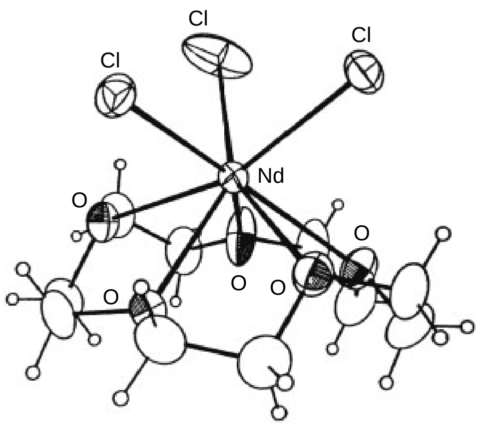

Figure 17 The structure of $NdCl_3$(15-crown-5)

tetradentate 13-crown-4 have been isolated in [Ln(NCS)$_3$(13-crown-4)(H$_2$O)$_2$] (Ln = La, Pr–Tb, Er–Yb) whilst lanthanum is 10-coordinate in [La(NCS)$_3$(18-crown-6)(dmf)] In the compounds [Ln(dibenzyldiaza-18-crown-6)(NCS)$_3$] (Ln = Ce, Nd, Eu), the lanthanide is bound to two nitrogens and four oxygens in the crown ether as well as three N-bonded thiocyanates. The CeN$_3$ (NCS) moiety exists as a trigonal planar arrangement at the centre of the macrocycle cavity with the trigonal plane perpendicular to the plane of the macrocycle. Steric factors can be important in complexation. Thus only the lighter, larger, lanthanides form stable complexes with 18-crown-6. Small crowns such as 12-crown-4 give 2:1 complexes with lanthanide perchlorates, although these are not obtained with lanthanide nitrates where the anion can readily coordinate.

Crown ethers have been used to stabilise alkyl complexes, in the form of [Ln(CH$_2$SiMe$_3$)$_3$(12-crown-4)] (Ln = Sc, Y, Sm, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu); structures of the Y and Lu complexes show facial coordination of the crown ether to the neutral lanthanide trialkyl unit. The cationic species [Ln(CH$_2$SiMe$_3$)$_2$(CE)(thf)$_n$]$^+$ [B(C$_6$X$_5$)$_3$(CH$_2$SiMe$_3$)]$^-$ (CE = [12]-crown-4, n = 1; CE = [15]-crown-5, [18]-crown-6, n = 0) have also been made.

Comparative studies between crown ethers and the noncyclic glymes (linear polyethers) suggest that glyme complexes are favoured, the chelate effect is thus more important than the macrocyclic effect. The ability of polyethylene glycols and glymes to wrap themselves round a lanthanide ion irrespective of size, and to accommodate water molecules and other small ligands (e.g. anions) more easily, makes them more flexible coordinating agents than crown ethers and giving a more favorable enthalpy change. Solubility effects may play a part too! The factors affecting the complexes formed by LnX$_3$, Ln(NCS)$_3$ and Ln(NO$_3$)$_3$ with polyethylene glycols have been examined; the chain length is the main factor controlling the coordination sphere and thus the number of additional inner-sphere ligands present. Pentaethylene glycol forms two series of nine-coordinate complexes with lanthanide chlorides, [LnCl$_2$(H$_2$O)(EO5)]Cl·2H$_2$O (Ln = La–Pr) and [Ln(H$_2$O)$_3$(EO5)]Cl$_3$·H$_2$O (Ln = Sm–Lu, Y). [Ln(EO3)$_3$]Cl$_3$ (Ln = Pr, Nd) are nine-coordinate, as are the lanthanides in [Ln(EO2)$_3$] (ClO$_4$)$_3$·3H$_2$O (Ln = Nd, Ho), whilst the lanthanide is 11-coordinate in [Nd(EO4)(NO$_3$)$_3$]. Cerium is nine-coordinate in [Ce(NCS)$_3$(EO4)(H$_2$O)].

Other significant complexes of this type, containing one or more lanthanides, are formed by calixarenes (*see Calixarenes*).[77,78] Much of this work has been prompted by their potential in separating lanthanides from uranium and other metals. A calixarene ligand with two amide substituents has been synthesised as an extractant for lanthanides; dimeric Sm and Eu and monomeric Lu complexes have been prepared. Another calixarene, with four phosphine oxides attached, has been fixed to silica particles and the resulting system has been found to give very efficient extraction of Eu^{3+} and Ce^{3+} from simulated waste. A calix[4]arene complex of Gd^{3+} binds noncovalently to human serum albumin and is a potential MRI contrast agent.

3.7.9 *Halide Complexes*[79]

Complexes with all the halides have been prepared, but the chlorides and particularly the fluorides are most stable and best characterized. The fluorides ALnF$_4$, A$_2$LnF$_5$, and A$_3$LnF$_6$ are known (A = alkali metal). The tetrafluoro complexes NaLnF$_4$ exist in two phases, the high-temperature form having eight-coordinate lanthanide (fluorite structure) while tricapped trigonal prismatic nine-coordination is found in the low-temperature form. Some hexafluoro complexes have the cryolite structure.

Six-coordinate chloride complexes Cs$_2$NaLnCl$_6$ with the cubic elpasolite structure have been made by fusion; the Ln^{3+} ions on the highly symmetric cubic sites exhibit very weak f–f transitions in their electronic spectra. (NH$_4$)$_3$YCl$_6$ and A$_3$LnCl$_6$ (Ln = Tb–Lu, Y) can be made similarly. Other hygroscopic complexes of the type (Ph$_3$PH)$_3$LnX$_6$ and (pyH)$_3$LnX$_6$ (X = Cl, Br, I) can be made by solution methods; the iodides are unusual and rather unstable. Octahedral YbCl$_6^{3-}$ units are found in (MeNH$_3$)$_4$YbCl$_7$. Compounds M$_2$LnCl$_5$ contain chains based on LnCl$_6$ octahedra sharing *cis* corners (X-ray for Cs$_2$DyCl$_5$; Ln = Y, heavy lanthanide). A different type of shared octahedra is found in a number of compounds M$_3$Ln$_2$X$_9$, where face sharing of octahedra obtains. A number of chlorides have been made (M = K or Cs) as well as several bromides and iodides such as Cs$_3$Y$_2$X$_9$ and Cs$_3$Er$_2$I$_9$.

3.7.10 *Complexes of N-Donor Ligands*[4,5]

Although pyridine and other amine-type ligands form adducts with lanthanide diketonates, few other lanthanide complexes have been made. However, the first homoleptic lanthanide ammine complexes, [Yb(NH$_3$)$_8$] [Cu(S$_4$)$_2$]·NH$_3$, [Yb(NH$_3$)$_8$] [Ag(S$_4$)$_2$]·2 NH$_3$, and [La(NH$_3$)$_9$] [Cu(S$_4$)$_2$], have been synthesised by reactions in aqueous ammonia.[80]

Direct reaction of the lanthanide halides with pyridine gives pyridine complexes of the lanthanides, with the synthesis of [YCl$_3$py$_4$] and [LnCl$_3$py$_4$]·0.5py (Ln = La, Er). These all have pentagonal bipyramidal structures, with two chlorines occupying the axial positions.[81] [MI$_3$py$_4$] (M = Ce, Nd) have also been reported. Various complexes of N-methylimidazole (N-Meim) have been made, [SmI$_3$(thf)$_3$] reacts with N-Meim forming square-antiprismatic [Sm(Meim)$_8$]I$_3$, whilst [YX$_2$(N-Meim)$_5$]$^+$X$^-$, (X = Cl, Br); [YCl$_2$(N-Meim)$_5$]$^+$ [YCl$_4$(N-Meim)$_2$]$^-$ and [Ce(NO$_3$)$_3$(N-Meim)$_4$] have also been prepared.

A number of MeCN complexes [Ln(MeCN)$_n$] X$_3$ have been made, with routes including the reaction of LnCl$_3$ with AlCl$_3$ in MeCN; reaction of the labile complexes La(OSO)$_x$(AsF$_6$)$_3$ with MeCN; and ultrasonication of mixtures of the lanthanide metal with AlCl$_3$ and MeCN in C$_2$Cl$_6$.

Structures of $[La(MeCN)_9]$ $(AsF_6)_3{\cdot}MeCN$; $[Sm(MeCN)_9]$ $(AsF_6)_3{\cdot}3MeCN$; $[Ln(MeCN)_9]$ $(AlCl_4)_3{\cdot}MeCN$ (Ln = Pr, Sm) and $[Yb(MeCN)_8]$ $(AlCl_4)_3$ are all known, the $[Ln(MeCN)_9]^{3+}$ ions having the familiar tricapped trigonal prismatic coordination of the lanthanide.[82]

The best studied monodentate N-donor is the thiocyanate ion, recent extensive studies[83] by Japanese workers showing it to participate in complexes with an interesting variety of stoichiometry and coordination geometry dependent upon counterion, solvent, and so on. They comprise $(Bu_4N)_3[M(NCS)_6]$ (M = Y, Pr–Yb) and $(Et_4N)_3[M(NCS)_6]{\cdot}$benzene (M = Er, Yb) with octahedrally coordinated lanthanide; $(Et_4N)_4[M(NCS)_7]{\cdot}$benzene (M = La, Pr with capped trigonal prismatic geometry) and $(Me_4N)_4[M(NCS)_7]$, (M = Dy, Er, Yb; pentagonal bipyramidal coordination); $(Et_4N)[M(NCS)_4(H_2O)_4]$ (M = Nd, Eu) and $(Me_4N)_3[M(NCS)_6(MeOH)(H_2O)]$ (M = La–Dy, Er), all square antiprismatic; $(Et_4N)_4[M(NCS)_7(H_2O)]$ (M = La–Nd, Dy, Er; cubic); and $(Me_4N)_5[M(NCS)_8]{\cdot}$benzene (M = La–Dy), intermediate between square antiprism and cubic.

A considerable number of complexes have been made using bidentate 1,10-phenanthroline, 2,2′-bipyridyl and similar ligands. Usually (but not invariably) phen and bipy form complexes with similar formulae and structures. Reaction of the hydrated lanthanide nitrate and the ligand in ethanol give complexes $LnL_2(NO_3)_3$ (L = phen, bipy), which have been studied in more detail than the others; both series are isomorphous throughout,[84] so all appear to possess 10-coordinate structures (Figure 18) with all nitrates present as coordinated bidentate groups (X-ray diffraction, L = bipy, Ln = La, Pr, Nd, Eu, Lu, Y; L = phen, Ln = La, Pr, Nd, Sm, Eu, Gd, Dy, Lu, Y) with a geometry approximating to a bicapped dodecahedron.[85] In the solid state, the individual complex molecules of $[Ln(phen)_2(NO_3)_3]$ associate by $\pi - \pi$ stacking into one-dimensional chains which themselves arrange into pseudo 1D close-packed patterns. Several tris complexes, $M(bipy)_3(NO_3)_3$, have been synthesised in a water-ethanol mixture, the Nd complex being shown to be $Nd(bipy)_2(NO_3)_3{\cdot}$bipy. In the presence of 15-crown-5, lanthanum nitrate reacts with bipy in MeOH-MeCN forming $[La(bipy)(NO_3)_3(H_2O)_2(MeOH)]{\cdot}$15-crown-5, which has 11-coordinate lanthanum. The presence of the coordinated MeOH molecule supplies a fifth hydrogen atom so that hydrogen bonds can be formed to all the crown ether oxygens. In another synthesis in the presence of a crown ether, a 10-coordinate complex, $[La(bipy)(NO_3)_3(H_2O)_2]{\cdot}$benzo-15-crown-5, is obtained. A complex of composition $La(phen)_4(NO_3)_3{\cdot}3H_2O$ is in fact $[La(phen)_2(H_2O)_2(NO_3)_2]{\cdot}NO_3$. 2 phen.$H_2O$ with intermolecular $\pi - \pi$ stacking (a phenomenon which is quite common in phen complexes of the lanthanides).

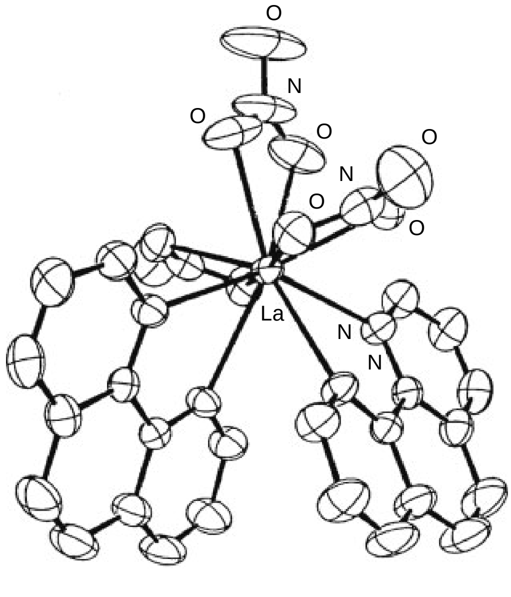

Figure 18 The structure of $La(phen)_2(NO_3)_3$

An extremely wide range of both 1:1 and 2:1 complexes of lanthanide chlorides with bipy and phen have lately received detailed and extensive crystallographic study.[86] For the 1:1 complexes of early lanthanides (La, Pr), the tendency seems to be for the formation of neutral complexes containing all available chloride ions, often binuclear in composition, usually containing at least two solvent molecules per lanthanide. By later in the series, mononuclear species tend to become more normal, and chloride ions are often excluded from the coordination sphere by solvent molecules. In the case of the 2:1 complexes, nine-coordination is possible at the start of the series in $[(bipy)_2Ln(OH_2)_4Cl]Cl_2{\cdot}2H_2O$, whilst by the end of the series ytterbium is seven-coordinate in $[(bipy)_2YbCl_3]$. M–N bond lengths contract from 2.724–2.787 Å in the lanthanum compound to 2.439–2.479 Å in the ytterbium compound. The situation has been described as 'a multidimensional jigsaw puzzle which still requires a great deal of work for its complete description'. Bipyridyl complexes of known structure include $[(bipy)_2Cl_2La(\mu\text{-}Cl)_2LaCl_2(bipy)_2]{\cdot}$EtOH, $[(bipy)_2Pr(OH_2)Cl_3]{\cdot}0.5$EtOH, $[(bipy)_2Ln(OH_2)Cl_3]{\cdot}$EtOH (Ln = Nd, Eu) $[(bipy)Ln(OH_2)_6]Cl_3$ (Ln = Ho–Lu, Y), and $[(bipy)_2YbCl_3]$.; phen complexes include $[(phen)_2Ln(OH_2)Cl_3]{\cdot}$MeOH (Ln = La, Pr, Nd, Eu), $[(phen)_2La(OH_2)_5]Cl_3{\cdot}$phen${\cdot}4H_2O$ and $[(phen)_2Lu(OH_2)_4]Cl_3{\cdot}2H_2O$. An apparent 3:1 complex, $La(phen)_3Cl_3{\cdot}9H_2O$ has been shown to be $[La(phen)_2(OH_2)_5]Cl_3{\cdot}4H_2O{\cdot}$phen; the ability of phen molecules to be held in lattice sites by $\pi - \pi$ interaction with coordinated phenanthroline molecules is not uncommonly encountered. Complexes with lanthanide bromides do not seem to have received attention, but one iodide complex, $[CeI_3(bipy)_2(py)]{\cdot}5py{\cdot}$bipy has been reported.

The thiocyanate complexes $Ln(phen)_3(NCS)_3$ (Ln = Pr, Nd) and $Pr(bipy)_3(NCS)_3$ are all nine-coordinate monomers.[85,87] A considerable number of bipy (and phen) adducts of lanthanide dithiocarbamates $[Ln(S_2CNR_2)_3(L)]$

have been synthesised, usually by one-pot syntheses involving a lanthanide salt, NaS_2CNR_2 and the neutral ligand. The interest here is in the potential of these compounds as precursors to lanthanide sulphides. Monomeric 8 coordinate structures are confirmed for $[Ln(S_2CNEt_2)_3(bipy)]$ (Ln = Pr, Sm, Eu, Er)[85] and $[Ln(S_2CNEt_2)_3(phen)]$ (Ln = Sm, Eu, Yb). $[Eu(L)(S_2PBu^i_2)_3]$ (L = phen, bipy) have also been made.

Carboxylate complexes are frequently dimeric. Thus $Lu(O_2CCH_3)_3\cdot(phen)\cdot H_2O$ is dinuclear $[(phen)(CH_3COO)Lu(\mu\text{-}O_2CCH_3)_4Lu(CH_3COO)(phen)]$. The terminal acetate groups are symmetrically bidentate; two of the bridging acetates are symmetrical, the other pair bridging in such a way that one of the two oxygens is bound to both lutetiums and the other is bound only to one lutetium. Similarly, $Ln(OAc)_3\cdot phen$ (Ln = Gd, Ce) are $[(AcO)(phen)Ln(\mu\text{-}OAc)_4Ln(phen)(OAc)]$ with two types of bridging acetate. The cerium compound gives a triplet EPR (*see Electron Paramagnetic Resonance*) spectrum at 4.2 K, showing an appreciable bridging interaction between the two ceriums ($D = 0.21\,cm^{-1}$); magnetic measurements to low temperatures on both compounds confirm weak interactions between the two metal ions. $[\{Pr(O_2CCMe_3)_3(bipy)\}_2]$ has two bidentate bridging and two tridentate cyclic bridging carboxylates; praesodymium is nine-coordinate.

The only complex with a non coordinating anion to be characterised fully is $[Ce(phen)_4(MeCN)_2]\ (ClO_4)_3\cdot 3MeCN$, which has 10-coordinate cerium in a bicapped square-antiprismatic geometry.

Another bidentate ligand whose complexes have been studied in some detail is 1,8-naphthyridine (naph) which, like nitrate, has a small bite angle and is similarly capable of affording high coordination numbers; two types of perchlorate complexes have been made, $M(naph)_6(ClO_4)_3$ (M = La–Pr) and $M(naph)_5(ClO_4)_3$ (M = Nd–Eu). The former complexes have 12-coordinate lanthanides, confirmed by diffraction methods for the praesodymium complex. The change in stoichiometry is doubtless a manifestation of the lanthanide contraction.

A number of complexes of 1,2-diaminoethane have been made. Infrared evidence for the complexes $Ln(en)_4(NO_3)_3$ indicated the presence of coordinated nitrate for the earlier metals, so that the complexes were formulated $[Ln(en)_4(NO_3)](NO_3)_2$ (La–Sm) and $[Ln(en)_4](NO_3)_3$ (Eu–Lu). Other complexes isolated include perchlorates $[Ln(en)_4](ClO_4)_3$ (Ln = La–Nd), chlorides, $Ln(en)_4Cl_3$, $[La(en)_4Cl]\ In_2Te_4$ and $[Y(en)_4](SH)_{2.72}I_{0.28}$, the latter two having nine- and eight- coordination respectively.

Complexes of the lanthanides with the rather similar terdentate ligands 2,2′:6′,2″-terpyridyl (terpy), 2,4,6-tris-2-pyridyl-1,3,5-triazine (tptz), 4-amino-bis(2,6-(2-pyridyl))-1,3,5-triazine (abptz), and related ligands have been studied in considerable detail and number, as these terdentate N-donor ligands are efficient in separating actinides from lanthanides selectively by solvent extraction, of obvious relevance to processing nuclear waste.

Reaction of aqueous lanthanide chlorides with alcoholic solutions of terpy affords complexes $Ln(terpy)Cl_3\cdot xH_2O$ ($x = 6-8$). They contain $[Ln(terpy)Cl(H_2O)_n]^{2+}$ ions (Ln = La–Nd, $n = 5$; Ln = Sm–Lu, $n = 4$). Within these two families of cations, there are the expected contractions in bond length with increasing atomic number (and decreasing ionic radius). Thus on going from La to Nd in the series of $[Ln(terpy)Cl(H_2O)_5]^{2+}$ ions, there are contractions in Ln–Cl, from 2.903 (2) to 2.855 (1) Å; in average Ln–N distance, from 2.688 to 2.616 Å; and in average Ln–O distance, from 2.561 to 2.505 Å. Similarly, in the $[Ln(terpy)Cl(H_2O)_4]^{2+}$ ions, on passing from Sm to Lu, there are decreases in Ln–Cl, from 2.794 (2) to 2.665 (2) Å; in the average Ln–N distance, from 2.513 to 2.457 Å; and in average Ln–O distance, from 2.475 to 2.317 Å. There are two families of bromide complexes, nine-coordinate $[Ln(terpy)(H_2O)_6]Br_3\cdot H_2O$ (Ln = La–Er) and eight-coordinate $[Ln(terpy)(H_2O)_5]Br_3\cdot 3H_2O$ (Ln = TmLu) all isolated from water-ethanol mixtures. Unlike in the chlorides, there is no bromide in the coordination sphere, a reflection of the weaker σ-donor power of bromide (though no studies have been reported in nonaqueous solvents). A hydroxy-bridged dimeric species to be formed with the heavier lanthanides, but usually acidification converts it into the mononuclear complex. The dimers contain bridging hydroxy groups, not halides, again reflecting the decreasing coordinating power of bromide. Iodide complexes have been isolated using nonpolar solvents, thus terpy reacts with solutions of LnI_3 in anhydrous pyridine forming eight-coordinate $[Ln(terpy)_2I_2]I$ (Ln = Ce, Nd), whilst $[Ce(terpy)_2I_2]I$ crystallises from slightly damp solvents forming nine-coordinate $[Ce(terpy)_2I_2(H_2O)]\ I$. A comparison of structural data for $[Ce(terpy)_2I_2(H_2O)]I$ and $[U(terpy)_2I_2(py)]I$ indicates that the average U-N distance is shorter by about 0.05 Å, though on size grounds they would be expected to be very similar. This shortening may reflect a π back-bonding interaction between the 5f orbitals of uranium and the terpyridyl ligand which is absent in the lanthanide complex. Thiocyanate complexes $[Ln(terpy)_2(NCS)_3]$ (Ln = Pr, Nd), contain nine-coordinate lanthanides.[87]

Reaction of terpy with lanthanide perchlorates in MeCN affords $[La(terpy)_3](ClO_4)_3\cdot 2MeCN\cdot 0.67H_2O$, $[Ln(terpy)_3](ClO_4)_3\cdot MeCN.H_2O$ (Ln = Ce, Pr, Sm, Eu), $[Ln(terpy)_3](ClO_4)_3$ (Eu, Lu, Y); all of these have nine-coordinate $[Ln(terpy)_3]^{3+}$ cations with near-D_3 symmetry,[88] a structure originally deduced from the fluorescence spectrum of the europium complex and subsequently confirmed by X-ray diffraction (Figure 19).

Complexes of 4-alkylated terpyridyls, $[Ln(4\text{-}Rterpy)_3](ClO_4)_3$ (Ln = La, Eu, Tb; R = Et, Bu^t) have much higher luminescence efficiency, possibly due to the bulk of the alkyl group preventing approach of deactivating molecules, as well as their electronic effects.

The chemistry of lanthanide nitrate complexes of terpy is complicated;[89,90] various formulae occur, depending not

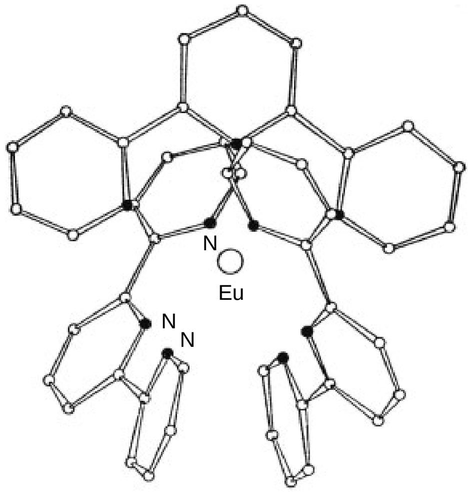

Figure 19 The structure of $Eu(terpy)_3{}^{3+}$

least upon the solvent used. Reaction of a 1:1 molar ratio of the hydrated lanthanide nitrate with terpy in MeCN, the initial products are $[Ln(terpy)(NO_3)_3(H_2O)_x]$. For the later lanthanides, $Ln(terpy)(NO_3)_3(H_2O)\cdot terpy$ (Ln = Ho, Er, Tm, Yb) can be obtained when an excess of terpy is used. Simple 1:1 complexes $Ln(terpy)(NO_3)_3(H_2O)$ (Ln = Nd, Eu, Tb) and $Ln(terpy)(NO_3)_3$ (Ln = Yb, Lu) have been described. All these complexes feature solely bidentate nitrates. In $[Lu(terpy)(NO_3)_3]$, the Lu–N distances are 2.379–2.407 Å and Lu–O bonds fall into the range 2.350–2.440 Å, so that even with the smallest lanthanide ion, all the nitrates are symmetrically bidentate. In contrast to the early lanthanides, where the same complex is obtained from synthesis in either acetonitrile or ethanol, the choice of solvent affects the structure for the 1:1 complexes of later lanthanides, with $[Ln(terpy)(NO_3)_3\cdot(C_2H_5OH)]$ (Ln = Y, Ho–Lu) being obtained from ethanol. These contain contains two bidentate nitrates and one monodentate nitrate as well as a coordinated ethanol, the lanthanide being nine-coordinate. Replacement of a bidentate nitrate trans- to the terpy by a coordinated ethanol and a monodentate nitrate causes a little reorganization in the coordination sphere; the $Lu–O(ONO_2)$ distance is 2.279 (3) Å, showing that the Lu–O bond is about 0.1 Å shorter than for an oxygen atom in a bidentate nitrate group. A second oxygen in this monodentate nitrate is hydrogen-bonded to the coordinated ethanol molecule (Lu–O = 2.297 (3) Å). Another feature of these compounds is short C–H···O interactions involving nitrate oxygens and hydrogens of the terpyridyl ligand in other molecules. Use of methanol as the reaction solvent results in a different product for La and Ce only, 11-coordinate $[La(NO_3)_3(terpy)(MeOH)_2]$ (Ln = La, Ce). If the hydrated lanthanide nitrates are reacted with 1 mol of terpy in MeCN, followed by recrystallisation of the initial complex from water, different complexes are obtained, 10-coordinate $[Ln(terpy)(NO_3)_2(H_2O)_3]$ NO_3 (Ln = La–Gd) and nine-coordinate $[Ln(terpy)(NO_3)_2(H_2O)_2]$ $NO_3\cdot 2H_2O$ (Ln = Tb, Lu, Y). They result from solvolysis by water of a nitrate group in $[Ln(terpy)(NO_3)_3(H_2O)_x]$. Structures show a girdle of ligands comprising a virtually planar terdentate terpy ligand and two or three water molecules coordinated round the lanthanide, with bidentate nitrates completing the coordination sphere above and below the metal ion.

Most lanthanide nitrate complexes have a 1:1 metal:terpy ratio. However, the complex $Ln(terpy)_{1.5}(NO_3)_3$ was isolated from a MeCN solution with a 8:1 terpy:La ratio and was found to be $[Ln(terpy)_2(NO_3)_2]^+$ $[Ln(terpy)(NO_3)_4]^-$. Reaction of hydrated lanthanide nitrates with up to 4 mols of terpy in CH_3CN afford complexes with a similar 1.5:1 stoichiometry, $[Ln(terpy)_2(NO_3)_2]^+$ $[Ln(terpy)(NO_3)_4]^-$ (Ln = Nd, Sm, Tb, Dy, Ho). In these, the lanthanide is 10-coordinate in both the cation and the anion, one nitrate group in the anion being monodentate, in contrast to the anion in the 1.5:1 complex of the larger lanthanum ion, where all nitrates are bidentate, this is evidently a consequence of congestion arising around the smaller lanthanide ions. Ce is also 11-coordinate in $(Hpy)[Ce(NO_3)_4(terpy)]\cdot py$. The $[Sm(terpy)(NO_3)_4]^-$ anion has also been isolated as the $(terpyH_2)^{2+}$ salt, this has an 11-coordinate anion with four bidentate nitrates, in contrast to the three bidentate and one monodentate group in the $[Sm(terpy)_2(NO_3)_2]^+$ salt, so solid-state packing effects seem important in determining coordination geometry.

A few lanthanide carboxylate complexes of terpy have been made, such as mononuclear $[Yb(O_2CCCl_3)_3\cdot(terpy)\cdot MeOH]$ in which coordinated methanol and two unidentate carboxylates and one bidentate carboxylate afford eight-coordinate ytterbium; in dimeric $[Ln(O_2CCCl_3)_3\cdot(terpy)\cdot(H_2O)]_2$ (Ln = La–Nd) the lanthanides are nine-coordinate. Some mixed-ligand quaternary complexes involving terpy, $[Ln(terpy)(NO_3)_2(acac)(H_2O)_n]$ (Ln = La, Pr, $n = 1$; Ln = Nd–Lu, $n = 0$), exhibit three different solid-state structures. $[La(terpy)(NO_3)_2(acac)(H_2O)]$ is 10-coordinate, with two bidentate nitrates and a chelating diketonate and a coordinated water; $[Pr(terpy)(NO_3)_2(acac)(H_2O)]$ is nine-coordinate, with one monodentate and one bidentate nitrate and a chelating diketonate and a coordinated water; and the remainder are $[Ln(terpy)(NO_3)_2(acac)]$ (Nd–Lu) with two bidentate nitrates and a chelating diketonate.

Structures are known of three types of complex of $tptz\cdot[Sm(tptz)(NO_3)_3(H_2O)]\cdot 2H_2O$ has 10-coordinate Sm with all nitrates bidentate; $[Eu(tptz)Cl_3(MeOH)_2]\cdot 2MeOH$ features eight-coordinate europium, and in dimeric $[Pr(tptz)(OAc)_3]_2\cdot 2MeOH$ praseodymium achieves 10-coordination through forming double (η^2,μ-1,1) acetate bridges familiar in other lanthanide carboxylate complexes. A study[91] of complexes of 4-amino-bis(2,6-(2-pyridyl))-1,3,5-triazine (abptz) with all the lanthanide nitrates gives a good deal of insight into how the stoichiometry and structure of complexes depend upon factors such as the radius

of the metal ion, the composition of the reaction mixture and the solvent employed. Complexes whose structures are known are [La(abptz)$(NO_3)_3(H_2O)_2$] (11-coordinate), [Ln(abptz)$(NO_3)_3(H_2O)$] (Ln = La, Pr–Sm; 10-coordinate), [Ln(abptz)$(NO_3)_3(H_2O)$] (Ln = Yb, Y; nine-coordinate, with one monodentate nitrate), [Ln(abptz)$(NO_3)_2(H_2O)_3$]NO_3 (Ln = Nd, Sm; 10- coordinate) and [Ln(abptz)$(NO_3)_2(H_2O)_2$] NO_3(Ln = Eu–Lu; nine-coordinate). Unlike the succeeding metals, La forms 10 and 11-coordinate [La(abptz)$(NO_3)_3(H_2O)_n$] (n = 1, 2), showing that the position of lanthanum as the largest lanthanide ion sometimes causes it to behave atypically; these complexes have similar solubilities and crystallize from the same reaction mixture. If the structures of these two complexes are compared, it can be seen that the decrease in coordination number from 11 to 10 is accompanied by a decrease in La–O (water) distance from 2.589 (4) and 2.610 (4) Å to 2.483 (5) Å; similarly, the La–N distances decrease from 2.739 (4), 2.755 (5) and 2.805 (6) in the 11-coordinate compound to 2.576 (5), 2.625 (5) and 2.641 (5) Å in 10-coordinate [La(abptz)$(NO_3)_3(H_2O)$]. The range of La–O (nitrate) distances decreases from 2.628 (4) – 2.702 (5) Å (with an outlying member at 2.805 (6) Å) in [La(abptz)$(NO_3)_3(H_2O)_2$], to 2.525 (5) – 2.620 (5) Å in [La(abptz)$(NO_3)_3(H_2O)$], indication of the congestion in the coordination sphere in the 11-coordinate complex. It indicates how nitrate is a versatile ligand in enabling lanthanide ions to achieve high coordination numbers. [Ln(abptz)$(NO_3)_2(H_2O)_3$] NO_3 (Ln = Nd, Sm; 10-coordinate) and [Ln(abptz)$(NO_3)_2(H_2O)_2$] NO_3 (Ln = Eu–Lu) are clearly analogous to terpy complexes mentioned above. On the other hand, the fact that abptz forms nine-coordinate [Ln(abptz)$(NO_3)_3(H_2O)$] (Ln = Yb, Y) are, with one monodentate nitrate, rather than the alternative [Ln(abptz)$(NO_3)_3$], with three bidentate nitrates, analogous to [Ln(terpy)$(NO_3)_3$] (Ln = Er–Lu) indicates the subtle factors that can be responsible for the adoption of a particular geometry in a lanthanide complex.

Other ligands of the type whose complexation has been examined in detail include a range of 2,6-bis(5, 6-dialkyl-1,2,4-triazin-3-yl)pyridines, 2,6-bis(benzimidazol-2′-yl)pyridine (bzimpy) and N,N,N',N'-tetraethylpyridine-2,6-dicarboxamide. In some cases, segmental ligands have been employed to obtain complexes with stranded helical structures.

Among tetradentate ligands, complexes of the tripodal tpza and tpa have been explored. [Ln(tpa)Cl_3] (Ln = Eu, Tb, Lu) have seven-coordination, whilst the larger neodymium ion can accommodate a coordinated solvent molecule in the eight-coordinate Nd analogue, [Nd(tpa)Cl_3(MeOH)]. Eight-coordinate lanthanum iodide complexes [La(tpza)I_3(NCMe)] and [La(tpza)I_3(thf)] exist. When lanthanide ions complex with the tripodal ligand tris(2-benzimidazol-2-ylmethyl)amine (ntb), bis complexes $[Ln(ntb)_2]^{3+}$ are formed where the ligand encapsulates the metal – to the exclusion of chloride from the coordination sphere, even when a deficit of ligand is used. Strong $\pi - \pi$ interactions between the benzimidazole rings may be responsible. However, 1:1 complexes [Ln(ntb)$(NO_3)_3$]·H_2O (Ln = La, Ce, Nd, Sm–Dy, Er) are formed when nitrate, with its stronger coordinating tendencies, is present. A chiral tris(2-pyridylmethyl)amine ligand has been used to form complexes [Ln(L)]$(CF_3SO_3)_3$ (Ln = Eu and Tb) whose emission spectra of the europium complex in particular are most sensitive in both intensity and in line shape to the presence of a wide range of anions (X = I^-, Br^-, Cl^-, F^-, ClO_4^-, NO_3^-, SCN^-, $CH_3CO_2^-$, HSO_4^- and $H_2PO_4^-$), working most effectively as a nitrate-specific luminescent sensor.[92]

The tetradentate quaterpyridine and hexadentate sexipyridine ligands form 1:1 complexes with yttrium and europium nitrates, respectively; the first-named ligand generates nine-coordinate $[Y(qtpy)(NO_3)_2(H_2O)]^+$ cations while the latter produces 10-coordinate $[Eu(spy)(NO_3)_2]^+$ cations where the ligand twists itself helically round the metal.[93]

3.7.11 *Complexes of Porphyrins, Phthalocyanines, Aza Macrocycles, Texaphyrins, and Related Ligands*

Reaction of $Ln(acac)_3$ with H_2TPP and other porphyrins (*see Porphyrin*) in solvents like trichlorobenzene (TCB) have been reported to give complexes Ln(acac)(porph), although for the early lanthanides LnH$(porph)_2$ seems to be the more usual product (on extended reflux, the double-decker sandwich $Ln_2(porph)_3$ may be obtained). Thus, refluxing [Eu$(acac)_3$] with H_2OEP in 1,2,4-trichlorobenzene for 4 h leads to a mixture of [Eu$(OEP)_2$] and [$Eu_2(OEP)_3$] (along with a small amount of [Eu(OEP)(OAc)]), the former being a good deal more soluble in organic solvents, so that the mixture is separable by crystallisation.[94] Other, less forcing, methods have been described, such as when [LuR_3] (R = CH$(SiMe_3)_2$) reacts with H_2OEP in toluene forming [Ln(OEP)CH$(SiMe_3)_2$], which has a square-pyramidal structure with a highly dished porphyrin skeleton.[95] Among adducts of porphyrins, a rare example of seven-coordination is found in [Ln(TPP)Cl(dme)] (Ln = Ho, Er, Tm, Yb) where the metal sits about 1.1 Å above the N_4 plane.[96] Bis(porphyrin) complexes with sandwich structures have also been synthesized. In general they are formally regarded as complexes of the trivalent lanthanide where one of the porphyrin ligands is a dianion and the other the oxidized cation radical. Genuine cerium(IV) complexes of both porphyrins and phthalocyanines have, however, been made. Phthalocyanine complexes can be made by heating a lanthanide compound such as the acetate with 1,2-dicyanobenzene.

A number of other complexes involve the lanthanide bonding to nitrogens in rings, either in aza crowns or in more classic macrocycles like cyclen. 1,4,7,10,13-pentaazacyclopentadecane (L) forms nitrate complexes [Ln(L)$(NO_3)_3$] (Ln = Y, La–Yb except Ce, Pm, Ho); the structure of [La(L)$(NO_3)_3$] shows it to have 11-coordinate lanthanum. As another example of structurally characterised

complex of a N-donor macrocycle, [Nd([18]aneN_6)$(NO_3)_3$] has two monodentate and one bidentate nitrate giving 10-coordination.

Cryptate complexes with macrobicyclic ligands containing three bipy units, in which the Ln^{3+} ion is contained within a ligand cavity, have been synthesized.[97] Such ligands will complex Ln^{2+} ions, such as Eu^{2+} and Sm^{2+}, under conditions where Ln^{3+} ions are not. An application has been using lanthanide cryptates of the early lanthanides (La, Ce, Eu) as catalysts in the hydrolysis of phosphate monoesters, diesters, and triesters. Schiff base complexes can be synthesized by the reaction of a lanthanide salt with a diamine and a suitable carbonyl derivative such as 2,6-diacetylpyridine.

Complexes, particularly of gadolinium, of ligands with a N_4-donor macrocyclic backbone that also supports carboxylate groups have assumed importance in the context of MRI contrast agents (see Section Magnetic Resonance Imaging and MRI Agents and *see also* ***Metal-based Imaging Agents***). The potentially octadentate ligand DOTA (1,4,7,10-tetra(carboxymethyl)-1,4,7,10-tetraazacyclododecane) has been widely studied. It forms very stable lanthanide complexes (one water usually molecule coordinated) [Ln(DOTA)(H_2O)]$^-$. These have slightly higher stability constants than the DTPA complexes; thus log K for [Gd(DOTA)(H_2O)]$^-$ is ∼24.7, in comparison with 22.46 for [Gd(DTPA)(H_2O)]$^{2-}$. [Gd(DOTA)(H_2O)]$^-$, (Figure 20) is in clinical use (gadoterate meglumine; Dotarem™).[98] The structures of several lanthanide complexes of DOTA have been examined. Na [Ln(DOTA)(H_2O)]·$4H_2O$ all contain nine-coordinate [Ln(DOTA)(H_2O)]$^-$ ions (Ln = Pr, Nd, Eu, Gd, Ho, Lu) with twisted square-antiprismatic arrangements of the antiprism (on which the coordinated water molecule is superimposed), whilst K[Tm(DOTA)]·$6H_2O$ contains no coordinated water, showing the role of the counterion in determining the species crystallizing.

If one carboxylic acid side chain in H_4DOTA is replaced by hydrogen, the resulting acid, H_3DO3A, forms neutral lanthanide complexes. In solution, they are believed to have two water molecules coordinated so that the species present is Gd(DO3A)$(H_2O)_2$·[Eu(DO3A)$(H_2O)_n$] is known to exhibit a hydration equilibrium with $n = 1, 2$, strongly weighed towards [Eu(DO3A)$(H_2O)_2$]. Other derivatives have been made in which the fourth carboxylic acid group is replaced by hydroxyalkyl groups that are marketed and approved for use (–$CH_2CH(CH_3)OH$ = ProHance™; –$CH(CH_2OH)CH(OH)CH_2OH$ = Gadovist™). These compounds have a side-chain hydroxyalkyl group coordinated, in addition to four nitrogens, three carboxylate oxygens, and a water molecule (Figure 21).

Quite apart from use as MRI contrast agents, there is considerable interest in applications of lanthanide complexes of DOTA and related complexing agents as spectroscopic probes.[99]

Examples of this include some Tb and Eu macrocyclic complexes, immobilised in a sol-gel glass, whose emission is made pH-dependent and can thus be used as narrow range pH sensors, and a terbium complex which behaves as a molecular logic gate; the output (a terbium emission line) is only observed when the 'inputs' (the presence of proteins and the absence of oxygen) are both satisfied. (Figure 22).

Texaphyrins. A new type of complex is provided by the texaphyrins, compounds of 'extended' porphyrins where

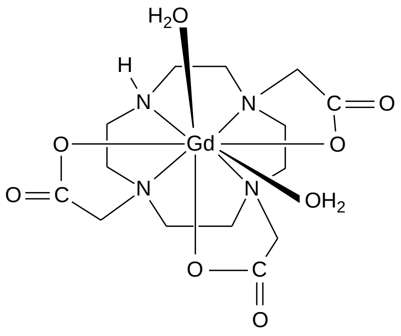

Figure 21 The neutral complex [Gd(DO3A)(H_2O)2]

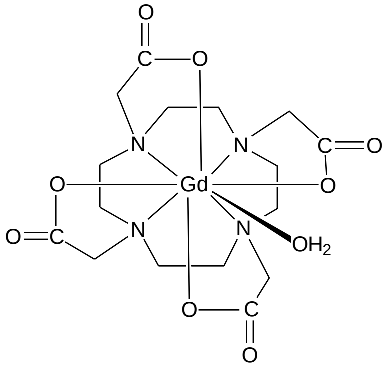

Figure 20 The MRI agent [Gd(DOTA)(H_2O)]$^-$

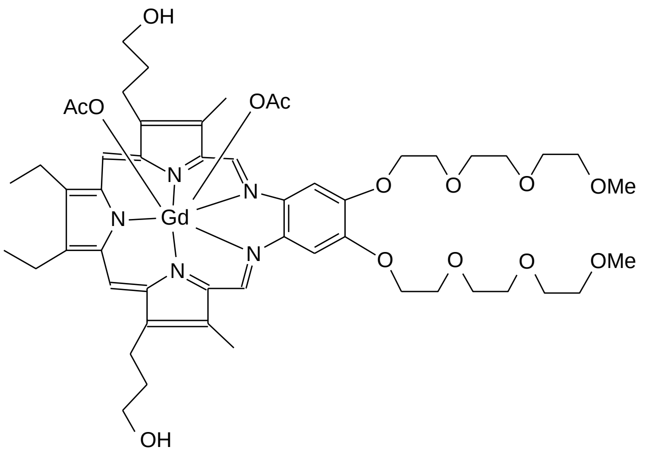

Figure 23 The gadolinium texaphyrin complex 'Gd-tex'

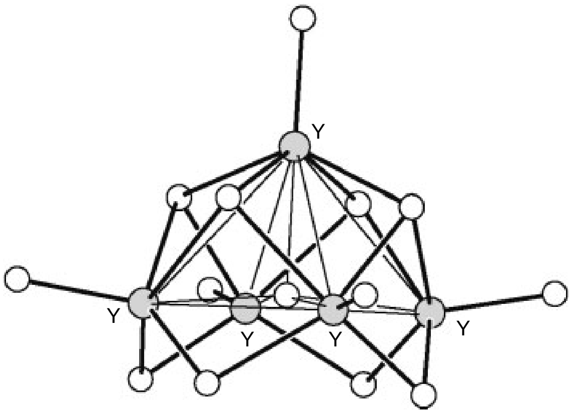

Figure 24 The structure of $Y_5O(O\text{-}i\text{-}Pr)_{13}$

the ring contains five donor nitrogens. These have attracted considerable interest because of their possible medicinal applications.[100] Two texaphyrin complexes are undergoing clinical trials; a gadolinium compound (Gd-tex; XCYTRIN™) is an effective radiation sensitiser for tumour cells (Figure 23). It assists the production of reactive oxygen-containing species, whilst the presence of the Gd^{3+} ion means that the cancerous lesions to which it localises can be studied by MRI. One form of the lutetium analogue (LUTRIN™), is being developed for photodynamic therapy for breast cancer, and another, (ANTRIN™) is being developed for photoangioplasty, where it has potential for treating arteriosclerosis.

3.7.12 Other Ligands

Alkoxides and Aryloxides[101]. Some of these compounds have been known for over 30 years, but interest in the former has been stimulated recently by their potential use as precursors for deposition of metal oxides using the sol–gel (*see* ***Sol–Gel Synthesis of Solids***) or Metal Organic Chemical Vapour Deposition (MOCVD) process (*see Metal–Organic Chemical Vapor Deposition*) In the case of alkoxides and aryloxides, it is harder to get monomers with low coordination numbers than with alkyl (and aryl-) amides, since –OR ligands by their own nature exert less second-order influence in the coordination sphere than the corresponding $-NR_2$, and, for the same reason, –OR groups are much more likely to be found in bridging positions. Thus, because of oligomerization and/or the presence of solvent in the coordination sphere, $Ln(OR)_3$ species are frequently not three-coordinate.

Simple methoxides like $La(OMe)_3$ are ill-defined structurally but are oligomeric; attempted isolation of corresponding isopropoxides has yielded the clusters $Ln_5O(O\text{-}i\text{-}Pr)_{13}$ (Figure 24) (Ln = Y, Yb) with a square-pyramidal core, $Nd_5O(O\text{-}i\text{-}Pr)_{13}(i\text{-}PrOH)_2$ (trigonal bipyramidal core), and $Nd_6(O\text{-}i\text{-}Pr)_{17}Cl$. Under other circumstances, a binuclear solvate, $[Nd(OCHPr^i_2)_3(thf)]_2$, with the structure $[(Pr^i_2CHO)_2(thf)Nd(\mu\text{-}OCHPr^i_2)_2Nd(thf)(OCHPr^i_2)_2]$ has been obtained. Similarly, the neopentoxides $Ln(OCH_2Bu^t)_3$ (Ln = La, Nd) are tetrameric $[Ln(OCH_2Bu^t)_3]_4$ based on a square of lanthanides with each lanthanide bound to one terminal and four bridging alkoxides. Using the bulkier *t*-butoxide ligand to minimize association gave $La_3(O\text{-}t\text{-}Bu)_9(thf)_2$ and $Ce(O\text{-}t\text{-}Bu)_3$ (believed to be monomeric); the latter undergoes thermolysis in high yield:

$$2Ce(O\text{-}t\text{-}Bu)_3 \longrightarrow [Ce(OCH\text{-}t\text{-}Bu_2)_3]_2 + 6C_4H_8 \qquad (9)$$

The product is an alkoxy-bridged dimer with four-coordinate cerium. Dimeric structures are also exhibited by $[Ln(OQPh)_3]_2$(Ln = La, Ce, Y; Q = C, Si), although the bridges are cleaved by Lewis bases forming adducts such as $Ln(OSiPh)_3(thf)_3$ (*fac*-octahedral; Ln = Y, La, Ce) and $Y(OSiPh)_3(OPBu_3)_2$ (trigonal bipyramidal). An unusual cyclic decameric structure is exhibited by $[Y(OC_2H_4OMe)_3]_{10}$ (Figure 25).

Synthesis of alkoxides from $LnCl_3$ is often complicated by chloride retention from the starting material, and for this reason they are often made by alcoholysis of $Ln(N(SiMe_3)_2)_3$.

A range of aryloxides exists. With 2,6-dimethylphenoxide, six-coordinate $Y(OR)_3(thf)_3$ (and dimeric $[Y(OR)_3(thf)]_2$ with five- coordination) are formed; replacement of methyl by phenyl substituents leads to the isolation of the 2,6-diphenylphenolates $[Ln(OC_6H_3Ph_2\text{-}2,6)_3]$ (Ln = La, Ce, Pr, Nd, Gd, Ho, Er, Lu, Y), which have monomeric structures with the lanthanide slightly out of the O_3 plane, but with some additional ring-metal interactions. $[Ln(OC_6H_3Ph_2\text{-}2,6)_3(thf)_2]\cdot 2thf$ (Ln = La, Nd) have conventional five-coordinate trigonal bipyramidal coordination of the metal with one axial and one equatorial thf; in contrast, $[Nd(OC_6H_3Ph_2\text{-}2,6)_3(thf)]$ has pseudo-tbp coordination with three equatorial

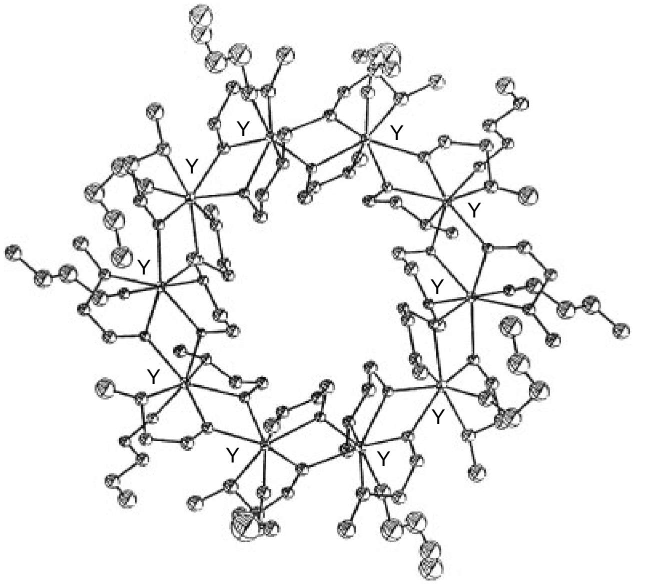

Figure 25 Cyclic decameric structure of $[Y(OC_2H_4OMe)_3]_{10}$

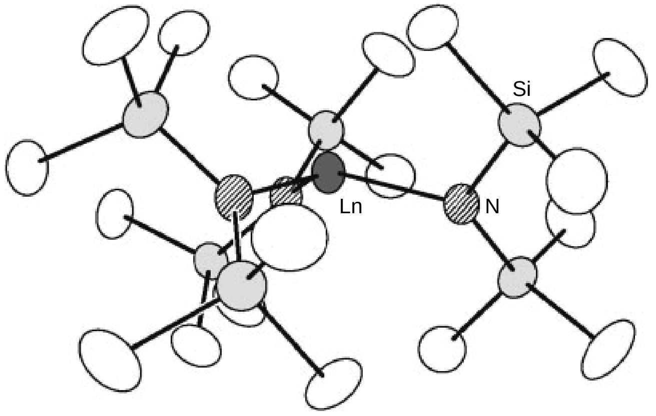

Figure 26 Three-coordinate $Ln[N(SiMe_3)_2]_3$

phenoxides, an apical thf and an apical position occupied by a phenyl group. Using the 2,6-diisopropylphenolate ligand leads to unsolvated $Ln(OC_6H_3Pr^i_2\text{-}2,6)_3$ species which are in fact η^6-arene bridged dimers $Ln_2(OC_6H_3Pr^i_2\text{-}2,6)_6$; in thf, they form conventional trigonal bipyramidal thf adducts $[Ln(OC_6H_3Pr^i_2\text{-}2,6)_3(thf)_2]$ (Ln = Pr, Nd, Sm, Gd, Er, Yb, Lu). When the bulk of the aryloxide is increased by putting two *t*-butyl groups into the 2,6-positions of the benzene ring, three-coordinate aryloxides, $Ln(O\text{-}2,6\text{-}t\text{-}Bu_2\text{-}4\text{-}R\text{-}C_6H_2)_3$, can be isolated (R = H, Ln = Y, La, Sm; R = Me, Ln = Y, La, Ce, Pr, Nd, Dy–Er, Yb). Trigonal planar geometry is found in $Y(O\text{-}t\text{-}Bu_2C_6H_3)_3$ but a pyramidal structure is adopted in $Ce(O\text{-}2,6\text{-}t\text{-}Bu_2\text{-}4\text{-}Me\text{-}C_6H_2)_3$. Possibly the balance of small and variable 'agostic' and Van der Waals forces, whether within the lattice or within the complex species, is the determining factor in determining the form of three-coordination. Alkyl and aryloxides have proved useful synthetic precursors.

Alkylamides. The volatile air-sensitive silylamides are the best characterized alkylamides. They are made by salt-elimination reactions:

$$LnCl_3 + 3Li\,N(SiMe_3)_2 \longrightarrow Ln(N(SiMe_3)_2)_3 + 3LiCl \qquad (10)$$

They are volatile in vacuo at 100 °C and dissolve in hydrocarbons; the first three-coordinate lanthanide compounds to be characterized, they have unusual pyramidal structures (Figure 26) in the solid state (similar structures have been reported for Y, Ce, Nd, Sm, Eu, Dy, Er, and Yb), but are believed to be planar in solution. Careful examination of the crystal structure of $[Sm\{(N(SiMe_3)_2)_3\}]$ shows that one methyl group in each amide is placed above the pyramid relatively close to the samarium (Sm–C 3.003(4) Å; compare Sm–N 2.284(3) Å) suggesting the presence of agostic interactions (*see Agostic Bonding*). DFT (Density Field Theory) calculations on it support this view, indicating the presence of β-Si–C agostic interactions.**[102]** $Ln(N(SiMe_3)_2)_3$ form stable four-coordinate Ph_3PO and Ph_2CO adducts; when excess phosphine oxide is used, five-coordinate peroxide-bridged dimers are obtained. $Eu[N(SiMe_3)_2]_3$ forms both 1:1 and 1:2 adducts with Me_3PO. $[Ln(N(SiMe_3)_2)_3]$ react with CyNC (Cy = cyclohexyl) forming trigonal bipyramidal five-coordinate adducts $[Ln(N(SiMe_3)_2)_3(CyNC)_2]$ (axial nitriles). $[Y(N(SiMe_3)_2)_3(PhCN)_2]$ has a similar structure.

When a deficit of the lithium alkylamide is used, dimeric chloride-bridged silylamides are obtained which are useful synthetic intermediates (Figure 27);**[103]** they can also be prepared by redistribution reactions between $LnCl_3$ and $[Ln(N(SiMe_3)_2)_3$; some bromo- and iodo- analogues have been reported.

Anhydrous lanthanide triflates are an alternative to the chlorides as starting materials for the synthesis of $[Ln(N(SiMe_3)_2)_3]$ as they obviate problems of chloride retention in the product, which can lead to several products, as reaction of $YbCl_3$ and $NaN(SiMe_3)_2$ in a 1:2 molar ratio gives $[Yb(N(SiMe_3)_2)_3]$, $[Yb(N(SiMe_3)_2)_2(\mu\text{-}Cl)(thf)]_2$ and $[Yb_3Cl_4O((N(SiMe_3)_2)_3(thf)_3)]$. The latter is a trinuclear cluster with a triangle of ytterbiums, where Yb is octahedrally coordinated by an amide nitrogen, a thf, two μ_2-chlorine atoms and a μ_3-chlorine and μ_3-oxygen.

The amide $Er\{NBu^t(SiMe_2H)\}_3$, which has an unexpectedly high vapour pressure, displays three agostic Er–H–Si interactions in the solid state. Other alkylamides $Ln(N\text{-}i\text{-}Pr_2)_3$ (Ln = Y, La, Nd, Yb, Lu,) are obtained with the less hindered isopropylamide ligand; the neodymium compound forms

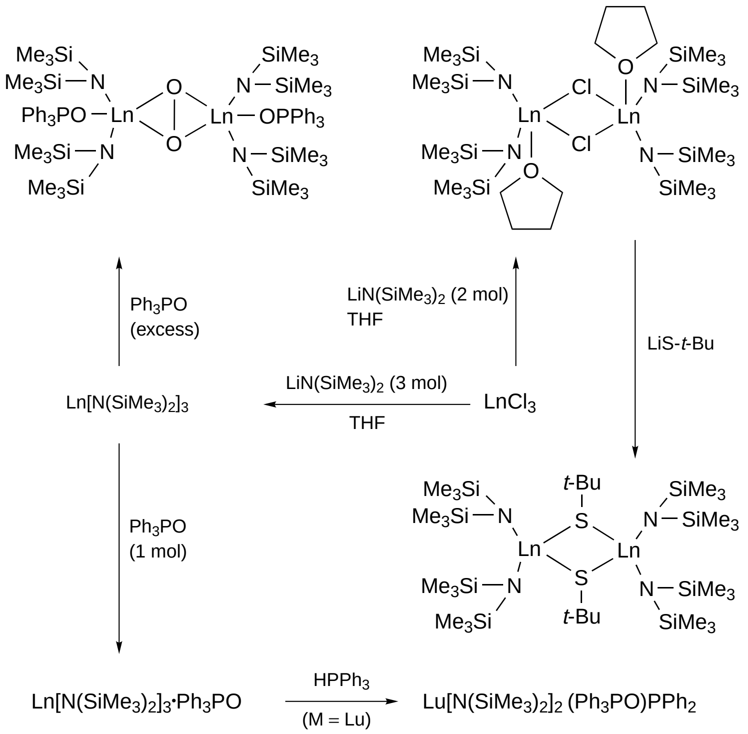

Figure 27 Reactions of lanthanide bis(trimethylsilyl)amide complexes. (Ref. 6. Reproduced by permission of Palgrave Macmillan)

a stable thf adduct [Nd(N-*i*-Pr_2)$_3$(thf)]. [Sm(Ncy_2)$_3$(thf)] is similar. In contrast to the three-coordinate silylamides and diisopropylamides, the lanthanides do not form simple homoleptic dimethylamides. Reaction of $NdCl_3$ with $LiNMe_2$ gives an adduct [Nd(NMe_2)$_3$(LiCl)$_3$], which with MMe_3 (M = Al, Ga) gives bridged [Nd(NMe_2)$_3$(MMe_3)$_3$].

Trigonal bipyramidal [Ln{N($SiHMe_2$)$_2$}$_3$(thf)$_2$] (Ln = Y, La–Lu) are isostructural; these amides have been anchored to the internal walls of the mesoporous silicate MCM-41 as potential catalyst precursors.

Rather less is known about lanthanide arylamides. Reaction of $NdCl_3$ with KNHAr (Ar = Ph) leads to [Nd(NHPh)$_3$·3KCl], reminiscent of the adducts of the dimethylamides. Using the sterically demanding 2,6-$Pr^i_2C_6H_3$ group leads to octahedral [Nd(NH-2,6-$Pr^i_2C_6H_3$)$_3$(thf)$_3$] and trigonal bipyramidal [Ln(NH-2,6-$Pr^i_2C_6H_3$)$_3$(thf)$_2$] (Ln = Y, Yb).

Several compounds with highly fluorinated amides have been synthesized; [Sm(N($SiMe_3$)(C_6F_5))$_3$] (Figure 28) contains three significant Sm···F and three Sm–C–H agostic interactions, which seem to be common in these compounds; the thf adduct [Sm(N(C_6F_5)($SiMe_3$))$_3$(thf)] has two Sm···F and one Sm–C agostic interaction. The toluene adduct [(η^6-C_6H_5Me)Nd(N(C_6F_5)$_2$)$_3$] has a η^6-bonded toluene molecule with a distorted piano-stool geometry. Tetrahedral anionic species [Li(thf)Ln(N-*i*-Pr_2)$_4$] (Ln = La, Y, Lu) and [Li(thf)$_4$][Ln(NPh_2)$_4$] (Ln = Er, Yb) have also been made.

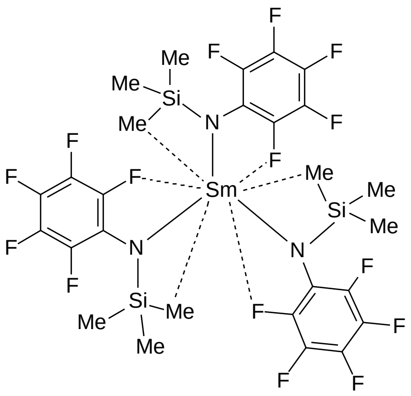

Figure 28 The samarium amide [Sm(N($SiMe_3$)(C_6F_5))$_3$], showing the agostic interactions

Polypyrazolylborates. This area of chemistry has developed considerably.[104] [$LnTp_3$] have nine-coordinate structures for early lanthanides (e.g. Pr, Nd), but eight-coordinate for the later metals (e.g. Yb). Seven-coordinate bis complexes [Ln$(Tp)_2$Cl] are formed using totally moisture-free conditions, but these readily add a Lewis base, for example, water forming [Ln$(Tp)_2$Cl(H_2O)]. A very wide range of compounds, many of Sm, Eu, and Yb, in both the +2 and +3 states, has been synthesized with Tp^{Me2}, this time with a maximum of two Tp^{Me2} bound. In triflate complexes

$Ln(Tp^{Me2})_2(OTf)$, triflate coordinates for the lighter lanthanides, as in $[Nd(Tp^{Me2})_2(O_3SCF_3)]$ whereas the smaller lanthanides form ionic $[Ln(Tp^{Me2})_2]$ O_3SCF_3, as in the ytterbium compound. The triflates form mono(MeCN) adducts, the MeCN being bound in $[La(Tp^{Me2})_2(MeCN)]$ O_3SCF_3 but not in $[Nd(Tp^{Me2})_2(O_3SCF_3)]$·MeCN. This can be regarded as a type of ionisation isomerism. In a range of $Sm(Tp^{Me2})_2X$ compounds, where X = F, Cl, these have monomeric seven-coordinate molecular structures, but for X = I and BPh_4, the compounds are $[Sm(Tp^{Me2})_2]^+X^-$. A comparison of the ytterbium(II) and (III) compounds $[Yb(Tp^{Me2})_2]$ and $[Yb(Tp^{Me2})_2]$ O_3SCF_3 show six-coordination for ytterbium in both cases, with Yb–N bond lengths ca. 0.16 A longer in the Yb(II) compound.

Simple Alkyls. These are primarily dealt with elsewhere (*see* ***Scandium, Yttrium & the Lanthanides: Organometallic Chemistry***) but the structural similarity of the distorted three-coordinate trigonal pyramidal structures of the alkyls $[Ln((CH(SiMe_3)_2)_3)]$ to the alkylamides $[Ln((N(SiMe_3)_2)_3)]$ (Ln = La–Lu) is notable. Density Functional Theory calculations indicate that β-Si–C agostic interactions are important in these structures (*see Agostic Bonding*), but that the hitherto favoured γ C–H agostic interactions are in fact repulsive. Another family of alkyls with simple coordination geometries is $[Ln(CH_2SiMe_3)_3(thf)_n]$. These appear to be very unstable for lanthanides larger than samarium, but $[Ln(CH_2SiMe_3)_3(thf)_3]$ (Ln = Sm, Y) have *fac*-octahedral structures, whilst $[Ln(CH_2SiMe_3)_3(thf)_2]$ (Ln = Er, Yb, Lu) all have five-coordinate trigonal bipyramidal structures (axial thf ligands). The $[Ln(CH_3)_6]^{3-}$ ions (all lanthanides except Eu) have the expected octahedral structures.[105]

Thiolates and Related Systems. Lanthanide thiolates have only been characterized in detail recently. Monomeric species have been obtained using bulky ligands, such as the three-coordinate (pyramidal) $Sm(SC_6H_2$-*t*-Bu-2,4,6$)_3$ (Figure 29).[106]

The intensively reactive $[Ln(SBu^t)_3]$ (Ln = La, Ce, Pr, Nd, Eu, Yb, Y) are made[107] from $[Ln\{N(SiMe_3)_2\}_3]$ and $HSBu^t$; their reactivity is doubtless due to coordinative unsaturation. Some thiophenolates have been isolated as Lewis base adducts. $[Ln(SPh)_3(py)_3]_2$ (Ln = Ho, Tm) have two thiolate bridges with seven-coordinate lanthanides; $[Sm(SPh)_3(py)_2]_4$ has a linear arrangement of four seven-coordinate samariums with 3, 2, and 3 μ_2-bridging thiolates and $[Sm(SPh)_3(thf)]_{4n}$ is a polymer. Use of SC_6F_5 as a ligand gives stabler (even to air) and more hydrocarbon-soluble products, also obtained as Lewis base adducts. The large Ce^{3+} ion forms the seven-coordinate dimer $[Ce(SC_6F_5)_3(thf)_3]_2$ with thiolate bridges, whilst Ho and Er give monomeric $[Ln(SC_6F_5)_3(thf)_3]$ (Ln = Ho, Er). Other adducts $[Ln(SC_6F_5)_3(py)_4]$ (Ln = Sm, Yb) and $[Er(SC_6F_5)_3(dme)_2]$ have also been isolated. Many of these compounds feature Ln···F interactions, of the type

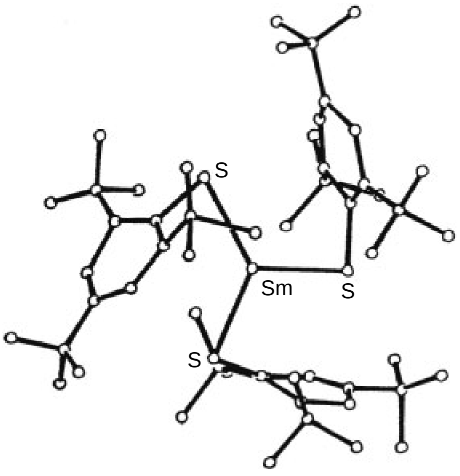

Figure 29 Structure of three-coordinate Sm in $Sm(SC_6H_2(Bu$-*t*$)_3$ -2,4,6$)_3$

noted in lanthanide amides. Another synthetic approach has utilized the reaction of lanthanide metals with disulphides and diselenides. Thus molecules such as $[Yb(SAr)_3(py)_3]$ (Ar = 2,4,6-triisopropylphenyl) and $Ln(SePh)_3py_3$ (Ln = Ho, Tm, Yb) have been made; the selenolates are dimeric with seven-coordinate lanthanides. In contrast, $[Yb(SPh)_3py_3]$ has a meridional, structure, whilst $[Ln(SePh)_3(thf)_3]$ (Ln = Tm, Ho, Er) have monomeric *fac*-octahedral structures. $[Sm(SePh)_3(py)_3]_2$ has two selenothiolate bridges with seven-coordinate samarium. An important reaction of these compounds is that they react with free chalcogens forming clusters. Thf solutions of thiolates $Ln(SPh)_3$ reacts with S forming octanuclear clusters $[Ln_8S_6(SPh)_{12}(thf)_8]$ (Ln = Ce- Sm, Gd–Er), their structure is based on a cube of lanthanides, edge bridged by mercaptides and face-bridged by sulphur; analogous pyridine clusters $[Ln_8S_6(SPh)_{12}(py)_8]$ (Ln = Nd, Sm, Er) have also been isolated. Reaction of Sm with PhSeSePh in thf gives a cluster $[Sm_8Se_6(SePh)_{12}(thf)_8]$ whilst $Sm(SePh)_3$ reacts with S in dme affording $[Sm_7S_7(SePh)_6(dme)_7]^+$ $[Hg_3(SePh)_7]^-$·$Nd(SePh)_3$ reacts with Se in pyridine to form $[Nd_8Se_6(SePh)_{12}(py)_8]$. Reaction of later lanthanides with mixtures of I_2 and PhSeSePh in thf, followed by reaction with Se in pyridine affords iodine-containing clusters $[(thf)_6Ln_4I_2(SeSe)_4(\mu_4$-Se$)]$·thf (Ln = Ho–Yb). These contain a square array of Ln(III) ions connected through a single (μ_4-Se) ligand. Another such cluster is $[Yb_6Se_6I_6(thf)_{10}]$. On thermolysis, these selenium rich compounds give iodine-free Ln_2Se_3.[108]

Much of this work has been directed towards materials-based applications, as volatile compounds might be CVD precursors (*see Chemical Vapor Deposition*) and the ability of the thiolates and their fellows to react with the free chalcogens may assist doping lanthanide ions into optical and electrical materials. Thus, thermolysis of the $[Ln(SePh)_3(thf)_3]$ (Ln =

Tm, Ho, Er) gives Ln_2Se_3 (Ln = Tm, Yb) and a mixture of MSe and MSe_2 (M = Ho).

3.7.13 Complexes of N,O-Donors

Complexes of Polyaminepolycarboxylic Acids[4,5]. Ligands like EDTA form stable lanthanide complexes; complexation is facilitated by the considerable entropy change, the enthalpy change being small (and endothermic):

$$[Ln(H_2O)_9]^{3+} + EDTA^{4-} \longrightarrow Ln(EDTA)(H_2O)_3]^{3-} + 6H_2O \quad (11)$$

In general, the early lanthanides form triaqua species $[Ln(EDTA)(H_2O)_3]^{3-}$ with nine-coordinate metal (Figure 30), but metals from erbium form eight-coordinate $[Ln(EDTA)(H_2O)_2]^-$ following the 'lanthanide contraction'. Thus, $Na[Ln(EDTA)(H_2O)_3]5H_2O$ (Ln = La–Dy) are isostructural, with nine-coordinate lanthanides; as are $K[Ln(EDTA)(H_2O)_3]$(Ln = La, Nd); $K[Yb(edta)(OH_2)_2]\cdot 5H_2O$ and Cs $[Yb(edta)(OH_2)_2]\cdot 5H_2O$ contain eight-coordinate ytterbium. Comparison with other structures show there to be a dependence upon the alkali-metal cation present in some cases. Thus, $Cs[Dy(edta)(OH_2)_2]\cdot 3H_2O$ and $Cs[Ho(edta)(OH_2)_2]\cdot 3H_2O$ have eight-coordinate lanthanides (unlike the nine-coordinate Na salt), whilst $Na[Er(edta)(OH_2)_3]\cdot 5H_2O$, $K[Ho(edta)(OH_2)_3]\cdot 2H_2O$, Cs $[Nd(edta)(OH_2)_3]\cdot 3.5\ H_2O$, $Cs[Sm(edta)(OH_2)_3]\cdot 4H_2O$ and $Cs[Gd(edta)(OH_2)_3]\cdot 4H_2O$ all have nine-coordinate lanthanides. Evidently there is a region towards the end of the lanthanide series where the eight and nine-coordinate anions have similar stabilities, and it is the solubility of the compound that determines which anion is isolated. The EDTA complexes are prototypes for a number of complexes of polyaminepolycarboxylic acids; they are historically important as an early established example of high coordination numbers for lanthanide complexes.

The potentially octadentate DTPA likewise forms stable complexes. These have lately attracted considerable interest with the use of its gadolinium complex as a contrast enhancing agent for body scanners (MRI, *see* ***Metal-based Imaging Agents***), probably the most important new application of lanthanide compounds to emerge in the last 20 years. The introduction of lanthanide-based contrast agents has revolutionised diagnostics, assisting doctors in distinguishing between normal and diseased tissue and thus improving prognosis.

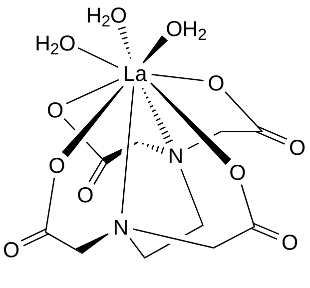

Figure 30 The structure of $La(EDTA)(H_2O)_3^-$

Magnetic Resonance Imaging and MRI Agents[109,110]. MRI relies on detecting the NMR signals of water molecules in the body as a function of space. Spatial information is obtained by making the ^1H resonance frequency position-dependent. The imaging agent enhances the contrast to distinguish between healthy and diseased tissue; the paramagnetic contrast agent, which shortens the relaxation time (T_1) for the protons in water molecules in that tissue and enhances the signal intensity. A number of factors have to be taken into account in designing a good MRI agents; they include (a) low toxicity; (b) high magnetic moment; (c) coordinated water molecules; (d) long electron-spin relaxation time; (e) osmolarity similar to serum; (f) water solubility; (g) targeting tissue. Gd^{3+} ions have a large number of unpaired electrons (S = 7/2) and high magnetic moment, additionally its magnetic properties are isotropic. Its electron-spin relaxation time $\sim 10^{-9}$ s, and is more suitable than other very paramagnetic lanthanide ions in the second half of the series, such as Dy^{3+}, Eu^{3+} and Yb^{3+} ($\sim 10^{-13}$ s). All these magnetic properties are desirable. The toxicity of the gadolinium aqua ion is too great for it to be used directly the LD50 is ~0.1 mmol/kg, which is less than the imaging dose, which is normally of the order of 5 g for a human, so complexed Gd^{3+} is used, using a ligand that forms a very stable complex in vivo (this can also avoid precipitation as the hydroxide at physiological pH) so a gadolinium complex is used, with a ligand that forms a very stable complex.

Complexes of polyaminocarboxylic acids such as $[Gd(DTPA)(H_2O)]^{2-}$ (Figure 31; gadopentetate dimeglumine; Magnevist) or $[Gd(DOTA)(H_2O)]^-$ (gadoterate meglumine;

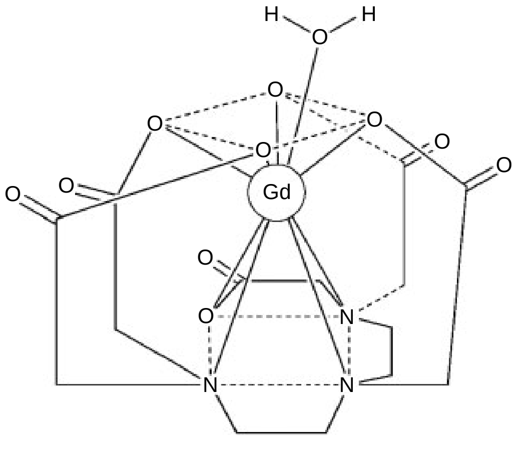

Figure 31 The structure of $Gd(DTPA)(H_2O)^-$

Dotarem) have been widely used; these meet most of the above criteria. Both neutral and charged complexes are used, the former having less osmotic effect and the latter being more hydrophilic, so that amide derivatives like [Gd(DTPA-BMA)(H_2O)] (gadodiamide; Omniscan) have advantages.

This complex again has a nine-coordinate lanthanide; because of the greater denticity of DTPA compared to EDTA, only one water molecule is coordinated in the solid-state structures of Na_2[Gd(dtpa)(H_2O)] Similar ions are present in the Ba[Gd(dtpa)(H_2O)] and $(CN_3H_6)_2$[Gd(dtpa)(H_2O)] and in Ba[Nd(dtpa)(H_2O)]. On the other hand, a few salts are known, like $(NH_4)_2$[Gd(dtpa)](H_2O), which have no water coordinated in the solid state. In $(NH_4)_2$[Gd(dtpa)](H_2O), a hydrogen-bonding network involving the ammonium ions causes Gd(dtpa) units to associate into dimers, in contrast to the monomeric nature of Na_2[Gd(dtpa)(H_2O)]. Similarly, Cs_4 $[Dy(dtpa)]_2$ has an unusual dimeric structure in which Dy is nine-coordinate (as in other dtpa complexes) but with the ninth coordination position occupied by a bridging carboxylate, rather than a water molecule. These disparate solid-state structures reflect the fine balance of forces influencing which species crystallises.

The structure found in salts like Na_2[Gd(dtpa)(H_2O)] is thought to represent the species found in solution – data from a number of measurements on solutions containing $[Ln(dtpa)(H_2O)_n]^{2-}$ species, such as luminescence spectra of the Eu and Tb analogues, indicate that one water molecule is coordinated. A wide variety of complexes of amide derivatives of DTPA have also been synthesised, in order to create neutral species.[111,112] Using $[Gd(DTPA)(H_2O)]^{2-}$ it has been shown that these complexes get absorbed by the DNA of the cell they have been used to locate and that they could act as an agent for neutron capture cancer therapy.

Dipicolinates (pyridine-2,6-dicarboxylates) have been investigated in some detail with structures determined for several tris complexes such as $Na_3[Nd(dipic)_3]\cdot15H_2O$ and $Na_3[Yb(dipic)_3]\cdot13H_2O$, typical of the early and later lanthanides, respectively. The lanthanides have essentially tricapped trigonal prismatic coordination geometries, isostructural along the lanthanide series; they have been the subject of important solution NMR studies. Mono and bis complexes can also be synthesized; the mono complex $[Nd(dipic)(H_2O)_4]$ ClO_4 has a polymeric structure in which each picolinate is bound to three different (nine-coordinate) neodymium ions.

3.7.14 Other Complexes of S-Donors[4,5]

As relatively hard acids, Ln^{3+} ions would not be expected to complex readily with soft donor atoms like sulfur. Apart from the thiolates discussed in (see Section 'Polypyrazolylborates'), several types of complex with chelating ligands such as dithiophosphates and dithiocarbamates have been synthesized by reaction in nonpolar solvents. These fall into two main classes, $Ln(S_2Q)_3$ and $[Ln(S_2Q)_4]^-$ (Q = R_2NC (dithiocarbamate) or R_2P (dithiophosphate)). Several crystal structures have been determined; $[Ln(S_2PCy_2)_3]$ (Ln = Sm, Pr) have distorted trigonal prismatic six-coordination, whereas on passing to the Dy and Lu analogs the geometry tends more towards octahedral. In $Et_4N[La(S_2CNEt_2)_4]$, the geometry is distorted dodecahedral while $(Ph_4P)[Pr(S_2PMe_2)_4]$ is reported to have a distorted square-antiprismatic coordination geometry. $(Ph_4As)[M(S_2PEt_2)_4]$ (M = La, Er) have a near-perfect dodecahedral coordination, as does Na $[Eu(S_2CNMe_2)_4]$. Eight-coordination is also confirmed for $(Ph_4P)[Eu(S_2P(OEt)_2)_4]$ and $[Me_2NH_2]$ $[Nd(S_2CNMe_2)_4]$. A number of adducts have been synthesised in which coordination is primarily by sulphur, $Ln(S_2CNR_2)_3$(bipy) and $Ln(S_2CNR_2)_3$(phen); these are discussed in (Section 3.7.10).

A few complexes with sulfur-based crown ether ligands have been characterized, with reaction of $LaI_3(thf)_3$ with 9S3 in MeCN affording eight-coordinate $[LaI_3(9S3)(MeCN)_2]$.[113]

3.8 Coordination Chemistry of the +2 and +4 States

Although relatively limited compared to that of the tripositive metal, these have remained relatively undeveloped until recently; with increasing emphasis on the use of nonaqueous solvents, many discoveries in the +2 state for Eu, Sm, and Yb in particular probably remain to be made.[4,5]

3.8.1 The +2 State

The zinc reduction of Eu^{3+} to Eu^{2+}, followed by its precipitation as the sulfate, is a traditional step in the separation of europium from other lanthanides. In general, the solubilities of the 'inorganic' compounds of the Ln^{2+} ions resemble those of the corresponding compounds of the alkaline earth metals (insoluble sulfate, carbonate, hydroxide, oxalate). Both europium and the Sm^{2+} and Yb^{2+} ions can also be prepared by other methods (e.g. electrolysis), although these solutions of the latter two metals tend to be short-lived and oxygen-sensitive in particular. Eu^{2+} is the only divalent aqua ion with any real stability in solution. Several divalent lanthanides can, however, be stabilized by the use of nonaqueous solvents such as HMPA and THF, in which they have characteristic colors, quite distinct from those for the isoelectronic trivalent ions on account of the decreased term separations.

3.8.2 Complexes

A large number of complexes of O-donors, particularly of SmI_2 have been examined, on account of the widespread use of SmI_2 as a 1-electron reductant in organic synthesis. HMPA has been widely used as the solvent, as it brings about a large increase in rate; HMPA is suspected to be a carcinogen, therefore alternative solvents (and ligands) have been investigated, so the structures of a number of complexes, both of hmpa and other O-donors, have been investigated, shedding light on SmI_2-promoted reactions. As

a rule, these compounds of amide ligands have a coordination number 6, suggesting steric effects at work, in addition to pointing to strong electron-donating power of the ligands; the coordination number of samarium(II) is usually in the range 7–9. Starting materials for these iodide complexes are usually $[LnI_2(thf)_n]$ (Ln = Sm, Yb, Eu) are useful starting materials; these can readily be made from the lanthanide and ICH_2CH_2I.

Changing reaction conditions and the solvent used can alter the stoichiometry of the product. The initial product of crystallisation of SmI_2 from thf is pentagonal bipyramidal $[SmI_2(thf)_5]$; other seven-coordinate complexes obtained using mixtures of thf and dimethoxyethane are $[SmI_2(thf)_3(dme)]$ and $[SmI_2(thf)(dme)_2]$. YbI_2 reacts with 4.5 mols HMPA in thf forming $[Yb(HMPA)_4(thf)_2]\ I_2$; a similar reaction with SmI_2 affords $[Sm(HMPA)_4I_2]$. Excess HMPA gives $[Sm(HMPA)_6]I_2{\cdot}SmI_2(thf)_2$ reacts with 2 mols of tetramethylurea forming all-*trans*-$[SmI_2(tmu)_2(thf)_2]$, but excess tmu does not replace the other thf ligands. Another complex to be isolated is *trans*-$[SmI_2(dmi)_4]$ here all the thf groups have been substituted. On the other hand, use of 4 mols (i.e. a deficit on the stoichiometric amount) of dmpu causes displacement of the iodides from $SmI_2(thf)_2$ forming $[Sm(dmpu)_6]\ I_2$ where the cation has a distorted trigonal antiprismatic geometry; Sm–O distances are 2.475–2.488 Å; however, if just 2 mols of dmpu are used in the reaction, $[SmI_2(dmpu)_3(thf)]$ results, in which the iodides are trans- and the dmpu ligands have a mer- arrangement. These compounds all have six-coordinate Ln^{II}. Some simple complexes of N-donor ligands have not dissimilar structures. $[SmI_2(thf)_2]$ reacts with *N*-methylimidazole (*N*-Meim) forming $[SmI_2(N\text{-}Meim)_4]$. On recrystallisation from hot thf, this loses a molecule of *N*-Meim and dimerises, forming $[\{SmI(\mu\text{-}I)(N\text{-}Meim)_3\}_2]$. Eu behaves similarly in forming $[EuI_2(N\text{-}Meim)_4]$ and $[\{EuI(\mu\text{-}I)(N\text{-}Meim)_3\}_2]$. LnI_2 (Ln = Sm, Yb) reacts with substituted pyridines in thf forming $[LnI_2(pyridine)_4]$; $[LnI_2(3,5\text{-lutidine})_4]$ (Ln = Sm, Yb) and $[YbI_2(4\text{-}t\text{-Butpy})_4]$ were determined; all have trans-structures.

The developing coordination chemistry of Sm(II) has thrown up interesting cases of isomerism. Reaction of $SmI_2(thf)_2$ with diglyme results in the isolation of *trans*-$[SmI_2\{O(CH_2CH_2OMe)_2\}_2]$, whilst the *cis*-isomer was obtained as a by-product in the reaction of SmI_2 with *t*-BuOK in diglyme. These were the first examples to be isolated of geometric isomers in an eight-coordinate complex.[114] The Sm–O distances in *cis*-$[SmI_2\{diglyme\}_2]$, fall into the range 2,653–2.699 Å, averaging 2.68 Å, which is slightly shorter than the value for the trans-isomer. The Sm–I distances in the *cis*-isomer, however, at 3.332–3.333 Å, are significantly longer than those in *trans*-$[SmI_2\{diglyme\}_2]$ (3.265 Å). In another study, reaction of SmI_2 with 1,2-diiodoethane at 50 °C yields $[SmI_2(dme)_3]$. Crystallisation at −20 °C affords racemic $[SmI_2(dme)_3]$, whilst crystallisation from solution at ambient temperature yields a mixture of crystals of the two different enantiomers. It was suggested that interactions between methyl groups prevent ready interconversion.

The ytterbium (II) complex $[Yb(NCS)_2(thf)_2]$ exhibits a rich range of oxidative addition reactions[115] affording complexes such as $Yb(NCS)_3(thf)_4$, $Yb(NCS)_3(Odpp)(thf)_3$ (HOdpp = 2,6-diphenylphenol), and $Yb(NCS)_2(Cp)(thf)_3$. It reacts with CCl_3CCl_3 forming $Yb(NCS)_2Cl(thf)_4$, which turns out to have the solid-state structure $[YbCl_2(thf)_5]^+\ [Yb(NCS)_4(thf)_3]^-$ in contrast to the monomer $Yb(NCS)_3(thf)_4$. Oxidation of $Yb(NCS)_2(thf)_2$ with TlO_2CPh initially affords a solvated form of $Yb(NCS)_2(O_2CPh)$ which then gives a mixture of $Yb(NCS)_3(thf)_4$ and dimeric $[[Yb(NCS)(O_2CPh)_2(thf)_2]_2]$. The thf ligands in $Yb(NCS)_2(thf)_2$ can be replaced by dme forming 8-coordinate $Yb(NCS)_2(dme)_3$.

The first simple Tm(II), Nd(II) and Dy(II) complexes have been synthesised recently. Reaction of Nd and Dy with I_2 at 1500 °C followed by dissolution of the product affords $[LnI_2(dme)_3]$ and $[LnI_2(thf)_5]$ (Ln = Nd, Dy). $[NdI_2(thf)_5]$ has the familiar pentagonal bipyramidal structure with axial iodines. $[TmI_2(dme)_2(thf)]$ has a similar coordination geometry.[116]

Among complexes with multidentate ligands, a few lanthanide(II) diketonates are known. $[Eu(tmhd)_2(dme)_2]$, has been made by reaction of $[EuI_2(thf)_2]$ with Kthd in thf, evaporation and crystallisation from DME; $[Sm(tmhd)_2(dme)_2]$ is made by a similar route.

A number of crown ether complexes exist. Thus $[Eu(benzo\text{-}15\text{-}crown\text{-}5)_2]\ (ClO_4)_2$ has been synthesised by electrochemical reduction of a solution of $Eu(ClO_4)_3$ and benzo-15-crown-5 in $MeOH/H_2O$. It contains 10-coordinate europium, with Eu–O distances in the range 2.662 (3)–2.728 (4) Å. This compound exhibits strong luminescence, taking on a violet hue in daylight. $[Eu(12\text{-}crown\text{-}4)(H_2O)_3Cl]Cl$ has eight-coordinate Eu; europium is 10-coordinate in the $[Eu((15\text{-}crown\text{-}5)_2)]^{2+}$ ion and in $[Eu(18\text{-}crown\text{-}6)(ClO_4)_2]$. Two Sm(II) complexes have been made. $[Sm(15\text{-}crown\text{-}5)_2]\ (ClO_4)_2$ has a sandwich structure with samarium bound to two 15-crown-5 molecules, whilst in $[Sm(18\text{-}crown\text{-}6)(ClO_4)_2]$ the metal cation is again 10-coordinate, bound to six oxygen atoms of the crown ligand and four oxygen atoms from two perchlorates.[117]

The Eu(II) edta complex $Na_3[Eu(edta)]Cl{\cdot}7H_2O$ is in fact polymeric in the solid state with europium bound to two nitrogens and to six carboxylate oxygens. $[(NH_2)_3]_3\ [Eu^{II}(dtpa)(H_2O)]{\cdot}8H_2O$ is isostructural with the Sr analogue. Perhaps unexpectedly, in solution, $[Eu^{II}(dtpa)(H_2O)]^{3-}$ is less stable to oxidation than Eu^{2+} (aq).

A number of aryloxides employing bulky ligands have been explored in some detail. The thf adducts $Yb(O2,6\text{-}Bu^t_2\text{-}4\text{-}Me\text{-}C_6H_2)_2(thf)_2$ are tetrahedral while $Yb(O2,6\text{-}Bu^t_2\text{-}4\text{-}Me\text{-}C_6H_2)_2(thf)_3$ are five- coordinate with square-pyramidal structures. $[Sm(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_2(thf)_3]{\cdot}thf$ and $[Sm(OC_6H_3Bu^t_2\text{-}2,6\text{-}Me\text{-}4)_2(thf)_3]$ are both five-coordinate trigonal bipyramidal.

The bis(silylamide) complexes $Ln\{N(SiMe_3)_2\}_2$ and their adducts with Lewis bases such as thf and tertiary phosphines

tend to be three- and four-coordinate. $Yb\{N(SiMe_3)_2\}_2$ is a dimer with two bridging alkylamides, giving three-coordination and $[Eu\{N(SiMe_3)_2\}_3]^-$ likewise is three-coordinate (surprisingly, planar, unlike the Eu^{III} analog), while $M\{N(SiMe_3)_2\}_2L_2$ (L = PBu_3, thf; L_2 = dmpe) are four-coordinate and $Eu\{N(SiMe_3)_2\}_2(glyme)_2$ is six-coordinate. $[Sm(N(SiMe_3)_2)_2(thf)_2]$ has significant short-Sm···C distances, evidence for agostic interactions (*see Agostic Bonding*). In $[Sm(NPh_2)_2(thf)_4]$, the coordination geometry approximates to trigonal prismatic (*see Trigonal Prism*).

Polypyrazolylborates have been extensively investigated.**[104]** $[Ln(Tp)_2(thf)_2]$ and $[Ln(Tp^{Me2})_2]$ (Ln = Eu, Sm, and Yb) have been synthesised; the latter are very insoluble and are usually purified by sublimation in the cases of the Eu and Yb compounds. The six-coordinate $[Sm(Tp^{Me2})_2]$ undergoes a range of 1- electron transfer reactions. In its wide range of oxidations, it forms $[Sm(Tp^{Me2})_2X]$ (X = Cl, Br, F) by halogen abstraction from organic compounds, and $[Sm(Tp^{Me2})_2]$ I by iodine oxidation. Reaction with $TlBPh_4$ gives $[Sm(Tp^{Me2})_2]$ BPh_4·$[Sm(Tp^{Me2})_2]$ cleaves dichalcogenides REER forming $[Sm(Tp^{Me2})_2(ER)]$ (R e.g. Ph, E = S, Se), and reacts with azobenzene forming $[Sm(Tp^{Me2})_2(N_2Ph_2)]$ where the Tp^{Me2} ligands remain tridentate. $[Sm\{Tp^{Me2}\}_2]$ reacts with dioxygen forming the first lanthanide superoxo complex $[Sm\{Tp^{Me2}\}_2(\eta^2\text{-}O_2)]$. It undergoes a one-electron oxidation with $[Hg(C{\equiv}CPh)_2]$ forming monomeric seven-coordinate $[Sm(Tp^{Me2})_2(C{\equiv}CPh)]$. Using the bulkier hydrotris(3-*t*-butyl-5-methylpyrazolyl) borate ligand ($Tp^{tBu,Me}$), it is still possible to obtain bis complexes with $Tp^{tBu,Me}$, but $[Ln(Tp^{tBu,Me})_2]$ (Ln = Sm, Yb) shows two different mode of ligand bonding; one is a conventional η^3-ligand, the other is bound via two nitrogen atoms and an agostic B–H···Sm interaction. The NMR spectrum of $[Yb(Tp^{tBu,Me})_2]$ shows ^{171}Yb–HB coupling, confirming that the agostic interaction persists in solution.

A number of organophosphides and organoarsenides of divalent lanthanides have been synthesised, with a certain similarity to the amides. $[YbI_2(thf)_2]$ and $[Yb\{N(SiMe_3)_2\}_2(thf)_2]$ react with $KPPh_2$ forming $[Yb(PPh_2)_2(thf)_4]$; the thf can be displaced by *N*-methylimidazole forming *trans*-$[Yb(PPh_2)_2$(*N*-Methylimidazole)$_4]$. These compounds, together with $[Eu(PPh_2)_2$(*N*-Methylimidazole)$_4]$, $[Sm(PPh_2)_2$(*N*-Methylimidazole)$_4]$, $[Yb(P(mesityl)_2)_2(thf)_4]$, $[Sm(P(mesityl)_2)_2(thf)_4]$ and $[Sm(As(mesityl)_2)_2(thf)_4]$ all having trans-octahedral structures.

Some compounds with heavier group 16 donor atoms have lately been reported, of the type $Yb(SAr)_2(DME)_2$ (six-coordinate) and $Ln(QMes)_2(thf)_n$ (Ln = Yb, Sm, Eu; Q = Se, Te). Transmetallation of Sm and Eu with $Hg(SC_6F_5)_2$ affords $Sm(SC_6F_5)_3$ and $Eu(SC_6F_5)_2$ respectively; these have the solid-state structures $[(thf)_2Sm(\mu_2\text{-}SC_6F_5)(SC_6F_5)_2]_2$ and $[(thf)_2Eu(\mu_2\text{-}SC_6F_5)_2]_n$, the latter being a 1-dimensional polymer; these undergo thermal decomposition to LnF_3. Ytterbium reacts with organic disulphides forming $[Yb(SAr)_2(py)_2]$ (Ar = 2,4,6-triisopropylphenyl). A sterically crowded Yb^{II} thiolate $[Yb(SAr^*)_2(thf)_4]$ (Ar^* = 2,6-$Trip_2C_6H_3$, where Trip is 2,4,6-$^iPr_3C_6H_2$) has the trans-structure now becoming familiar for these Ln^{II} systems. The overcrowding caused by the sterically encumbered Ar^* ligands is reflected in the large Yb–S–C angle of 151.16°. The unsolvated compound is formally two-coordinate, but there are η^6-π-interactions present. Lanthanide(II) selenolate and tellurolate complexes, usually obtained as etherates, are possible precursors to lanthanide monochalcogenides. $M(TePh)_2$(M = Yb, Eu) crystallize as 1-dimensional polymers like $[(thf)_2Eu(TePh)_2]_\infty$ and $[(thf)_2Yb(TePh)_2{\cdot}0.5(thf)]_\infty$. $[Ln(ESi(SiMe_3)_3)_2(tmeda)_2]$ (Ln = Eu, Yb; E = Se, Te) have been reported; the ytterbium tmeda complexes eliminate $E(Si(SiMe_3)_3)_2$ at 200 °C affording YbSe and YbTe. $Ln(SePh)_2$ reacts with selenium (rather as the trivalent analogues do) in dme forming heterovalent clusters $[Ln_4Se(SePh)_8(dme)_4]$ (Ln = Sm, Yb, Nd^{III}/Yb^{II}, Sm^{III}/Yb^{II}) which contain a square of lanthanide ions with a capping selenide.

A variety of halometallates exist. For example, Rb_4TmI_6, synthesised by heating a mixture of RbI, Tm, and HgI_2, has the K_4CdI_6 structure with trigonal antiprismatic coordination of Tm. $RbYbI_3$ has a structure based on edge-sharing $[YbI_6]$ octahedra. Reduction of MX_3 (M = Sm, Dy, Tm, Yb; X = Br, I) with alkali metals, In and Tl (A) leads in general to the ternary compounds AMX_3 and AM_2X_5; some similar compounds with divalent metals (Ca, Sr, Ba) have also been made. $LiDy_2Br_5$, prepared by reduction of $DyBr_3$ with Li metal at 700 °C, is isostructural with $LiDy_2Cl_5$, $LiYb_2Cl_5$ and $LiLn_2Br_5$ (Ln = Sm, Tm).

3.8.3 The +4 State

Cerium is the only lanthanide with an extensive chemistry in this oxidation state. The cerium(+4) aqua ion, obtained by acid dissolution of CeO_2, is thermodynamically unstable (E = 1.6 V in 1 M HNO_3); the reduction potential is anion-sensitive, indicating that complexes are present rather than a simple aqua ion. The salts $Ce(NO_3)_4{\cdot}5H_2O$ and $CeSO_4{\cdot}4H_2O$ can be crystallized from solution, the former probably having 11-coordinate $Ce(NO_3)_4(H_2O)_3$ molecules like the thorium analog. The most familiar nitrate complex is $(NH_4)_2Ce(NO_3)_6$, a traditional oxidizing agent in titrimetry and in organic chemistry as well as a convenient synthetic starting material. The $Ce(NO_3)_6{}^{2-}$ ion has 12-coordinate cerium while cerium is 10-coordinate in the $Ce(CO_3)_5{}^{6-}$ ion. $MgCe(NO_3)_6{\cdot}8H_2O$ and $K_2Ce(NO_3)_6$ containing 12-coordinate $[Ce(NO_3)_6]^{2-}$ ions too. Hydrated cerium(IV) triflate dehydrates on stirring with triflic anhydride. It is potentially a valuable source of other Ce^{IV} compounds. The iodates $Ce^{IV}HIO_6{\cdot}4H_2O$ and $MCe^{IV}IO_6{\cdot}nH_2O$ (M = alkali metal) have also been made.

A number of fluoride complexes have been made, both by crystallization for the ammonium salts like $(NH_4)_4CeF_8$, which has square-antiprismatic coordination of cerium, also found in the $(CeF_6{}^{2-})_\infty$ chains in $(NH_4)_2CeF_6$, its thermal decomposition product. $(NH_4)_3CeF_7{\cdot}H_2O$ acquires dodecahedral eight-coordination by dimerization. $(NH_4)_4[CeF_8]$ can

also be made by fluorination of cerium oxide with NH_4HF_2. Alkali-metal cerates M_2CeF_6 and M_3CeF_7 (M = alkali metal) are moisture sensitive and are made by fluorination of MCl/CeO_2 mixtures. Several hexachlorocerate(IV) salts are known, perhaps the most convenient starting material for further syntheses being the $(H_2\ diglyme_3)^+$ salt, made from the reaction of CeO_2 with $SOCl_2$ in diglyme; these react with HBr to give moisture-sensitive $CeBr_6{}^{2-}$ salts. Ce^{IV} is presumably too strongly oxidizing to coexist with I^- as no corresponding iodocerates have been made.

A number of neutral complexes of O-donor Lewis bases have been made, such as 10-coordinate $Ce(NO_3)_4(Ph_3PO)_2$, and octahedral $CeCl_4L_2$ (L = Ph_3PO, Ph_3AsO, HMPA, urea, t-Bu_2SO). The Ph_3PO complex is *cis*, like the uranium analog, while X-ray diffraction study of the (*trans*) HMPA complex shows a close structural correspondence to the corresponding U^{IV} compound.

Cerium(III) tris(β-diketonate) complexes are readily oxidized to the cerium(IV) compounds. They are volatile with vapor pressures high enough for MOCVD use. A number of diketonates are now better characterised, prompted by the possibility of using them as CVD materials and petrol additives, as well as a source of cerium oxide as an oxygen store for catalytic converters. $[Ce\{Me_3CCOCHCOCMe_2(OMe)\}_4]$, $Ce(acac)_4$ (Figure 32), $Ce(dbm)_4$, $[Ce(pmhd)_4]$, and $Ce(tmhd)_4$ all have square-antiprismatic coordination of cerium (in the $[Ce(catecholate)_4]^{4-}$ ion the coordination is dodecahedral).

The alkoxides $Ce(OR)_4$ are another well-developed class of Ce^{IV} compounds. The alkoxide group plays an important role in stabilising the Ce(IV) state, witness the existence of $[CeCp_2(OBu^t)_2]$ and $[CeCp_3(OBu^t)]$, when other Ce(IV) organometallics cannot be isolated. The isopropoxide is volatile in vacuo below 200 °C (its bis(isopropanol) adduct has six-coordinate cerium). General methods are available to make many $Ce(OR)_4$ (R e.g. Me, Et, OPr^i, n-C_8H_{17}):-

$$(NH_4)_2Ce(NO_3)_6 + 4ROH + 4NH_3 \longrightarrow Ce(OR)_4 + 6NH_4NO_3 \quad (12)$$

$$(NH_4)_2Ce(NO_3)_6 + 4ROH + 6NaOMe \longrightarrow Ce(OR)_4 + 6NaNO_3 + 2NH_3 + 6MeOH \quad (13)$$

As usual, many of these are oligomers, though coordinative saturation can be achieved by adduct formation. Crystals of $[Ce(OSiPh_3)_4(DME)]$ display octahedral coordination of cerium with Ce–O (Si) 2.10–2.14 Å and two rather long Ce–O (ether) bonds at 2.58–2.59 Å. Although the solid is air- and moisture-stable, it undergoes immediate reaction with Hacac forming $Ce(acac)_4$. Thermal desolvation of $[Ce(OPr^i)_4(HOPr^i)_2]$ affords $[Ce_4O(OPr^i)_{14}]$, which has the structure $[Ce_4(\mu_4\text{-}O)(\mu_3\text{-}OPr^i)_2(\mu\text{-}OPr^i)_8(OPr^i)_{14}]$. $(NH_4)_2Ce(NO_3)_6$ reacts with $NaOCMe_3$ forming various products, including $Na_2Ce(OCMe_3)_6(DME)_2$ which has octahedral $[Ce(OCMe_3)_6]^{2-}$ ions surrounded by $Na(DME)^+$ ions.

The first Ln(IV) amides have been made.[118] Although it cannot be oxidised with Cl_2, $[Ce(N(SiMe_3)_2)_3]$ reacts with $TeCl_4$ forming $[CeCl(N(SiMe_3)_2)_3]$; this has a trigonal pyramidal structure, with Ce 0.36 Å out of the N_3 basal plane (and, interestingly a 0.05 Å lengthening of the N–Si bond). PPh_3Br_2 reacts with $[Ce(N(SiMe_3)_2)_3]$ forming the isostructural $[CeBr(N(SiMe_3)_2)_3]$. Another Ce(IV) amide was synthesised by iodine oxidation of a cerium(III) compound of a triamidoamine, affording a notable compound with a rare Ce^{IV}-I linkage; analogous oxidation with X_2 (X = Cl, Br) yields mixed-valence dimers (Figure 33).[119]

2,4,6-tri-t-butylpyridyl-1,3,5-triazine (L) reacts with $(NH_4)_2[Ce(NO_3)_6]$ forming 11-coordinate $[Ce(L)(NO_3)_4]$. In contrast to the other lanthanides, cerium forms genuine bis(porphyrin) and bis(phthalocyanine) complexes with the metal in the +4 oxidation state. Solution NMR shows that the two porphyrin rings do not rotate with respect to each other even at 140 °C.

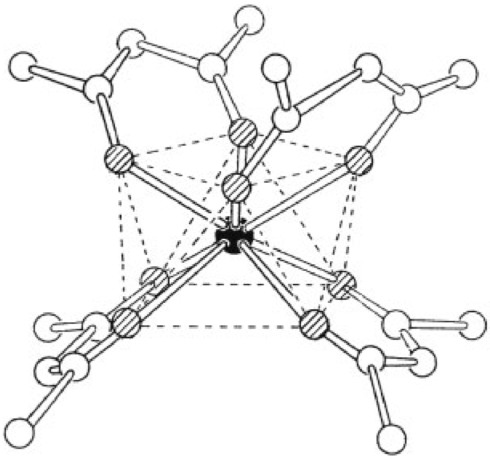

Figure 32 The structure of $Ce(acac)_4$

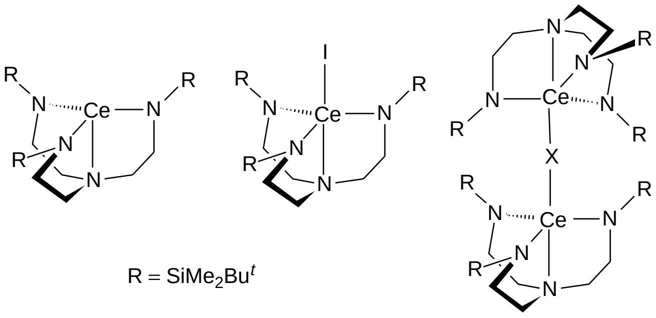

Figure 33 Cerium complexes of a tripodal triamidoamine ligand

4 PROMETHIUM

On account of this element's rarity, a separate account of it is desirable.[120,121] Although the existence of promethium was predicted as early as 1913, it was not definitely discovered until 1945, since all isotopes are radioactive with the longest-lived isotope having a half-life of 17.7 years (^{145}Pm). It is a fission product of ^{238}U and is thus obtained on work-up of reprocessing wastes.

Although early attempts to identify it in lanthanide ores were not successful, it has been detected at the level of 4×10^{-15} g kg^{-1} in Congolese pitchblende. It has also been detected at a low level in apatite (10^{-11} g from 6 million kg mineral), although it may have originated there from neutron irradiation of neodymium or by spontaneous fission of ^{238}U.

Relatively little is known about the chemistry of promethium, although the established facts highlight the resemblance of promethium to the lanthanides that flank it. The halides are well defined, and have been shown to have the expected structures (Table 2). Thus in a recent study, starting with some 100 µg of Pm_2O_3, the halides were synthesized microchemically, using the reaction with fluorine for PmF_3 and the reaction with HX (X = Cl, Br) for the chloride and bromide; the latter two reacted with HI to give the iodide. Pm_2O_3 is one of the few lanthanide oxides to crystallize in three modifications.[122]

It would be expected that promethium would form some stable compounds in the +2 oxidation state, but no definite evidence has yet been obtained since studies have been hindered both by the small quantities available and by its radioactivity.

5 LANTHANIDES IN ORGANIC SYNTHESIS

Lanthanide complexes have increasingly been used as reagents,[123,124] two of the main areas being SmI_2 as a one-electron reducing agent[125,126] and the use of lanthanide triflates (and scandium triflate especially) as reusable water-soluble Lewis Acid catalysts.[127,128]

6 USES OF THE LANTHANIDES[3,129,130]

There are increasingly numerous uses of these metals that make use of particular electronic, magnetic, and optical properties of individual lanthanides; most current applications involve the earlier rather than the later metals, there being no major uses for the metals Ho–Lu at present.

The main optical uses are in lasers, phosphors, and lenses. The single most important phosphors contain europium(III) in a yttrium host such as Y_2O_2S, which is used for the red phosphor in TV color screens; other phosphors are used (Tm, Tb) in X-ray image intensifying screens. Neodymium-doped yttrium–aluminum garnet (YAG) is an important laser material, whilst erbium-YAG lasers are starting to be used in cosmetic skin resurfacing. Erbium-doped fibre amplifiers are becoming significant in telecommunications. Neodymium-containing glass is used in protective goggles, owing to its absorption around 580 nm. while La_2O_3 is used in manufacturing optical glass of a high refractivity. CeO_2 is used in polishing glass and also in decolourising glass.

Principal magnetic uses employ either the samarium–cobalt or $Nd_2Fe_{14}B$ permanent magnet materials. The latter give slightly stronger products and employ materials with more assured supply, but the samarium magnets can be used at much higher temperatures.

There are a number of current optical and magnetooptical applications and several at the development stage. The use of LaB_6 in electron guns has long been established, as has that of yttrium–iron garnet (YIG) in microwave devices, while gadolinium–gallium garnet is used for bubble memory storage devices. Developing uses include yttrium-stabilized zirconia (YSZ) in particular as a solid electrolyte and as an oxygen-sensor in automobile exhaust systems, rare-earth-doped barium titanates in thermistors, and $LaNi_5$ in rechargeable batteries. Yttrium–barium copper oxide and other lanthanide-containing oxides are likely to become important commercially in warm superconductors.

Probably the biggest use in terms of quantity is that of lanthanide-exchanged zeolites as cracking catalysts in the petrochemical industry (mainly La and Ce), using about 500 t a day in the USA alone.

Because of its high refractive index and hardness, YSZ is a superior material for artificial diamonds to YAG, also used for this purpose. The praesodymium–neodymium mixture known as didymium is traditionally used to color welders' goggles (as well as a strengthening agent for Mg-based alloys). Several lanthanide oxides, particularly Nd_2O_3, are used as glass-coloring agents. CeO_2 has been used as an ingredient of automobile catalytic converters and in self-cleaning ovens as an oxidation catalyst whose oxygen storage role is presumably a consequence of the ability of cerium to switch oxidation states.

Medical applications are so far limited in number, but gadolinium complexes of DTPA and other ligands have become highly important injectible MRI contrast agents (*see* ***Metal-based Imaging Agents***). The luminescent properties of the lanthanides are becoming exploited in luminescent sensors and bioassays.

7 TOXICITY OF THE LANTHANIDES[35,131]

The lanthanides are generally not regarded as particularly toxic. Studies on animals indicate that the toxicity depends

on how the lanthanide was introduced. Little appears to be absorbed in oral ingestion although it appears considerably more toxic in intravenous administration. Inhalation of vapor and dust should be avoided as solid compounds if inhaled tend to remain in the lungs and are only slowly ingested on account of their insolubility (This could be an occupational hazard in lanthanide refining and in 'new' lanthanide industries.) Lanthanides tend to accumulate in the liver, spleen, kidneys, and bone.

The use of complexed Gd^{3+} in MRI relies on the high stability of the Gd–DTPA complex to maintain an extremely low level of free Gd^{3+}, but some side-effects have been observed using such ionic compounds, prompting current research to produce nonionic contrast agents.

Abbreviations

Cp = cyclopentadienyl (C_5H_5); Cp′ = general substituted or unsubstituted Cp; Cp* = pentamethylcyclopentadienyl (C_5Me_5); X_nCp = Cp with n Hs substituted by X; Ind = indenyl (C_9H_7); COT = cyclooctateraenyl (C_8H_8); Mes = mesityl ($C_6H_2Me_3$); Cy = cyclohexyl C_6H_{11}; Ln = lanthanide and group 3 metals.

1 INTRODUCTION

Organometallic compounds of the rare earth metals have been a curiosity till only a few decades ago. That changed in the last 20 years of the twentieth century after the availability of modern preparative and analytical techniques and with the discovery of the high potential of those compounds, which are all extremely sensitive to oxygen and water, as reagents in organic synthesis and as very active catalysts. Following the discovery of the tricyclopentadienyl derivatives of the lanthanides by *Wilkinson* and *Birmingham* in 1954,[1] most of the organolanthanide compounds prepared during the first 20 years have been sandwich complexes (*see Sandwich Compound*), containing unsubstituted or substituted cyclopentadienyl ligands. In contrast, cyclopentadienyl-free organolanthanide compounds, like alkyl or aryl derivatives, alkenyl, alkynyl, allyl, hydrido, and carbene complexes, as well as cyclooctatetraenyl, pentadienyl derivatives, and lanthanidocenes with nitrogen and phosphorus containing heterocycles, which are incredibly active catalysts, developed new fields in organolanthanide chemistry recently, establishing a new area of organometallic chemistry.

The research in this field has been well documented in review articles[2–6] and a book.[7] Recent reviews concerning the state of the art in 2002 can be found in the special issue of Chemical Reviews: Frontiers in Lanthanide Chemistry.[8]

This article discusses the preparation, structure, and chemistry of rare earths complexes with bonds to carbon. An emphasis is given to compounds prepared and characterized after EIC1 appeared in 1994 up to the end of 2003, but only papers, which appeared after 2000, are cited in the reference list. Inorganic compounds that may be bonded through carbon, such as carbides (*see* ***Carbides: Transition Metal Solid-state Chemistry***) or cyanides (*see* ***Cyanide Complexes of the Transition Metals*** and ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***), are also excluded as well as the chemistry of rare earth cations with organic compounds in the gas phase. While at the moment of finishing this chapter for EIC-I most organo rare earth complexes have been cyclopentadienyl derivatives, the development of this area of organometallic chemistry produced new classes of compounds in the common oxidation state Ln(III) as well as in the more unusual oxidation states Ln(0), Ln(I), Ln(II), and Ln(IV) in recent years. Therefore the organization of this chapter is somewhat different compared to EIC1. The use of organolanthanides as reagents in organic synthesis as well as in catalysis is not covered here, although Ln to carbon bonds may be involved in these processes. Those subjects have been treated in comprehensive book articles recently, for example, for organolanthanides in organic synthesis[9] and in catalysis.[10]

2 LANTHANIDE COMPLEXES WITH σ-BONDED HYDROCARBYL LIGANDS

Over the years the homoleptic (*see Homoleptic Compound*) alkyl and aryl complexes were one of the major challenges in organolanthanide chemistry. The simplest organometallic

compounds of the rare earths are the solvated or solvent-free species LnR_2 or LnR_3 with the rare earth metals in their common oxidation states Ln^{2+} and Ln^{3+}. This is usually insufficient to meet the lanthanides' demands of steric saturation through high coordination numbers. The isolation and characterization of compounds belonging to this class were achieved using bulky alkyl ligands. When less bulky alkyl ligands are used, *ate* complexes containing more then three alkyl ligands attached to the metal $[R_{3+n}Ln]^{n-}$ are often formed. Mono- and dialkylcomplexes of the lanthanides are more frequent than homoleptic complexes, because in those cases the bulky ancillary ligands were usually used for the coordinative saturation of the metal center. This section deals only with Ln(III)-alkyl derivatives, for alkyl complexes of the divalent lanthanides see Section 11. Two reviews appeared for work up to 1994[3] and up to 2001.[11]

2.1 Complexes with Three and More σ-Bonded Hydrocarbyls

The reactions of $LnCl_3$ (Ln = Y, La, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu) with MeLi in Et_2O in the presence of TMEDA or DME yields *ate* complexes $[Li(L)]_3[LnMe_6]$ (L = TMEDA, DME) (equation 1).

$$LnCl_3 + 6MeLi + 3TMEDA \xrightarrow[-3LiCl]{Et_2O} [Li(TMEDA)]_3[LnMe_6] \quad (1)$$

The crystal structure of $[Li(TMEDA)]_3[LnMe_6]$ (Ln = Ho, Er) and $[Li(DME)]_3[LuMe_6]$ shows an octahedral $LnMe_6$ arrangement with Me bridges to the Li atoms (Figure 1). Alkylation of $(L)LnCl_3$ (Ln = Sc, Y; L = 1,4,7-trimethyl-1,4,7-triazacyclononane) with MeLi in THF gives the corresponding species $(L)Ln(CH_3)_3$, and the reaction of $LuCl_3$ with NaCp* and LiMe in THF in the presence of TMEDA yields $[Li(TMEDA)_2][Cp^*LuMe_3]$, showing the Lu atom tetrahedrally coordinated by the Cp* ring and the three Me groups.[11]

Homoleptic (*see Homoleptic Compound*) complexes $Ln(CH_2SiMe_3)_3(THF)_n$ (M = Sm, Y, $n = 3$; Tb, Er, Yb, Lu, $n = 2$) were prepared by the reactions of the respective $LnCl_3$ with Me_3SiCH_2Li in THF (equation 2 and 3). $Yb(CH_2SiMe_3)_3(THF)_2$ and the related neopentyl derivative $Yb(CH_2{}^tBu)_3(THF)_2$ are formed by the reaction of

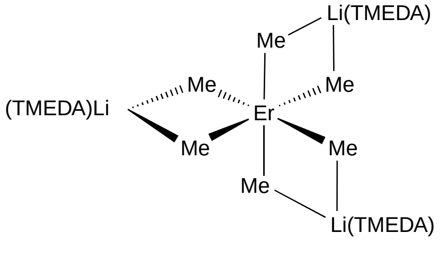

Figure 1 Structure of $[Li(TMEDA)]_3[ErMe_6]$

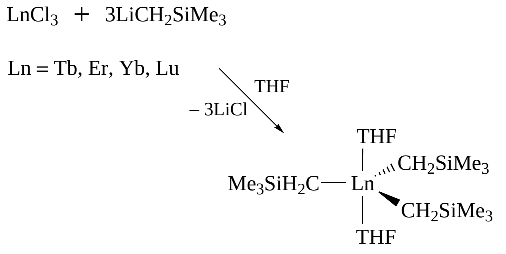
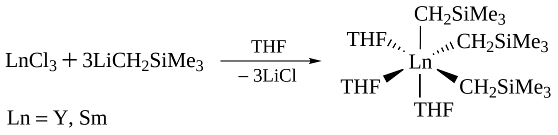
ytterbium metal with ICH_2SiMe_3 or neopentyl iodide in THF.[12] X-ray structural analyses of the Sm, Er, Yb, and Lu derivatives show the Sm atom in a *fac*-octahedral coordination and the heavier lanthanides Er, Yb, and Lu trigonal bipyramidally coordinated with three alkyl ligands in equatorial and two THF molecules in axial positions (equation 2).[13] The tris(trimethylsilylmethyl)scandium and -yttrium derivatives are thermally unstable. The bulky $PhMe_2SiCH_2$ ligand allows the isolation of thermally more robust analogues $Ln(CH_2SiMe_2Ph)_3(THF)_2$ (M = Sc, Y).[14] Reaction of $Ln(CH_2SiMe_3)_3(THF)_2$ (Ln = Y, Lu) with $B(C_6X_5)_3$ (X = H, F) in the presence of crown ethers yields cationic lanthanide-alkyl complexes, for example, $[Ln(CH_2SiMe_3)_2(CE)(THF)_n]^+$ $[B(CH_2SiMe_3)(C_6X_5)_3]^-$ (CE = 12-crown-4, $n = 1$; CE = 15-crown-5 and 18-crown-6, $n = 0$) (equation 3).[15] The use of four equivalents of $LiCH_2SiMe_3$ results in the formation of *ate* complexes $[Li(TMEDA)_2][Ln(CH_2SiMe_3)_4]$ (Ln = Y, Er, Yb). Similar homoleptic tetrakis-alkyl anions are formed when YCl_3 reacted with 2 equiv. of $LiCH_2SiMe_3$ and 2 equiv. of $LiOCMe_3$ to yield $\{(Me_3SiCH_2)_x(Me_3CO)_{1-x}Y(\mu\text{-}OCMe_3)_4[Li(THF)]_4(\mu_4\text{-}Cl)\}^+$ $[Y(CH_2SiMe_3)_4]^-$.[11]



(2)



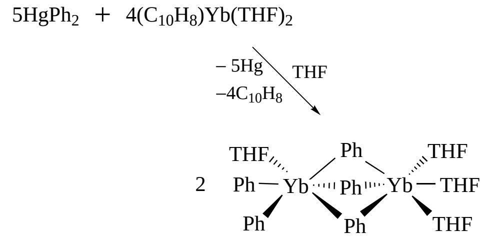
(3)

A number of analogous bis(trimethylsilyl)methyl lanthanide complexes have also been reported. $[(Et_2O)_3Li(\mu\text{-}Cl)Y\{CH(SiMe_3)_2\}_3]$ and the solvent-free $Y[CH(SiMe_3)_2]_3$ have been prepared and structurally characterized recently.[3,11]

Mixed lanthanide metal(III) alkyl complexes $R_3Ln(\mu\text{-}Me)Li(pmdeta)$ [Ln = La, Sm; R = $CH(SiMe_3)_2$; pmdeta = $MeN(CH_2CH_2NMe_2)_2$] were prepared from LnR_3, LiMe, and pmdeta. The reaction of $YbCl_3$ with 3-(dimethylamino) propyllithium in THF affords the *ate* complex $Li[(Me_2NCH_2\text{-}CH_2CH_2)_4Yb]$, in which two Me_2N groups intramolecularly chelate the Yb atom whereas the other two donor functions are coordinated to lithium.

Homoleptic aryl-lanthanides are less studied then alkyl complexes. After the first lanthanide aryl complex $[Li(THF)_4][Lu(C_6H_3\text{-}2,6\text{-}Me_2)_4]$, neutral triphenyllanthanides $Ph_3Ln(THF)_3$ (Ln = Er, Tm, Yb) were synthesized in THF by reaction of metallic lanthanides with Ph_2Hg or

Ph_3Bi in the presence of catalytic amounts of LnI_2 or LnI_3. X-ray diffraction studies showed that these compounds represent monomeric complexes with a distorted *fac*-octahedral arrangement of ligands around the Ln atom. Transmetallation of $(C_{10}H_8)Yb(THF)_2$ with Ph_2Hg or Ph_3Bi in THF affords $Ph_2(THF)Yb(\mu\text{-}Ph)_3Yb(THF)_3$ (equation 4)

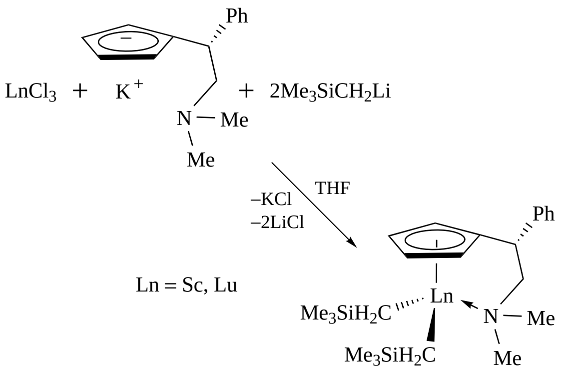


(4)

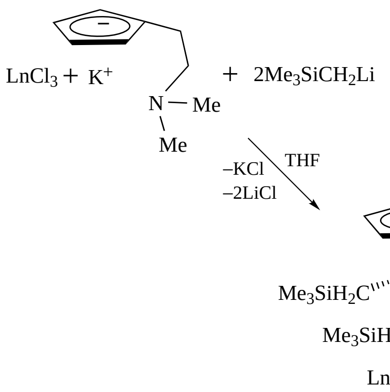
The X-ray crystal structure analysis of $Ph_3Sc(THF)_2$ reveals a trigonal-bipyramidal coordination sphere with the THF molecules in axial positions. The 1:1 or 2:1 reactions of $Li[C_6H_3\text{-}2,6\text{-}(O^iPr)_2]$ with anhydrous $SmCl_3$ in THF gave $[2,6\text{-}(^iPrO)_2C_6H_3]_3Sm$ exclusively, while the 3:1 reaction gave $[2,6\text{-}(^iPrO)_2C_6H_3]_4SmLi$ as the major product, which has been characterized by X-ray crystallography.[11]

2.2 Complexes with Two η^1-Bonded Hydrocarbyls

Dibenzylyttrium bromides like $[(TMEDA)(PhCH_2)_2\text{-}Y(\mu\text{-}Br)_2Li(TMEDA)]$ are formed from YBr_3 and $PhCH_2Li(TMEDA)$.[11] Different ancillary ligands provide stabilization of bis(alkyl)lanthanide derivatives such as described earlier in $Cp_2Lu(\mu\text{-}Me)_2Li(TMEDA)$, $[Cp^*_2\text{-}Lu(CH_2SiMe_3)_2][Li(DME)_2]$, and $[Cp_2Y(CH_2SiMe_3)_2]_2\text{-}Li_2(DME)_2(dioxane)$.[6] The reactions of $ScCl_3$ and $LuCl_3$ with one equiv. of $K[(S)\text{-}C_5H_4CHPhCH_2NMe_2]$ or $K[C_5H_4CH_2CH_2NMe_2]$ followed by two equiv. of $LiCH_2\text{-}SiMe_3$ yield the complexes $[(S)\text{-}C_5H_4CHPhCH_2NMe_2]\text{-}Ln(CH_2SiMe_3)_2$ (equation 5) and $(C_5H_4CH_2CH_2NMe_2)\text{-}Ln(CH_2SiMe_3)_2$ (equation 6), respectively.[16]



(5)



(6)

$SmBr_3$ and $GdBr_3$ react with $NaCH_2Ph$ and KCp* in THF to give $[Cp^*_2Sm(CH_2Ph)_2K(THF)_2]_\infty$ and $Cp^*Gd(CH_2Ph)_2(THF)$, respectively.[11] Rare earth metal complexes of the type $Ln\{\eta^5:\eta^1\text{-}C_5Me_4SiMe_2(C_4H_3O\text{-}2)\}(CH_2Si\text{-}Me_3)_2(THF)$ (Ln = Y, Lu) (Figure 2a) were prepared by alkane elimination reaction of $Ln(CH_2SiMe_3)_3(THF)_2$ with the 2-furyl-functionalized tetramethylcyclopentadiene. Reaction of these dialkyl complexes with BPh_3 in THF give thermally stable cations $[Ln\{\eta^5:\eta^1\text{-}C_5Me_4SiMe_2(C_4H_3O\text{-}2)\}(CH_2SiMe_3)(THF)_n]^+$.[17] The in situ generated $Sc(CH_2SiMe_3)_3(THF)_2$ reacts with the protonated hydrotris-pyrazolylborate ligands (*see Tris(pyrazolyl)borates*) $Tp^{Me,Me}H$ and $Tp^{tBu,Me}H$ affording $(Tp^{Me,Me})Sc(CH_2SiMe_3)_2$ and $(Tp^{tBu,Me})Sc(CH_2SiMe_3)_2$ (Figure 2b), respectively. Treatment of $(Cp_2YCl)_2$ with two equiv. of 2-dimethylaminomethylferrocenyl lithium Li(FcN) affords the heterotrimetallic complex $Li[Cp_2Y(FcN)_2]$ (Figure 2c).[6,11]

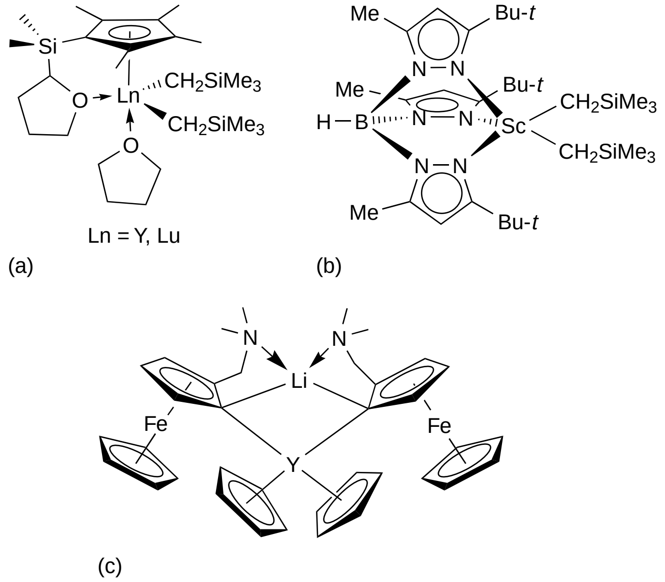


Figure 2 (a) $Ln\{\eta^5:\eta^1\text{-}C_5Me_4SiMe_2(C_4H_3O\text{-}2)\}(CH_2SiMe_3)_2\text{-}(THF)$ (Ln = Y, Lu), (b) $(Tp^{tBu,Me})Sc(CH_2SiMe_3)_2$, and (c) $Li[Cp_2\text{-}Y(FcN)_2]$

Addition of RLi (R = Me, Et, and CH_2SiMe_3) to $ScCl_2(THF)[N(SiMe_2CH_2P^iPr_2)_2]$ gives bis-alkyl derivatives $R_2Sc[N(SiMe_2CH_2P^iPr_2)_2]$. The X-ray structural analysis of $Et_2Sc[N(SiMe_2CH_2P^iPr_2)_2]$ and $(Me_3SiCH_2)_2Sc$-$[N(SiMe_2CH_2P^iPr_2)_2]$ show mononuclear molecules with distorted trigonal-bipyramidal geometries.[11] The alkane elimination reaction between $Y(CH_2SiMe_2Ph)_3(THF)_2$ and 1 equiv. of salicylaldimine (LH) results in the formation of the dialkyl derivatives $LY(CH_2SiMe_2Ph)_2(THF)$ (Figure 3a).[14] Bis-alkyl derivatives $(L')Ln(CH_2SiMe_3)_2(THF)$ (Ln = Sc or Y) were obtained by the reaction of equimolar amounts of the related salicylaldimine ligand 2-(2,4,6-$Me_3C_6H_2N$=CH)(6-^{t}Bu)C_6H_3OH (L′H) with $Ln(CH_2SiMe_3)_3(THF)_3$. The trigonal-bipyramidal structure of the scandium dialkyl complex was confirmed crystallographically.[11] The scandium alkyl complexes are efficient catalysts for the ring-opening polymerization of ε-caprolactone.[18] The ß-diketiminate complex $(L)_2CeCl$ [L = N(R)C(Ph)C(H)C(Ph)NR; R = $SiMe_3$] reacts with either one or two equiv. of $Li(CHR_2)$ in Et_2O, forming $(L)Ce[CH(SiMe_3)_2]_2$ (Figure 3b).[11]

Several diorganoscandium complexes stabilized by the ß-diketiminato ligands (Ar)NC(R)CHC(R)N(Ar) (L′: Ar = 2,6-$^iPr_2C_6H_3$, R = CH_3; L″: Ar = 2,6-$^iPr_2C_6H_3$, R = ^{t}Bu) have been reported. Thus, reactions of the lithium salts of the ligands L′ and L″ with $ScCl_3(THF)_3$ lead to the complexes $(L')ScCl_2(THF)_n$ and $(L'')ScCl_2(THF)_n$, which are readily alkylated with various organolithium compounds or Grignard reagents to form the dialkyl derivatives $(L')ScR_2$ (R = $PhCH_2$, $^tBuCH_2$ and Me_3SiCH_2) and $(L'')ScR_2$ (R = CH_3, CH_3CH_2, $PhCH_2$, $^tBuCH_2$ and Me_3SiCH_2). Most of them are isolated as base-free, four-coordinate complexes and characterized via X-ray crystallography. Steric interactions between Ar and the Sc-alkyl groups force the scandium to adopt an out-of-plane bonding mode.[19] The reaction of $(L')ScMe_2$ with 1 equiv. of $B(C_6F_5)_3$ yields monomeric monomethyl cations $[(L)ScMe]^+$ $[MeB(C_6F_5)_3]^-$.[20] The reaction of $[(L)LuCl_2(\mu\text{-Cl})(\mu\text{-Li(THF)}_2)]_2$ [L = 2,6-$(Me_2NCH_2)_2C_6H_3$] with Me_3SiCH_2Li gives the monoalkyl complex $[(L)Lu(\mu\text{-Cl})(CH_2SiMe_3)]_2$, which reacts with a second equiv. of Me_3SiCH_2Li to produce the bis-alkyl complex $(L)Lu(CH_2SiMe_3)_2$ (Figure 4a).[11] YCl_3 reacts with the lithium salt of an anilido-imine ligand and 2 equiv. of $LiCH_2SiMe_2R$ (R = Me, Ph) yielding monomeric bis(alkyl)yttrium complexes $(L)Y(CH_2SiMe_2R)_2$ (R = Me, Ph) (Figure 4b).[21]

The sequential reaction of YCl_3 with $Li[^tBuC(N^iPr)_2]$ and 2 equiv. of $LiCH(SiMe_3)_2$ form the mono(amidinate) dialkyl yttrium complex $[^tBuC(N^iPr)_2]Y[CH(SiMe_3)_2]_2(\mu\text{-Cl})Li(THF)_3$. Using the tridentate amidinate-amine ligand $PhC(NSiMe_3)N(CH_2)_2NMe_2$ (L) results in the formation of the salt-free dialkyl complex $(L)Y[CH(SiMe_3)_2]_2$ (Figure 5a). Attempts to prepare analogous benzyl or CH_2SiMe_3 complexes yielded the *ate* complexes $Li[(L)_2YR_2]$ (R = CH_2Ph, CH_2SiMe_3).[22] The reaction between aza-18-crown-6 (H-MAC) and $Y(CH_2SiMe_3)_3(THF)_2$ proceeded via elimination of $SiMe_4$, yielding $Y(MAC)(CH_2SiMe_3)_2$ (Figure 5b).[11] Yttrium dialkyl complexes supported by tetradentate ligands [N,N'-R_2-tacn-N''-$(CH_2)_2N^tBu$] (R = Me, tacn = 1,4,7-triazacyclononane) have been prepared analogously using H-tacn (Figure 5c).[23]

Mixed dialkyl-alkoxide complexes are also known, for example, $(Me_3SiCH_2)Sm[(\mu\text{-OAr})(\mu\text{-CH}_2SiMe_3)Li(THF)]$-$[(\mu\text{-OAr})_2Li(THF)]$ (Ar = 2,6-$^iPr_2C_6H_3$), containing a pentacoordinate Sm center ligated by one terminal and one bridging CH_2SiMe_3 and three bridging 2,6-$^iPr_2C_6H_3$ ligands. The anionic dialkyl–diaryloxide complex $[(Me_3SiCH_2)_2Lu(OC_6H_3{}^tBu_2\text{-}2,6)_2][Li(THF)_4](THF)_2$ has a distorted tetrahedral coordination geometry around both

Figure 5 (a) (L)Y[$CH(SiMe_3)_2$]$_2$, (b) Y(MAC)(CH_2SiMe_3)$_2$, and (c) [tacn]Y(CH_2SiMe_3)$_2$

metals, whereas the related complex [$(Me_3Si)_2CH$]$_2$Y(μ-O^{t}Bu)$_2$Li(THF) has a distorted tetrahedral coordinated yttrium and a trigonal planar lithium. The reaction of YCl_3 with 2 equiv. of $LiCH_2SiMe_3$ and 1 equiv. of $LiOC_6H_3{}^tBu_2$-2,6 in THF forms the neutral dialkyl aryloxide complex $(Me_3SiCH_2)_2Y(OC_6H_3{}^tBu_2\text{-}2,6)(THF)_2$. The coordination geometry around Y is distorted trigonal bipyramidal with the THF groups in the apical positions.[11]

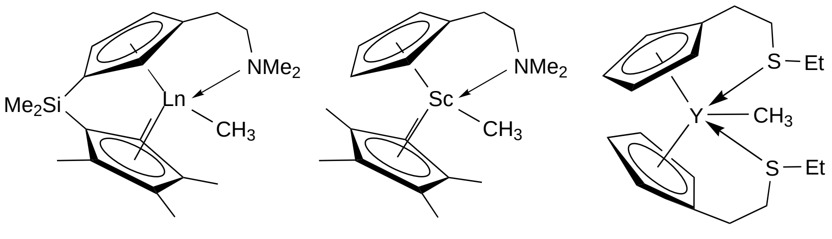
2.3 Complexes with One η^1-Bonded Hydrocarbyl Ligand

Organolanthanides of this class, especially dicyclopentadienyl derivatives Cp_2LnR are the most effective catalysts for olefin polymerization and they are selective and effective reagents for organic synthesis.[9,24,25] They were prepared by alkylation of Cp_2LnCl or by treatment of methylaluminates $Cp_2Ln(\mu\text{-}Me)_2AlMe_2$ with equimolar amounts of pyridine.[6,25] More recently [$(C_5H_4SiMe_2R)_2Ln(\mu\text{-}Me)$]$_2$ (R = ^{t}Bu, Ln = Y, Sm, Lu; R = Me, Ln = Y, Sm, Lu), [η^5-1,3-$C_5H_3(SiMe_3)_2$]$_2$LnMe(THF) (Ln = Sm, Lu),[26] {[1,3-$(Me_3Si)_2C_5H_3$]$_2$LnMe}$_2$ (Ln = Sm, Nd),[27] *rac*-[O(CH_2CH_2-C_9H_6)$_2$]$LnCH_2SiMe_3$ (Ln = Y, Lu), [$Me_2Si(C_5Me_4)(C_5H_3$-$CH_2CH_2NMe_2$)]LnMe (Ln = Y, Ho, Lu) (Figure 6a), Cp*($C_5H_3CH_2CH_2NMe_2$)ScMe (Figure 6b), Cp*($C_5H_3CH_2$-CH_2NMe_2)LnMe (Ln = Nd, Sm, Ho, Lu), Cp*($C_5H_3CH_2$-CH_2NMe_2)$LuCH_2SiMe_3$, $(C_5H_4CH_2CH_2SEt)_2YMe$ (Figure 6c), and Cp*($C_5H_4CH_2CH_2SEt$)$LuMe$[28] have been described. Single-crystal X-ray structure analysis of the N- and S-donor functionalized complexes showed that donor atoms are intramolecularly coordinated to the metal. {[1,3-$(Me_3Si)_2C_5H_3$]$_2$LnMe}$_2$ (Ln = Sm, Nd) performs the living polymerization of methylmethacrylate and the block copolymerization of L-lactide with ε-caprolactone in high yields in the absence of any cocatalysts.[29] Lanthanidocene methyl complexes are effective precatalysts for the hydrosilylation of alkenes and alkynes.[24]

Dimeric [$(C_4Me_4P)_2LnCH(SiMe_3)_2$]$_2$ (Ln = Nd, Sm) supported by the 2,3,4,5-tetramethylphospholyl ligand can be prepared in a one-pot procedure starting from $LnCl_3$, K(C_4Me_4P), and $LiCH(SiMe_3)_2$. Reaction of $(C_4Me_4P)_2LnCH(SiMe_3)_2$ with H_2 gives $(C_4Me_4P)_2NdH$ with Ln = Nd, in the case of Ln = Sm, reduction to $(C_4Me_4P)_2Sm$ takes place.[11]

$(Me_3Si)_2CH$ derivatives can be prepared as monomeric alkali salt- and solvent-free complexes, like Cp*$_2LnCH(SiMe_3)_2$ (Ln = La, Nd, Sm, Lu), $(C_5Me_4Et)_2LnCH(SiMe_3)_2$ (Ln = Y, Nd, Sm), ($C_5Me_4{}^i$Pr)$_2$-$LnCH_3$(THF) (Ln = Y, Sm), ($C_5Me_4{}^i$Pr)$_2$Ln{$CH(SiMe_3)_2$} (Ln = Y, Sm), $Me_2Si(C_5Me_4)_2LnCH(SiMe_3)_2$ (Ln = Y, Nd), [$R_2Si(C_5H_4)(C_5Me_4)$]$LnCH(SiMe_3)_2$ (Ln = Y, Lu), and (*R*)- and (*S*)-$Me_2Si(C_5Me_4)(C_5H_3R^*)LnCH(SiMe_3)_2$ [Ln = Y, Sm; R* = (+)-neomenthyl or (−)-menthyl]. However, alkylation of the bis(cyclopentadienyl)lanthanide halides with MeLi or Me_3SiCH_2Li often produces the *ate* complexes, for example, $Cp_2Ln(\mu\text{-}Me)_2Li(TMEDA)$, Cp*$_2Ln(\mu\text{-}Me)_2Li(THF)_2$, Cp*$_2Ln(\mu\text{-}Me)_2Li(THF)_2$, Cp*$_2Ln(\mu\text{-}CH_2SiMe_3)_2Li(DME)_2$, and $(C_5H_4SiMe_3)_2Ln(\mu\text{-}Me)_2Li(THF)_2$.[8]

Compounds Cp*$_2LnCH(SiMe_3)_2$ can be converted to the highly reactive hydrides (Cp*$_2$LnH)$_2$ by reaction with

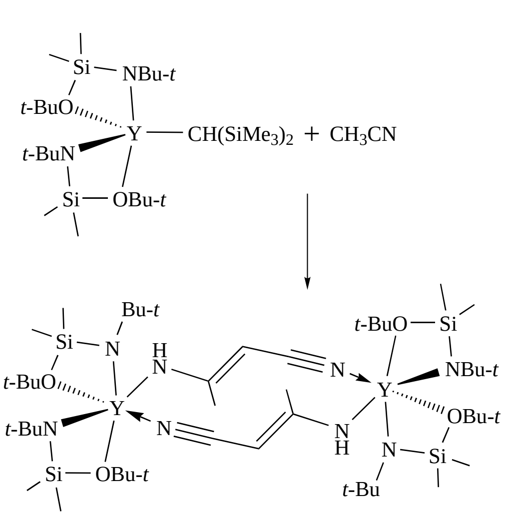


(a) (b) (c)

Figure 6 (a) [$Me_2Si(C_5Me_4)(C_5H_3CH_2CH_2NMe_2)$]LnMe, (b) Cp*($C_5H_3CH_2CH_2NMe_2$)ScMe, (c) $(C_5H_4CH_2CH_2SEt)_2YMe$

hydrogen. For instance, $(Cp^*{}_2YH)_2$ metalates pyridine selectively in *ortho*-position to yield $Cp^*{}_2Y$(2-pyridyl), which further reacts with ethylene or propylene to give the monoinsertion products $Cp^*{}_2YCH_2CH_2(2\text{-}NC_5H_4)$ and $Cp^*{}_2YCH_2CHMe(2\text{-}NC_5H_4)$, respectively. With 2-butyne, the propargylic metallation product $Cp^*{}_2YCH_2C{\equiv}CMe$ was obtained.

$[Me_2Si(N^tBu)(O^tBu)]_2YCH(SiMe_3)_2$ reacts with N≡CMe via C–H activation forming $[\{Me_2Si(N^tBu)(O^tBu)]_2Y(\mu\text{-}(N,N')\text{-}NHCMe{=}CHCN)\}_2$ (equation 7). With pyridine and picoline, the metallation of either cyclic or exocyclic positions yields pyridyl and picolyl complexes, $[Me_2Si(N^tBu)(O^tBu)]_2YR$ (R = η^2-(C,N)-2-NC_5H_4, η^2-(C,N)-CH_2-2-NC_5H_4, η^2-(C,N)-C(H)Me-2-NC_5H_4, η^2-(C,N)-C(H)Me-2-NC_5H_3-6-Me), respectively.



(7)

The reaction of the half-sandwich complex (*see Half-sandwich Complexes*) $(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)Y(CH_2SiMe_3)(THF)$ with furan and thiophene yields $[(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)Y(\mu_2\text{-}C_4H_3E)]_2$ (E = O, S) (Figure 7). In contrast to THF and pyridine, DME forms isolable, crystalline adducts $(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)Y(2\text{-}C_4H_3E)(DME)$. The reaction of $[Y(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)(CH_2SiMe_3)(THF)]$ with excess DME yields the five-coordinate complex $[Y(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)(CH_2SiMe_3)(DME)]$ that does not react with furan or thiophene, indicating an associative mechanism.[30]

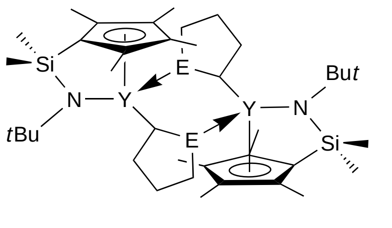


Figure 7 $[(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)Y(\mu_2\text{-}C_4H_3E)]_2$ (E = O, S)

The dimeric rare earth hydrides based on the same Cp/amide 'constrained geometry' ligand $[Ln(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)(THF)(\mu\text{-}H)]_2$ (Ln = Y, Yb) react with an excess of α-olefins $H_2C{=}CHR$ (R = Et, ^{n}Pr, ^{n}Bu) in a 1,2-insertion manner to give the series of THF-free dimeric *n*-alkyl complexes $[Ln(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)(\mu\text{-}CH_2CH_2R)]_2$. Single-crystal X-ray diffraction studies on $[Y(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NCMe_2R')(\mu\text{-}CH_2CH_2R)]_2$ (R′ = Me, R = Et, ^{n}Bu; R′ = Et, R = Et, ^{n}Pr) and $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N^tBu)(\mu\text{-}CH_2CH_2{}^nBu)]_2$ revealed that the centrosymmetric dimeric complexes consist of two trans arranged $[Ln(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NCMe_2R')]$ fragments connected by two μ-alkyl ligands, showing an agostic interaction (*see Agostic Bonding*) of the ß-CH_2 hydrogen atoms of the *n*-alkyl groups with the formally 12-electron lanthanide metal center. α-Olefins having two or more substituents on the γ-carbon do not react with the hydride complexes.[31] The scandium complex $[C_5H_3(1\text{-}SiMe_2N^tBu)(3\text{-}CH_2CH_2NMe_2)]Sc(CH_2SiMe_3)$ was prepared via alkane elimination by treatment of in situ generated $Sc(CH_2SiMe_3)_3$ with the free ligand.

A number of chelating polydentate N-based ligands are useful to stabilize monoalkyl lanthanide complexes. The synthetic approach is alkane elimination from tris(alkyl)lanthanide precursors by treatment with protonated N-ligands. Deprotonation of *N*,*N*-dihydro-4,13-diaza-18-crown-6 (H_2DAC) with $Y(CH_2SiMe_3)_3$ yields the salt-free monoalkyl derivative $(DAC)Y(CH_2SiMe_3)$ (Figure 8), which is related to $(MAC)Y(CH_2SiMe_3)_2$ (Figure 5b).[11]

The reaction of $(DAC)Y(CH_2SiMe_3)$ with PhC≡CH produces a mixture of the alkynide-coupled butatrienediyl complex $[(\mu\text{-}DAC)Y]_2(\mu\text{-}(Z)\text{-}PhC{=}C{=}C{=}CPh)$ and the uncoupled bridging alkynide dimer $[(DAC)Y(\mu\text{-}C{\equiv}CPh)]_2$. Reaction of $Lu[CH(SiMe_3)_2]_3$ with octaethylporphyrin (H_2OEP) affords $(OEP)Lu[CH(SiMe_3)_2]$. Its crystal structure showed a highly bowl-shaped porphyrin skeleton with the square-pyramidal, five-coordinate lutetium atom 0.918 Å out of the N_4 plane of the porphyrin ligand. Monoalkyl diamide complexes $(BDPPpyr)Ln(CH_2SiMe_3)(THF)_n$ (n = 1, Ln = Sc (Figure 9a), Lu; n = 2, Ln = Y), $(BMespyr)Ln(CH_2SiMe_3)(THF)_n$ (n = 1, Ln = Sc; n = 2, Ln = Lu), and $(BDPPoxyl)Ln(CH_2SiMe_3)(THF)$ (Ln = Sc (Figure 9b), Lu, Y) were prepared from 2,6-bis[{(2,6-diisopropylphenyl)amino}methyl]pyridine ($H_2BDPPpyr$), 2,6-bis[(mesitylamino)methyl]pyridine ($H_2BMespyr$), or 1,2-bis[{(2,6-diisopropylphenyl)amino}methyl]benzene ($H_2BDPPoxyl$) respectively using $Ln(CH_2SiMe_3)_3$.[32]

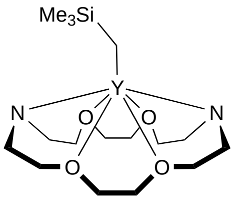

Figure 8 $(DAC)Y(CH_2SiMe_3)$

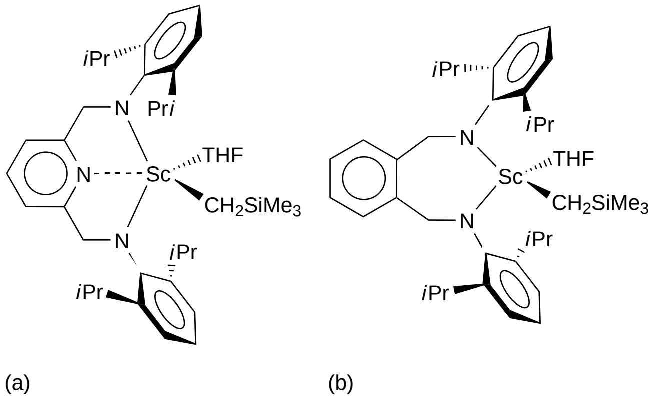

Figure 9 (a) (BDPPpyr)Sc(CH_2SiMe_3)$(THF)_n$ and (b) (BDPPoxyl)Sc(CH_2SiMe_3)(THF)

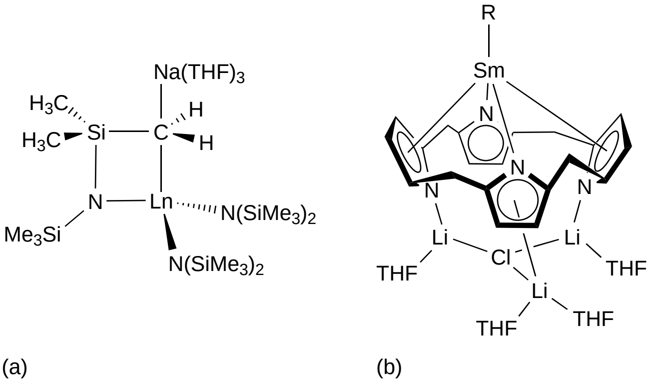

Figure 11 (a) $[(Me_3Si)_2N]_2LnN(SiMe_3)SiMe_2CH_2Na(THF)_3$ and (b) (Et_8-calix-pyrrole)(R)Sm(μ_3-Cl)[Li(THF)]$_2$[Li(THF)$_2$] (R = Me, CH=CH$_2$)

$[ArN(CH_2)_3NAr]Y[CH(SiMe_3)_2](THF)$ (Ar = 2,6-iPr$_2$-C_6H_3) is formed by alkali metal–salt elimination. The '*ate*-complex' is not formed because of the low solubility of KI and its complete precipitation.[33] Yttrium bis(silylamido)biphenyl complexes [DADMB]YMe(THF)$_2$ and [DADMB]Y[CH(SiMe$_3$)$_2$](THF)(OEt$_2$) (DADMB = 2,2′-bis[(*tert*-butyldimethylsilyl)amido]-6,6′-dimethylbiphenyl) result from the reaction of [DADMB]YCl(THF)$_2$ and MeLi or (Me$_3$Si)$_2$CHLi, respectively. Both compounds react with PhSiH$_3$ or H$_2$ to give insoluble {[DADMB]Y(μ-H)(THF)}$_2$, which reacts rapidly with ethene or 1-hexene to give a single insertion product.[11]

Amidinate ligands stabilize monoalkyl lanthanide derivatives like [PhC(NSiMe$_3$)$_2$]$_2$YCH(SiMe$_3$)$_2$, [PhC(NSiMe$_3$)$_2$]-Y(μ-Me)$_2$Li(TMEDA), [p-MeOC$_6$H$_4$C(NSiMe$_3$)$_2$]$_2$YCH(SiMe$_3$)$_2$, [(Me$_3$Si)$_2$NC(N^{i}Pr)$_2$]$_2$YCH(SiMe$_3$)$_2$, [(Me$_3$Si)$_2$NC(N^{i}Pr)$_2$]$_2$Y(μ-Me)$_2$Li(TMEDA), [(Me$_3$Si)$_2$NC(N^{i}Pr)$_2$]$_2$Y(^{t}Bu),[34] [Me$_3$SiNC(Ph)N(CH$_2$)$_3$NC(Ph)NSiMe$_3$]Y[CH(SiMe$_3$)$_2$](THF),[35] {CyNC[N(SiMe$_3$)$_2$]NCy}$_2$LnCH(SiMe$_3$)$_2$ (Ln = Sm, Yb), [(Me$_3$Si)$_2$NC(N^{i}Pr)$_2$]$_2$Ln(μ-Me)$_2$Li(TMEDA) (Ln = Yb, Nd (Figure 10)),[36] [PhC(NSiMe$_3$)$_2$]$_2$ScR (R = CH$_2$SiMe$_3$, Mes), and [PhC(NSiMe$_3$)$_2$]$_2$ScMe(THF).

In THF, deprotonation of Ln[N(SiMe$_3$)$_2$]$_3$ (Ln = Sc, Yb, Lu) with NaN(SiMe$_3$)$_2$ leads to complexes containing a planar four-membered LnCSiN ring system with a linear Ln–C–Na arrangement (Figure 11a). Methyl- and vinyl-substituted Sm derivatives supported by a calix-tetrapyrrole ligand (Et$_8$-calix-pyrrole)(R)Sm(μ_3-Cl)[Li(THF)]$_2$[Li(THF)$_2$] (R = Me, CH=CH$_2$) (Figure 11b) were prepared by the reaction of (Et$_8$-calix-pyrrole)(Cl)Sm-[Li$_2$(THF)$_3$] with the corresponding organolithium reagents. The methyl derivative reacts with hydrogen affording the corresponding samarium hydride (Et$_8$-calix-pyrrole)(THF)Sm-[Li(THF)]$_2$(μ_3-H).[37]

Monoalkyl complexes, (L)LnCH$_2$SiMe$_3$ (L = 1,3-di[2-(N-isopropylamino)troponimine]propane, Ln = La, Lu) (Figure 12a)[38] and a scandium alkyl complex bearing a diamide–diamine donor ligand (Figure 12b) are also known.[39,40]

The neutral monobenzyl compound Cp*$_2$Y(CH$_2$Ph)(THF) was obtained by the reaction of YBr$_3$ with benzylpotassium and KCp* in THF.[11] Terphenyl complexes (Dmp)LnCl$_2$(THF)$_n$ [Dmp = 2,6-di(mesityl)phenyl; Ln = Sc,

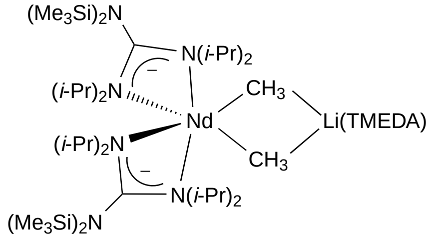

Figure 10 [(Me$_3$Si)$_2$NC(N^{i}Pr)$_2$]$_2$Nd(μ-Me)$_2$Li(TMEDA)

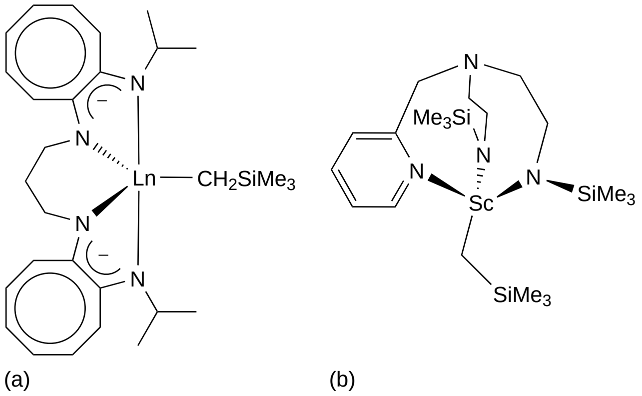

Figure 12 (a) (^{i}PrNC$_8$H$_6$NCH$_2$CH$_2$NC$_8$H$_6$N^{i}Pr)LnCH$_2$SiMe$_3$ and (b) [N(CH$_2$CH$_2$NSiMe$_3$)CH$_2$C$_5$H$_4$N]ScCH$_2$SiMe$_3$

Yb, $n = 2$; Ln = Y, $n = 3$] and (Dnp)$LnCl_2(THF)_2$ [Dnp = 2,6-di(1-naphthyl)phenyl, Ln = Yb, Tm, Y] were prepared in THF from $LnCl_3$, and (Dmp)Li and (Dnp)Li, respectively. The Dnp complexes are monomeric with distorted trigonal-bipyramidal (Sc and Yb) or octahedral (Y) coordination geometry about the metal atom, with the two Cl atoms occupying the axial positions.[41] Complexes (Dnp)$LnCl_2(THF)_2$ (Ln = Yb, Tm, Y) exhibit distorted trigonal-bipyramidal coordination environments at the metal center, with the two O atoms of the THF ligands occupying the axial positions of a trigonal-bipyramidal coordination polyhedron.[42] The complexes with donor-functionalized terphenyl ligands [(Danip)Yb(μ-Cl)$_2$(μ_3-Cl)Li(THF)]$_2$ and [(Danip)Ln(μ_2-Cl)$_2$(μ_2-Cl)Li(THF)$_2$]$_2$ (Ln = Y, Sm; Danip = 2, 6-di(*o*-anisol)phenyl) are obtained from the reaction of equimolar amounts of (Danip)Li and $LnCl_3$ (Ln = Yb, Y, Sm) in THF. These complexes are dimeric and composed of lithium chloride–bridged (Danip)$LnCl_2$ moieties, stabilized through additional coordination of two methoxy functions to the lanthanide atom.[43] The structurally characterized lanthanidocene terphenyl derivatives $(C_5H_4Me)_2YbR$ and Cp_2SmR [R = 2,6-(2,4,6-$Me_3C_6H_2)_2C_6H_3$] were obtained by the reaction of RLi with $(C_5H_4Me)_3Yb$ or Cp_3Sm in toluene.[11]

$Cp^*{}_2SmPh(THF)$ is available by transmetalation between $Cp^*{}_2Sm(THF)_2$ and Ph_2Hg. The solvent-free complex $[Cp^*{}_2SmPh]_2$ thermally decomposes to yield benzene and the phenylene-bridged disamarium complex $Cp^*{}_2Sm$(μ-1,4-C_6H_4)$SmCp^*{}_2$.[44] $SmBr_3$ reacts with $Li^+{}_2(biph)^{2-}$ in THF to form dimeric [(quaph)SmBr(THF)$_2$]$_2$ (quaph = o-quaterphenyl) in which both Sm atoms are coordinated by a quaph ligand each and two THF molecules besides two bridging Br atoms resulting in a distorted octahedral coordination of the Sm atoms (Figure 13).[12]

$Cp_3La(THF)$ reacts with Li[$C_6H_3(CH_2NMe_2)_2$-2,6] yielding Cp_2La[$C_6H_3(CH_2NMe_2)_2$-2,6] (Figure 14a); lanthanide complexes with the related mono-(Me_2N)-substituted phenyl ligand, (COT)Ln(THF)($C_6H_4CH_2NMe_2$-2) (Ln = Er, Lu) and Cp_2Y($C_6H_4CH_2NMe_2$-2), were prepared by alkylation of (COT)LnCl(THF) and Cp_2YCl, respectively, with $LiC_6H_4CH_2NMe_2$-2; reactions of $LnCl_3$ (M = Er, Yb, Lu) with 3 equiv. of $LiC_6H_4CH_2NMe_2$-2 gave the homoleptic tris(aryl)lanthanides Ln($C_6H_4CH_2NMe_2$-2)$_3$; and treatment of $(Cp^*{}_2SmH)_2$ with 2-phenyl-1-pyrroline causes

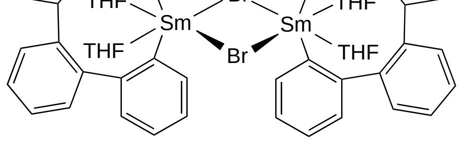

Figure 13 [(quaph)SmBr(THF)$_2$]$_2$ (quaph = o-quaterphenyl)

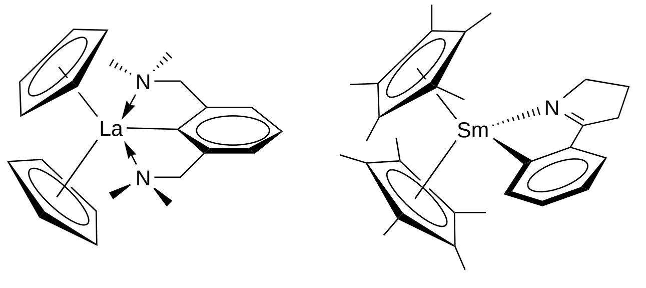


(a) (b)

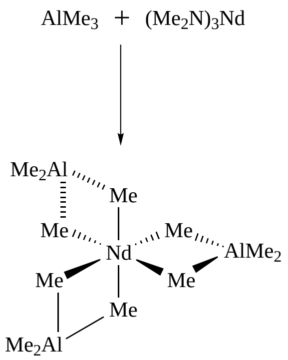
Figure 14 (a) $Cp_2LaC_6H_3(CH_2NMe_2)_2$ and (b) $Cp^*{}_2SmC_6H_4$-C_4H_6N-2

orthometalation (*see Orthometalation*) resulting in the formation of $Cp^*{}_2SmC_6H_4$(2-NC_4H_6) (Figure 14b).

The first organolanthanide alkynide complexes [Cp_2Ln(μ-C≡C ^{t}Bu)]$_2$ (Ln = Er, Yb) were synthesized by the halide-free reactions of [Cp_2Ln(μ-Me)]$_2$ with HC≡C ^{t}Bu.[6] Alkynide bridged complexes [(^{t}BuCp)$_2$Ln(μ-C≡CPh)]$_2$ (Ln = Nd, Gd) were prepared similarly. According to X-ray data for the Er, Nd, and Gd complexes, the two Cp_2Ln units of the dimers are connected by asymmetric alkynide bridges. Dimeric [$(MeC_5H_4)_2$SmC≡C ^{t}Bu]$_2$ has been synthesized from $(MeC_5H_4)_2SmCl$ and LiC≡C ^{t}Bu in THF. The early lanthanide alkyls $Cp^*{}_2LnCH(SiMe_3)_2$ (Ln = Ce, La) react with terminal alkynes HC≡CR (R = Me, ^{t}Bu) to produce oligomeric acetylides [$Cp^*{}_2$LnC≡CR]$_n$ (Ln = Ce, R = Me, ^{t}Bu; Ln = La, R = Me), which, in solution, rearrange to give the carbon–carbon coupled products, [$Cp^*{}_2Ln$]$_2$(μ-η^2:η^2-R_2C_4) (Ln = Ce, R = Me, ^{t}Bu; Ln = La, R = Me). The X-ray structures of [$Cp^*{}_2Ce$]$_2$(μ-η^2:η^2-R_2C_4) (R = Me, ^{t}Bu) show two $Cp^*{}_2Ce$ units bridged by a conjugated R_2C_4 group. The reaction of 2,4-dimethylpentadienylneodymium, $(C_7H_{11})_3Nd$, with HC≡CPh in toluene also leads to dimeric phenylethynyl derivatives [$(C_7H_{11})_2$NdC≡CPh]$_2$. The monomeric, solvent-free lanthanide alkynide tris(pyrazolyl)borate ($TpMe_2$) complex $(TpMe_2)_2$Sm(C≡CPh) results from the reaction of $(TpMe_2)_2Sm$ with Hg(C≡CPh)$_2$ in THF.[45]

2.4 Lanthanide Alkylaluminates

Homoleptic (*see Homoleptic Compound*) alkylaluminates of the lanthanide metals like Nd[(μ-Me)$_2AlMe_2$]$_3$ are formed when an excess of $AlMe_3$ reacts with $(Me_2N)_3Ln$ complexes (equation 8). Earlier Cp_2Ln(μ-R)$_2AlR_2$ (Ln = Sc, Y, Ga, Dy, Ho, Er, Tm, Yb, R = Me; Ln = Sc, Y, Ho, R = Et) have been prepared from $(Cp_2LnCl)_2$ with Li(AlR_4) or Mg(AlR_4)$_2$, as well as [$Cp^*{}_2Ln$(μ-Me_2)MMe_2]$_2$ (Ln = Y, Yb; M = Al, Ga),[6] [$Cp^*{}_2Yb$(μ-Me_2)$AlMe_2$]$_2$ and [$Cp^*{}_2Yb$(S-*p*-tolyl)(Me_3Al)$_2$]$_2$,[46] and *rac*-Me_2Si(2-MeC_9H_5)$_2$Y(μ-R)$_2AlR_2$ (R = Me, Et, iso-Bu).[47]



(8)

The reaction of $[Cp'_2Y(\mu\text{-Me})]_2$ ($Cp' = C_5H_5, C_5H_4SiMe_3$) with $B(C_6F_5)_3$ affords the complexes $Cp'_2Y\{MeB(C_6F_5)_3\}$. In $(\eta^5\text{-}Me_3SiC_5H_4)_2Y\{(\mu\text{-}FC_6F_4)(\mu\text{-Me})B(C_6F_5)_2\}$, the yttrium atom is coordinated in a chelating fashion via one ortho-F atom and agostic interactions (*see Agostic Bonding*) to Me groups. The alkylation of $Ln(O^tBu)_3$ with $AlMe_3$ leads to the mixed-bridged alkyl–alkoxy complexes $Ln[(\mu\text{-}O^tBu)_3(\mu\text{-Me})AlMe_2)]_3$ (Ln = Pr, Nd or Y). Bis-trialkylaluminum adducts $(ArO)Ln[(\mu\text{-OAr})(\mu\text{-R})AlR_2]_2$ (Ln = La, R = Me; Ln = La, R = Et; Ln = Sm, R = Et) were prepared by the reaction of $[Ln(OAr)_3]_2$ with four equiv. of trialkylaluminum.[48] Highly substituted lanthanide(III) aryloxide trimethylaluminum complexes are known. $Y(OC_6H_3{}^iPr_2\text{-}2,6)[(\mu\text{-}OC_6H_3{}^iPr_2\text{-}2,6)(\mu\text{-Me})AlMe_2]_2$ and $Ln(OC_6H_3{}^tBu_2\text{-}2,6)_2[(\mu\text{-Me})_2AlMe_2]$ (Ln = Y, Lu) have been characterized by X-ray structures.[49] The reaction of $Nd(NHPh)_3(KCl)_3$ with $AlMe_3$ afforded a heteroleptic mixed-metal complex $\{[Me_2Al(\mu\text{-}Me_2)]_2Nd(\mu_3\text{-NPh})(\mu\text{-Me})AlMe\}_2$. $Nd[(\mu\text{-}NMe_2)(\mu\text{-Me})MMe_2]_3$ (M = Al, Ga) were prepared from $Nd(NMe_2)_3(LiCl)_3$ and 3 equiv. of MMe_3 (M = Al, Ga) and the reaction of $Nd(NMe_2)_3(LiCl)_3$ with excess of $GaMe_3$ gave homoleptic $Nd\{(\mu\text{-Me})_2GaMe_2\}_3$. Aluminates $\{AlMe_2(O_2CC_6H_2{}^iPr_3\text{-}2,4,6)_2\}_2LnAlMe_4$ (Ln = Y, La, Nd, Lu), supported by carboxylate ligands, are available from lanthanide tris(carboxylates) and Me_3Al. These aliminates are highly active in the polymerization of isoprene forming more than 99% cis polymers.[50]

2.5 Lanthanide Complexes with Carbenes, Ylides, Bis(imino)phosphoranides, and Phosphomethanides

Imidazolin-2-ylidenes $C(NRCHR')_2$ react with coordinatively unsaturated organolanthanides and with THF or Lewis base stabilized organolanthanide complexes under replacement forming organolanthanide carbene adducts. Until now there are only a few examples of Ln(III) carbene adducts known, for example, $[(Me_2HSi)_2N]_3Y(C_3N_2H_2Me_2)_n$ ($C_3N_2\text{-}H_2Me_2$ = 1,3-dimethylimidazolin-2-ylidene, n = 1,2) (Figure 15a), $L_3Eu(C_3N_2Me_4)$ (L = 2,2,6,6-tetramethylheptan-3,5-dionate; $C_3N_2Me_4$ = 1,2,3,4-tetramethylimidazolin-2-ylidene), and the silylene derivative $Cp_3LnSi[\{N(CH_2{}^tBu)\}_2\text{-}C_6H_4\text{-}1,2]$ (Ln = Y, Yb).[51] For carbene complexes of Ln(II)

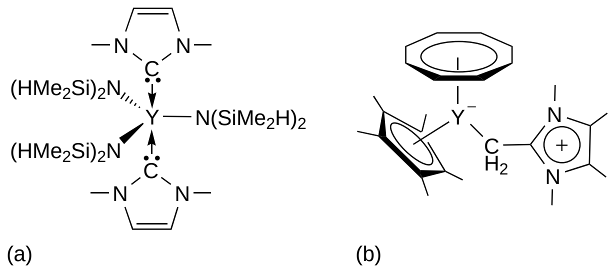


Figure 15 (a) $[(Me_2HSi)_2N]_3Y(C_3N_2H_2Me_2)_2$ and (b) (COT)-$Cp^*YCH_2C(NMeCHMe)_2$

compounds, see Section 11. $[(Me_3Si)_2N]_3Ln$ (Ln = La, Nd) and (COT)YCp* react with 1,3,4,5-tetramethylimidazoline-2-ylidene to yield the ylidic olefin complexes $[(Me_3Si)_2N]_3Ln\text{-}CH_2C(NMeCHMe)_2$ and $(COT)Cp^*YCH_2C(NMeCHMe)_2$ (Figure 15b) respectively.

Organolanthanide-phosphorus ylide complexes $(C_5H_4R)_3NdCH_2P(Me)Ph_2$ (R = H, ^tBu) and $(C_5H_4{}^tBu)_2Yb(Cl)\text{-}CH_2P(Me)Ph_2$ were synthesized from $Li[(CH_2)_2PPh_2]$ and the respective Cp_2LnCl precursors. Variable temperature $^{31}P\{^1H\}$ NMR spectroscopy indicates an equilibrium between $(C_5H_4R)_3NdCH_2P(Me)Ph_2$ and $[(C_5H_4R)_3Nd(THF) + CH_2{=}P(Me)Ph_2]$ in THF solution. The bisiminophosphorane $CH_2(Ph_2P{=}NSiMe_3)_2$ reacts with $Sm(NCy_2)_3(THF)$ in toluene to give $[(Ph_2P{=}NSiMe_3)_2C]Sm(NCy_2)(THF)$ (Figure 16).[52]

Phosphinomethanide complexes of the lanthanides $[Me_3SiC(PMe_2)_2]_3Lu(THF)$ and $[Me_3SiC(PMe_2)_2]_3Lu$ are prepared by reaction of $Lu(OSO_2CF_3)_3$ with $Li[Me_3SiC\text{-}(PMe_2)_2]$. Alkylation with MeLi forms $[Me_3SiC(PMe_2)_2]_2\text{-}Lu(Me)(THF)$ (Figure 17a). Reaction of $K\{CH(PPh_2NSiMe_3)_2\}$ with $LnCl_3$ forms $[\{CH(PPh_2NSiMe_3)_2\}LnCl_2]_2$ (Ln = Y, Sm, Er, Dy, Yb, Lu). Further reaction of the Y and Sm derivatives with $KNPh_2$ affords $[\{CH(PPh_2NSiMe_3)_2\}Ln\text{-}(NPh_2)_2]$ (Ln = Y, Sm).[53] The corresponding dicyclopentadienyl complexes $Cp_2Ln\{CH(PPh_2NSiMe_3)_2\}$ (Figure 17b)[54] are also known.

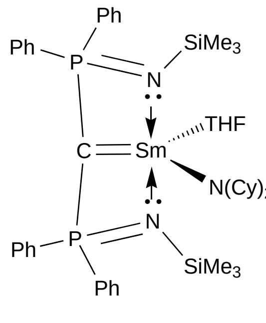

Figure 16 $[(Ph_2P{=}NSiMe_3)_2C]Sm(NCy_2)(THF)$

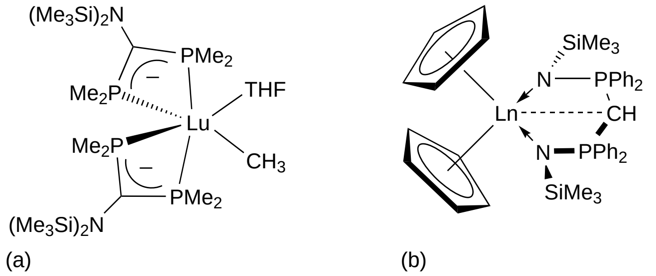

Figure 17 (a) $[Me_3SiC(PMe_2)_2]_2Lu(Me)(THF)$, (b) $Cp_2Ln\{CH(PPh_2NSiMe_3)_2\}$ (Ln = Y, Sm, Er)

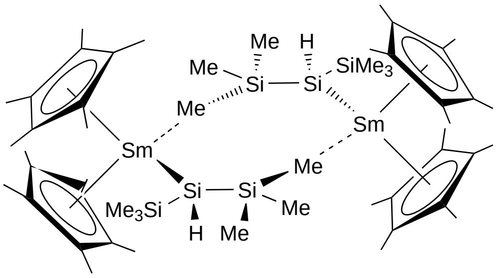

Figure 18 Dimeric $Cp^*{}_2LnSiH(SiMe_3)_2$

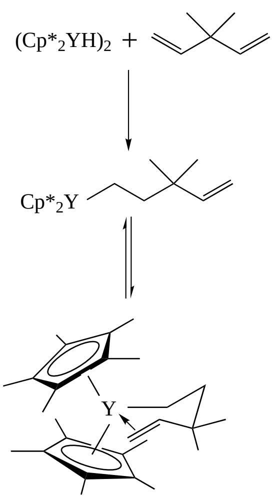
2.6 σ-Silyl-, Germyl-, and Stannyl-derivatives

$Cp^*{}_2LnCH(SiMe_3)_2$ (Ln = Sm, Nd, Y) and $(C_5Me_4Et)_2LnCH(SiMe_3)_2$ (Ln = Sm, Nd) react with $H_2Si(SiMe_3)_2$ to form the silyl complexes $Cp^*{}_2LnSiH(SiMe_3)_2$ (Ln = Sm, Nd, Y) and $(C_5Me_4Et)_2LnSiH(SiMe_3)_2$ (Ln = Sm, Nd), respectively. The X-ray crystal structure of $Cp^*{}_2LnSiH(SiMe_3)_2$ shows dimers in the solid state via intermolecular Sm$\cdots$$CH_3$–Si interactions (Figure 18). The samarium hydride $[Cp^*{}_2Sm(\mu\text{-}H)]_2$ reacts with *o*-$MeOC_6H_4SiH_3$ via Si–H activation affording $Cp^*{}_2SmSiH_2(OC_6H_4\text{-}OMe\text{-}2)$, which rapidly decomposes to the dimeric aryl complex $[Cp^*{}_2Sm(\mu\text{-}C_6H_4Me\text{-}2)]_2$,[44] and $[Cp^*{}_2Sm(\mu\text{-}H)]_2$ reacts with $PhSiH_3$ forming $[Cp^*{}_2SmSiH_3]_3$, which reacts with benzophenone yielding $Cp^*{}_2SmOCPh_2(SiH_3)$.[55] $[Li(DME)_3][Cp_2Ln(SiMe_3)_2]$ (Ln = Sm, Lu) was prepared from $Cp_2Ln(\mu\text{-}Cl_2)Na(DME)_2$ and Me_3SiLi in DME and the scandocene complexes $Cp_2Sc(ER_3)(THF)$ [ER_3 = $Si(SiMe_3)_3$, $Si(SiMe_3)_2Ph$, $Si(^tBu)Ph_2$, $SiPh_3$, $Ge(SiMe_3)_3$] were prepared by reacting the appropriate silyl- or germyllithium reagent with $(Cp_2ScCl)_2$.

3 ALKENE AND ALKYNE COMPLEXES

Organolanthanide(III) complexes with η^2 coordinated alkene or alkyne ligands are very rare. For alkene complexes of Ln(II) compounds, see Section 11. The coordination of the olefinic double bond to Y in $Cp^*{}_2YCH_2CH_2CMe_2CH{=}CH_2$ (equation 9) could be proved by NMR.



(9)

The reaction of *meso*-octaethylporphyrinogen (oepg) lanthanide complexes, $[\{(oepg)Ln\}Na(THF)_2]$ (L = Pr, Nd) with $NaC_{10}H_8$ in an ethene atmosphere in the presence of 18-crown-6 (*see Crown Ethers*) in THF yields dimeric species, where the metals are bridged by the $[C_2H_4]^{2-}$ anion. According to the X-ray crystal structure of the Nd derivative, the $[CH_2CH_2]^{2-}$ unit is side-on bonded to the two metal atoms (Figure 19a).

Similar reaction in an acetylene atmosphere gives the neutral dimers $[(oepg)Ln]_2[(\mu\text{-}C_2)(\mu\text{-}Na)_4]$. X-ray crystal structure analysis of the neodymium derivative (Figure 19b) shows the acetylide dianion end on bonded to the two metal centers.

The reaction of YCl_3 with $K_2(Ph_2C{=}CPh_2)$ followed by cation exchange with $NaBPh_4$ in THF yields $[Na(THF)_6][Y(Ph_2C{=}CPh_2)_2](THF)_2$. According to the X-ray crystal structure, the unit $[Y(Ph_2CCPh_2)_2]^-$ has a sandwich-like structure in which each $(Ph_2CCPh_2)^{2-}$ dianion has six carbon atoms oriented toward the metal center with Y–C distances between 2.518 and 2.689 Å.[11]

4 ALLYL AND ALLENYL COMPLEXES

Allyl complexes of the lanthanides are very efficient catalysts for stereospecific butadiene polymerization. The smaller size of the allyl anion compared to other ionic π-systems like Cp^- allows the formation of homoleptic anionic complexes of the type $[(allyl)_4Ln]^-$ with all four ligands η^3-bonded to the Ln metal. Complexes $[Li(dioxane)_n][Ln(\eta^3\text{-}C_3H_5)_4]$ (Ln = Ce, Pr, Nd, Sm, Gd, $n = 2$; Ln = Y, $n = 2.5$; Ln = La, $n = 3$), $[Li_2(THF)_n][Ln(\eta^3\text{-}C_3H_5)_5]$ (Ln = Y, La, $n = 2.5$; Ln = Ce, Pr, Nd, Sm, $n = 3$), and $[Li_2(dioxane)_n][Ln(\eta^3\text{-}C_3H_5)_5]$ (Ln = Ce, Nd, Sm, Gd, Dy, Ho, Er; $n = 1$, 3) are available by treatment of anhydrous lanthanide trichlorides with

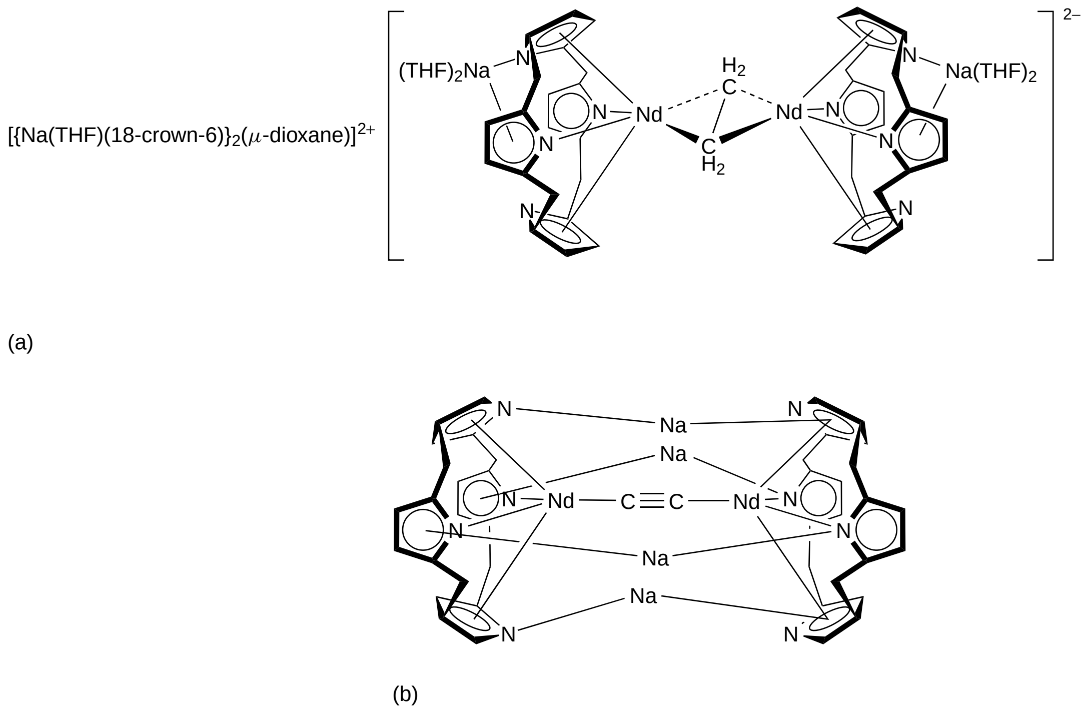


Figure 19 (a) $[\{Na(THF)(18\text{-crown-}6)\}_2(\mu\text{-dioxane})][\{(oepg)Nd\}Na(THF)_2]$ and (b) $[(oepg)Nd]_2[(\mu\text{-}C_2)(\mu\text{-}Na)_4]$

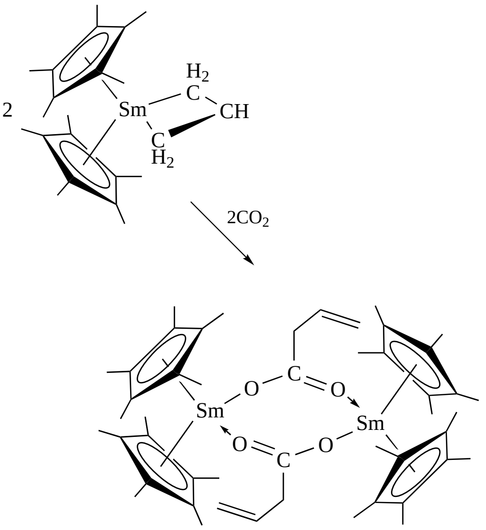
allyllithium (equation 10). Neutral tris(allyl)lanthanide complexes $Ln(\eta^3\text{-}C_3H_5)_3(dioxane)_n$ (Ln = La, $n = 1.5$; Ln = Nd, $n = 1$) are prepared from $Li[Ln(C_3H_5)_4]$ (Ln = La or Nd) via allyllithium abstraction with BEt_3 in dioxane. The La derivative is a dimer $[\{La(\eta^3\text{-}C_3H_5)_3(\eta^1\text{-dioxane})\}_2(\mu\text{-dioxane})]$, whereas the Nd derivative forms a coordination polymer $[Nd(\eta^3\text{-}C_3H_5)_3(\mu\text{-dioxane})]_n$. Bis(allyl)- and mono(allyl)neodymium(III) compounds $Cp^*Nd(\eta^3\text{-}C_3H_5)_2(dioxane)$ and $[Nd(\eta^3\text{-}C_3H_5)Cl(THF)_5][BPh_4](THF)$ were examined as catalysts for butadiene polymerization.[56]

$$NdCl_3 + 4Li(C_3H_5) \xrightarrow[\text{2) } Et_2O/\text{dioxane}]{\text{1) DME, 50 °C}} [Li(dioxane)_2][Nd(C_3H_5)_4] \quad (10)$$

The bis- and mono(allyl)neodymium(III) chlorides, $Nd(\eta^3\text{-}C_3H_5)_2Cl(THF)_{1.5}$ and $Nd(\eta^3\text{-}C_3H_5)Cl_2(THF)_2$, were prepared by the reaction between $Nd(\eta^3\text{-}C_3H_5)_3(dioxane)$ and $NdCl_3(THF)_2$ in the corresponding molar ratio in THF. In combination with MAO, they catalyze the 1,4-*cis*-polymerization of butadiene in toluene and heptane, with extremely high activity and selectivity (≥98%). The bis(η^3-allyl)lanthanum(III) halides $La(\eta^3\text{-}C_3H_5)_2X(THF)_2$ (X = Cl, Br, I) are also available by partial protolysis of $La(\eta^3\text{-}C_3H_5)_3(dioxane)_{1.5}$ with Me_3NHX (X = Cl, Br, I) in THF.

The allyl complexes $[Cp'_2Sm(C_3H_5)]_n$ ($Cp' = {}^tBuC_5H_4$) and *ansa*-$Me_4C_2(\eta^5\text{-}C_5H_4)_2Sm(C_3H_5)_2Li(DME)$ were synthesized from $(Cp'_2SmCl)_2$ and *ansa*-$Me_4C_2(\eta^5\text{-}C_5H_4)_2SmCl$-$[MgCl_2(THF)_4]$, respectively. The mono-allyl complex $Cp^*_2Sm(\eta^3\text{-}C_3H_5)$ reacts with CO_2 in toluene at room temperature to form $[Cp^*_2Sm(\mu\text{-}O_2CCH_2CH{=}CH_2)]_2$. In THF it exists as solvated monometallic species $Cp^*_2Sm(\mu_2\text{-}O_2CCH_2CH{=}CH_2)(THF)$ but it crystallizes from hexane as a bimetallic complex that contains an eight-membered SmOCOSmOCO ring (equation 11).

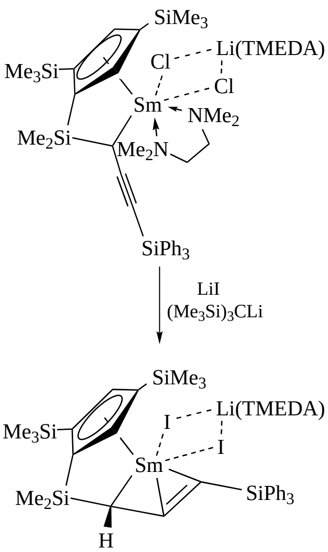


(11)

Variable temperature ^1H NMR spectroscopy of a series of Sc and Y metallocene allyl complexes indicates fluxional (*see Fluxional Molecule* and ***Structure & Property Maps for Inorganic Solids***) behavior involving C–C

double-bond dissociation from the metal center, that is, an η^3 to η^1 change in coordination. Activation barriers to olefin dissociation were determined for η^5-$Cp^*_2Sc(C_3H_5)$, *meso*-$Me_2Si(\eta^5$-3-$^t BuC_5H_3)_2Sc(C_3H_5)$, *meso*-$Me_2Si(\eta^5$-2,4-$^i Pr_2C_5H_2)_2Sc(C_3H_5)$, *meso*-$Me_2Si\{\eta^5$-3-[2-(2-Me)adamantyl]$C_5H_3\}_2Sc(C_3H_5)$, *meso*-$Me_2Si\{\eta^5$-3-[2-(2-Me)adamantyl]$C_5H_3\}_2Y(C_3H_5)$, *rac*-$Me_2Si(\eta^5$-2,4-$^i Pr_2C_5H_2)_2Sc(C_3H_5)$, and (*R*)-$(C_{20}H_{12}O_2)Si(\eta^5$-2-$SiMe_3$-4-$^t BuC_5H_2)_2Sc(C_3H_5)$. It has been found that donor solvents do not significantly affect the rate of this process. X-ray structure analysis of *rac*-$Me_2Si(\eta^5$-2,4-$^i Pr_2C_5H_2)_2Sc(C_3H_5)$ showed the allyl ligand η^3 coordinated to the metal.[11]

The reaction of $Li_2[(Me_3Si)_2C_5H_2]SiMe_2(CHC{\equiv}CSiMe_3)$ with $SmCl_3$ yields the allenyl complex $\{[(Me_3Si)_2$-$C_5H_2]SiMe_2(\eta^3$-$CH{=}C{=}CSiMe_3)\}SmCl_3Li_2(TMEDA)_2$, whereas the reaction of the dilithium salt of the triphenylsilyl substituted ligand with $SmCl_3$ yielded the η^1-propargyl derivative $\{[(Me_3Si)_2C_5H_2]SiMe_2(\eta^1$-$CHC{\equiv}CSiPh_3)\}Sm(TMEDA)[Cl_2Li(TMEDA)]$. A conversion of the bonding mode from η^1-propargyl to η^3-allenyl was observed when the later compound was treated with $(Me_3Si)_3CLi/LiI$ to give the η^3-allenyl complex $\{[(Me_3Si)_2(C_5H_2)]SiMe_2(\eta^3$-$CH{=}C{=}CSiPh_3)\}SmI_2Li$-(TMEDA) (equation 12).[57]



(12)

Thermal decomposition of $Me_2Si(C_5Me_4)(CH_2CH{=}CH_2)Y(CH_2SiMe_3)_2(THF)_2$, containing an allyl(dimethylsilyl)substituted cyclopentadienyl ligand, yields $[Y\{\eta^5{:}\eta^1$-$C_5Me_4SiMe_2(\mu$-η^3-$C_3H_3)\}L]_2$ (L = DME or THF). X-ray diffraction studies showed that the novel trianionic ligand bridges the two yttrium atoms by coordinating $\eta^5{:}\eta^1$ to one and η^3 to the other metal (Figure 20).[58]

Several lanthanide(II) and lanthanide(III) complexes with aza-allyl ligands $Ln(L)_2X(THF)_n$ (L = η^3-$Me_3SiN{=}C(^t Bu)$-$CHSiMe_3$; X = Cl, $n = 1$, Ln = Ce or Nd; X = I, $n = 1$, Ln = Sm; X = I, $n = 0$, Ln = Yb), $Sm(L)_2(THF)$ and $Yb(L)_2$, were synthesized by the reaction of the appropriate

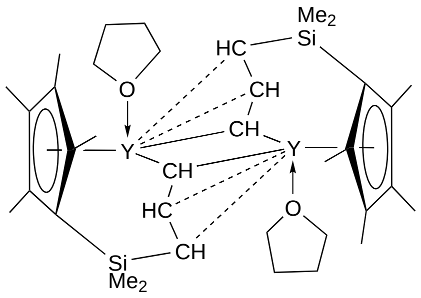


Figure 20 $[Y\{\eta^5{:}\eta^1$-$C_5Me_4SiMe_2(\mu$-η^3-$C_3H_3)\}THF]_2$

lanthanide(II) or lanthanide(III) halides with two equiv. of 1,3-bis(trimethylsilyl)-1-aza-allylpotassium.

5 DIENE COMPLEXES

Lanthanide complexes with neutral coordinated diene ligands are unknown. In contrast, a few examples containing anionic diene ligands, for example, $[Cp^*_2La(THF)(\mu$-η^1,η^3-$C_4H_6)LaCp^*_2]$ and $[LaI_2(THF)_3]_2(\mu$-$Ph_2C_4H_4)$, have been described.[6] The related gadolinium complex $[GdCl_2$-$(THF)_3]_2(\mu$-$Ph_2C_4H_4)$ was obtained by the reaction of $GdCl_3$ with potassium diphenylbutadienide generated in situ.[4] The structurally characterized lutetium compound $[(\mu$-$PhCHCHCHCHPh)_2Lu(THF)_2K(THF)_2]_n$ contains two η^4-diphenylbutadiene ligands and two THF molecules coordinated to the central lutetium ion. The diphenylbutadiene is bonded in its *cis* conformation. In the crystal, a polymeric chain structure results from additional η^6-coordination of two phenyl rings to potassium. Since the oxidation state of lutetium is +3, the two diene ligands must be formally dianions to result in a monoanionic species with potassium as the counterion (Figure 21).[11]

Pentamethylcyclopentadienyllanthanide dichlorides Cp^*-$LnCl_2$ (Ln = Sm, Lu) react with diarylbutadienes and lithium under elimination of the pentamethylcyclopentadienyl

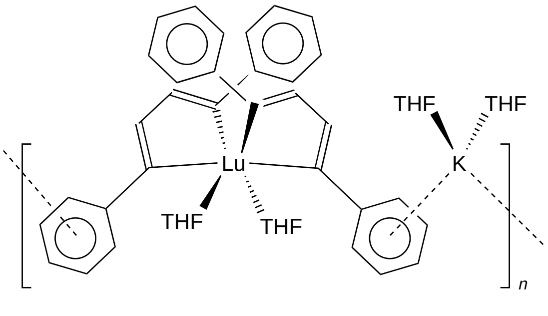

Figure 21 $[(\mu$-$PhCHCHCHCHPh)_2Lu(THF)_2K(THF)_2]_n$

ligand and formation of anionic (butadiene)lanthanide complexes [Li(THF)$_3$][Sm(1,4-Ph$_2$C$_4$H$_4$)$_2$] and [Li(DME)][(1,4-Ar$_2$C$_4$H$_4$)LuCl$_2$] (in THF and DME, respectively). A slightly different lithium salt [Li(THF)$_3$][Sm(1,4-Ph$_2$C$_4$H$_4$)$_2$] was isolated in the form of black–red crystals starting directly from SmCl$_3$. A mononuclear samarium complex [1,4-(*p*-MeC$_6$H$_4$)$_2$C$_4$H$_4$]SmI(THF)$_3$ containing a terminal 1,4-di-*p*-tolylbutadiene ligand results from the reaction of metallic samarium with iodine and the butadiene derivative in THF.

The reduction of diphenylacetylene with [CpLu(C$_{10}$H$_8$)(DME)]$^{2-}$ results in C–C coupling and formation of a dinuclear complex with a bridging [C$_4$Ph$_4$]$^{4-}$ ligand: [CpLu(DME)]$_2$[μ-η^4:η^4-PhCC(Ph)=C(Ph)CPh]. The crystallographic and spectral data suggest a dialkylidene bridging ligand in this complex.[11]

CpLuCl$_2$(THF)$_2$ reacts with 2 equiv. of Na[PhCH=CHPh] in DME with dimerization of the stilbene radical anions to form [Na(DME)$_3$][Cp$_2$Lu{μ-CH(Ph)CH(Ph)-CH(Ph)CH(Ph)}] containing a dianionic 1,2,3,4-tetraphenylbutadiene ligand. X-ray crystal structure determination shows Lu coordinated to two Cp rings and the dianionic butadiene ligand in an η^5 and 1,4-diyl fashion.[59]

A nonreductive reaction pathway has been also used for coupling of alkynes to produce complexes with dianionic butadiene ligands. Thus, the reaction of Cp*$_2$LaCH(SiMe$_3$)$_2$ with PhC≡CH at room temperature yields the binuclear product (Cp*$_2$La)$_2$(μ-Ph$_2$C$_4$) and CH$_2$(SiMe$_3$)$_2$. Although the uncoupled dimer (Cp*$_2$LaC$_2$^{t}Bu)$_2$ is formed in the reaction of Cp*$_2$LaCH(SiMe$_3$)$_2$ with ^{t}BuC≡CH at 0 °C, it undergoes clean unimolecular conversion in toluene solution at 60 °C to the coupled dimer (Cp*$_2$La)$_2$(μ-^{t}Bu$_2$C$_4$). The related Sm(III) complex (Cp*$_2$Sm)$_2$(μ-η^2:η^2-Ph$_2$C$_4$) has been prepared using both reductive and nonreductive conditions reacting Cp*$_2$Sm(THF)$_2$ and PhC≡C–C≡CPh or by thermolysis of Cp*$_2$Sm(C≡CPh)(THF) at 80–145 °C. The later compound can be prepared also from PhC≡CH and [Cp*$_2$SmH]$_2$ or Cp*$_2$Sm[CH(SiMe$_3$)$_2$].[6]

6 PENTADIENYL COMPLEXES

Owing to relationship between cyclopentadienyl and pentadienyl ligands, the complexes of the later ligand are often termed *open metallocenes*. Lanthanide derivatives with 'open cyclopentadienyl ligands' have been described since 1982, for example, Tris(2,4-dimethylpentadienyl)neodymium Nd(C$_7$H$_{11}$)$_3$. The X-ray crystal structure shows three equivalent η^5-coordinated 2,4-dimethylpentadienyl ligands. The related complexes of La, Sm, Gd, Tb, and Lu are also known. Owing to the smaller ionic radius of Lu^{3+} only two 2,4-dimethylpentadienyl ligands are η^5-coordinated in the Lu derivative, while the third ligand is bonded to lutetium in an η^3-allyl-like fashion. Later work showed the formation of a minor by-product, which has been

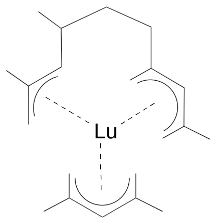

Figure 22 Lu(η^5-C$_7$H$_{11}$)(η^5:η^3-MeC$_5$H$_5$CH$_2$CH$_2$CHMeC$_3$H$_3$Me)

shown by X-ray crystallography to be Lu(η^5-C$_7$H$_{11}$)[η^5:η^3-MeC$_5$H$_5$CH$_2$CH$_2$CH(Me)C$_3$H$_3$(Me)], containing a dimeric chelate ligand derived from end-to-end fusion of two 2,4-dimethylpentadienyl groups (Figure 22).[11]

Homoleptic tris(2,4-dimethylpentadienyl) derivatives of gadolinium and erbium have been used to synthesize phenylalkynyl derivatives via reactions with equimolar amounts of phenylacetylene (equation 13)

$$2Ln(C_7H_{11})_3 + 3PhCCH \xrightarrow{\text{toluene}} [(C_7H_{11})_2Ln(\mu\text{-CCPh})]_2 + 2C_7H_{12} \quad (13)$$

Several other pentadienyllanthanide complexes have been reported, including the mono(pentadienyl) derivatives (η^5-C$_7$H$_{11}$)LnCl$_2$(THF)$_3$ (Ln = Nd, Sm, Gd) and bis(pentadienyl)lanthanide halides (η^5-C$_7$H$_{11}$)$_2$LnCl(THF) (Ln = Nd, Sm, Gd). The mono(pentadienyl) derivative (η^5-C$_7$H$_{11}$)NdCl$_2$ is a hexamer (η^5-C$_7$H$_{11}$)$_6$Nd$_6$Cl$_{12}$(THF)$_2$, which consists of two Nd$_3$Cl$_5$ entities connected via two chloro bridges. The structure of the Nd$_3$Cl$_5$ moiety contains a distorted hexagonal bipyramidal polyhedron with C$_7$H$_{11}$ anions connected to the neodymium atoms in a η^5 fashion.[11] The reaction of LnCl$_3$ (Ln = Nd, Er) with K$_2$COT followed by treatment with K(C$_7$H$_{11}$) gave (COT)Ln(η^5-C$_7$H$_{11}$)(THF).

7 CYCLOPENTADIENYL, INDENYL, & FLUORENYL COMPLEXES

Most of all organometallic compounds of the rare earth metals known to date are cyclopentadienyl complexes. There is a large variety of cyclopentadienyl derivatives used as ligands such as mono-, bis-, and poly-substituted moieties; cyclopentadienides containing donor-functionalized substituents; bridged *bis*-cyclopentadienides forming ansa complexes; cyclopentadienide ligands with other adjacent π-coordinating ligands like carboranes or pyrroles; and annelated ligands with cyclopentadienyl segments such as indenyls and fluorenyls. A complete survey of this class of organolanthanides up to 1994 is given in Ref. 6. Later reviews are published in 2002.[8] This chapter deals only with tris(cyclopentadienyl)lanthanide complexes, bis(cyclopentadienyl)lanthanide and mono(cyclopentadienyl)lanthanide derivatives in which the lanthanide is

bonded to elements other than carbon besides the cyclopentadienyl ligands, and corresponding complexes with annelated cyclopentadienyl ligands. For bis(cyclopentadienyl)lanthanide and mono(cyclopentadienyl)lanthanide alkyl, aryl, alkene, alkyne, or allyl complexes, see Sections 2 to 6.

7.1 Tris(cyclopentadienyl) Complexes

Tris(cyclopentadienyl)lanthanide complexes are prepared by salt elimination from the corresponding lanthanide trichlorides and NaCp or KCp in Et_2O, THF, or benzene. In contrast to cyclopentadienyl complexes of the transition metals, the bonding of the lanthanide atoms to the cyclopentadienyl ring is best described as ionic with only little participation of covalency. Thus, the ^{151}Eu Moessbauer spectra of $CpEuCl_2(THF)_3$, $CpEu(NCO)_2(THF)$, and $CpEu(NCS)_2(THF)_3$ have been measured at 4.2 K and show hyperfine parameters that are normal for organoeuropium(III) compounds, whereas the Moessbauer spectrum of $Cp_3Eu(THF)$ is very different with a negative isomer shift of $-1.77\,mm\,s^{-1}$ and a large negative quadrupole interaction of $-33.6\,mm\,s^{-1}$. This isomer shift corresponds to the transfer of ca. 0.14 electrons from the cyclopentadienyl ligands into the 4f orbitals of europium via covalent bonding. Most tris(cyclopentadienyl)lanthanide complexes have been investigated by X-ray crystallography. The structure is highly dependent on the size of the metal. A strictly monomeric compound with three η^5-Cp ligands is found for Yb only. The smaller Sc and Lu (Figure 23) have a reduced formal coordination number of eight with two η^5-Cp ligands and two bridging η^1-Cp ligands so that a polymeric chain results. The larger metals increase their coordination number gradually by weak van der Waals interactions [Y, Er (Figure 24), Tm] or by increasing coordination [Nd: η^1-Cp; Pr: η^{1-2}-Cp; La: η^2-Cp (Figure 25)] to neighboring Cp_3Ln units so that polymeric chains are also formed.[6]

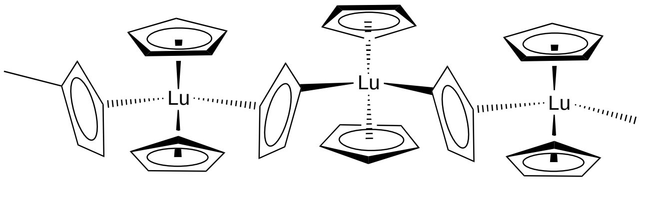

Figure 23 Structure of Cp_3Lu

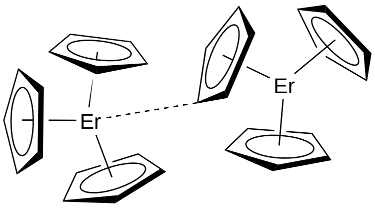

Figure 24 Structure of Cp_3Er

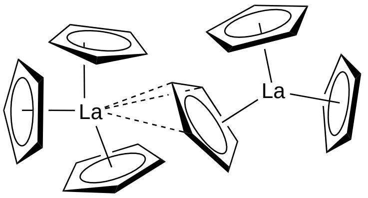

Figure 25 Structure of Cp_3La

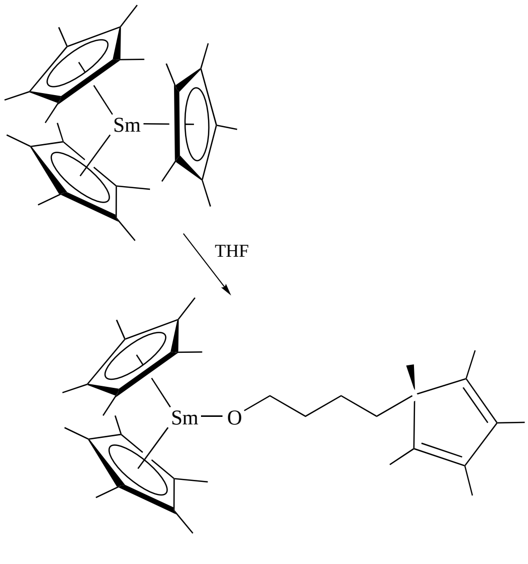
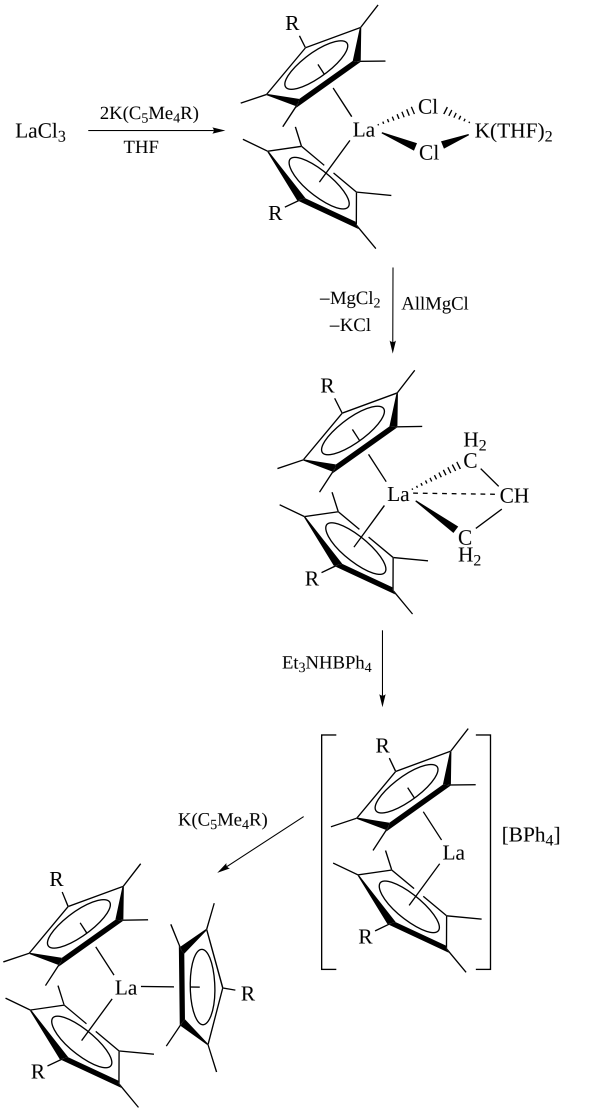
A series of homoleptic substituted tris(cyclopentadienyl) lanthanide(III) complexes $Cp^R{}_3Ln$ (Ln = La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Er, Tm, Yb), $Cp^t{}_3Nd$, $Cp^{tt}{}_3Ce$, $Cp^{tt}{}_3Nd$ [CpR = η^5-$C_5H_4CH(SiMe_3)_2$, Cp^t = η^5-$C_5H_4(SiMe_2{}^tBu)$, Cp^{tt} = η^5-$C_5H_3(SiMe_2{}^tBu)_2$-1,3], and $[(Me_3Si)_2C_5H_3]_3Ln$ (Ln = La, Nd, Sm, Gd or Dy) have been synthesized by reaction of anhydrous lanthanide(III) halides with the appropriate sodium or potassium cyclopentadienide in THF. Mixed cyclopentadienyl complexes $Cp^*{}_2CpLn$ (Ln = La, Nd) were prepared by ring metathesis between $Cp^*{}_2Ca$ and Cp_3Ln in toluene. Only one ring is exchanged between $Cp^*{}_2Ca(THF)$ and $Cp_3La(THF)$ in toluene to yield $Cp^*Cp_2La(THF)$. The trichlorides of La, Nd, Sm, and Tb react with $Na(C_5HMe_4)$ in THF to yield the homoleptic complexes $(C_5HMe_4)_3Ln$ (Ln = La, Nd, Sm, Tb). On the other hand, the reactions of $HoCl_3$, $TmCl_3$, and $LuCl_3$ with $Na(C_5HMe_4)$ result only with formation of the dicyclopentadienyl complexes $(C_5HMe_4)_2LnCl(THF)$ (Ln = Ho, Tm, Lu).

Tris(cyclopentadienyl)lanthanide complexes with sterically more crowded Cp ligands such as C_5Me_4R (R = Me, Et, ^{i}Pr, and $SiMe_3$) are not assessable by simple metathesis between lanthanide trihalides and the respective alkali metal salt of the bulky Cp ligand. For instance, $Cp^*{}_3Sm$, obtainable from $Cp^*{}_2Sm$ and cyclooctatetraene, reacts with THF with ring-opening forming $Cp^*{}_2Sm[O(CH_2)_4Cp^*](THF)$ (equation 14).



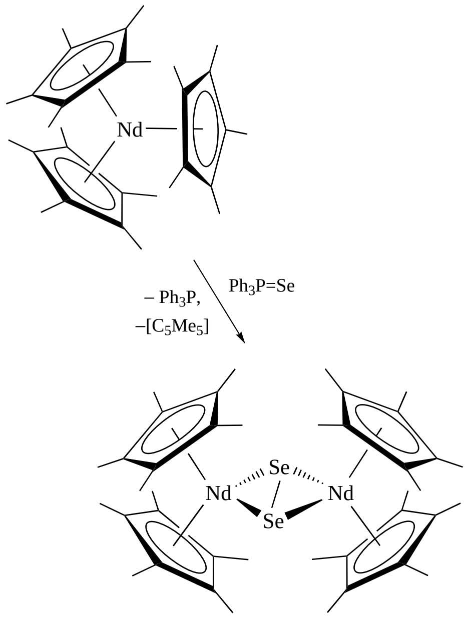
(14)

However, $Cp^*_2Sm(OEt_2)$ reacts cleanly with Cp^*_2Pb to give Cp^*_3Sm in >90% yield. This route has been used to synthesize the more sterically crowded $(C_5Me_4Et)_3Sm$. In general, $(C_5Me_4R)_3La$ (R = Me, Et, ^{i}Pr, and $SiMe_3$) complexes can be prepared in four steps by reaction of $LaCl_3$ with KC_5Me_4R to form $(C_5Me_4R)_2LaCl_2K(THF)_2$, followed by addition of allylmagnesium chloride to produce $(C_5Me_4R)_2La(C_3H_5)$, then protonolysis with Et_3NHBPh_4 yielding $[(C_5Me_4R)_2La][BPh_4]$, and finally by replacement of BPh_4^- with $C_5Me_4R^-$ using KC_5Me_4R affording $(C_5Me_4R)_3La$ (equation 15). X-ray crystallography shows monomer complexes $(C_5Me_4R)_3La$ (R = Me, Et, ^{i}Pr, $SiMe_3$) with three C_5Me_4R ring centroids defining a trigonal planar geometry around the La atom.[60]



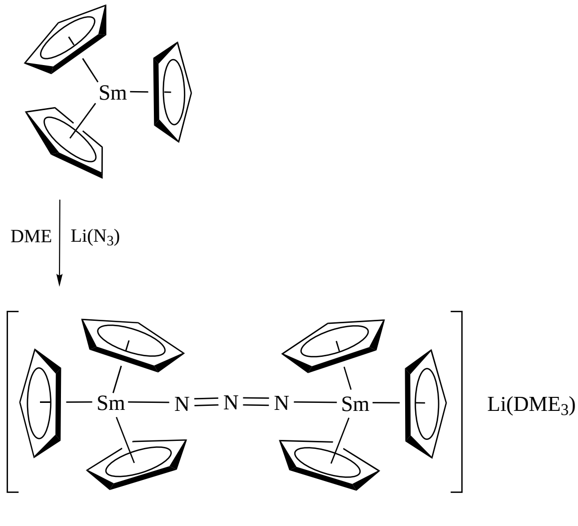
(15)

Related tris(peralkylcyclopentadienyl) complexes were also reported for smaller lanthanides than Nd and Sm. Such lanthanide(III) complexes behave as one-electron reductants, although the oxidation state of the metal retains +3. Thus, Cp^*_3Nd reduces $Ph_3P{=}Se$ to Ph_3P forming $\{Cp^*_2Nd\}_2(\mu\text{-}\eta^2{:}\eta^2\text{-}Se_2)$ (equation 16). Cp^*_3Sm reacts with a variety of substrates including CO, THF, ethylene, hydrogen, nitriles, isonitriles, isocyanates, cyclooctatetraene, azobenzene, and $Ph_3P{=}E$ (E = O, S, Se). Depending on the substrate, Cp^*_3Sm can react either as a bulky alkyl complex Cp^*_2SmR with R = η^1-C_5Me_5 or as zwitterionic $[Cp^*_2Sm]^+$ $[Cp^*]^-$ with the $[Cp^*]^-$ anion as the one-electron reductant.

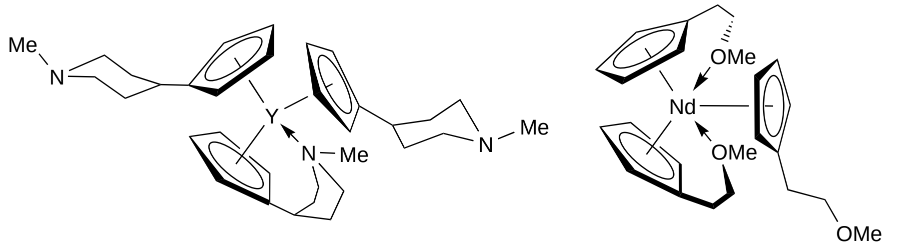


(16)

Tris(cyclopentadienyl)lanthanides form adducts with a variety of neutral Lewis bases such as THF; esters; sulfoxides; phospineoxides, for example, $(C_5H_4PPh_2)_3Ln(OPPh_3)$ (Ln = La, Pr, Nd, Sm, Er, Y); NH_3; various amines, for example, $Cp_3Ln(Nic)$ (Nic = (*S*)-(−)-nicotine)[61] and $Cp_3Yb(NC_4H_4N)YbCp_3$; phosphines, for example, $(C_5H_4Me)_3Yb(PMe_3)$; nitriles, for example, $Cp_3Sm(NCCH_3)$ and $Cp_3Pr(NC_6H_{11}\text{-}c)$; and anions like halides, for example, $[Cp_3Ln(\mu\text{-}Cl)LnCp_3]^-$ or azide, for example, $[Cp_3Sm(\mu\text{-}N_3)SmCp_3]^-$ (equation 17).



(17)

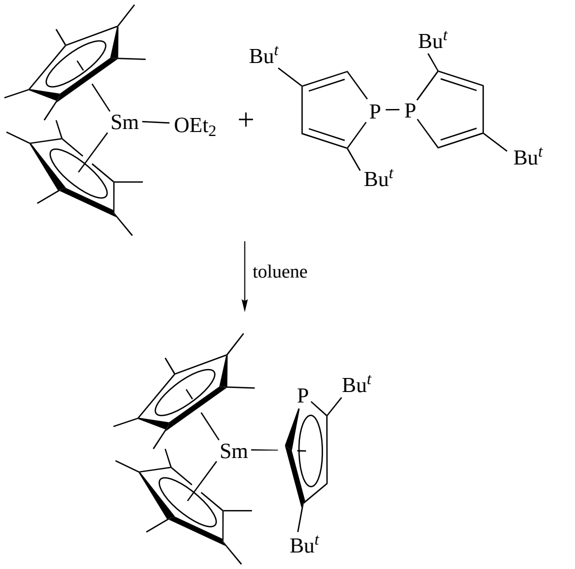


(a) (b)

Figure 26 (a) $[\eta^5\text{-}C_5H_4CH\{(CH_2)_2\}_2NMe_2]_3Y$ and (b) $(C_5H_4CH_2CH_2OMe)_3Nd$

Stabilization by Lewis base donors can also be achieved by using donor-substituted cyclopentadienyl ligands, as shown in $[\eta^5\text{-}C_5H_4CH\{(CH_2)_2\}_2NMe]_3Y$[62] (Figure 26a) or in $(C_5H_4CH_2CH_2OMe)_3Ln$ (Ln = La, Pr, Nd, Gd or Y) (Figure 26b). Crystal structure determinations revealed that, in these unsolvated monomeric metallocenes, the lanthanide metals are coordinated by three cyclopentadienyl rings and two oxygen atoms whereas the third oxygen atom is not coordinated. A similar situation is observed in the phosphorus-functionalized complex $[Cp(CH_2)_2PMe_2]_3La$.

Bis(pentamethylcyclopentadienyl)phospholyl and -arsolyl-samarium(III) complexes $Cp^*{}_2SmL$ (L = $C_4H_2Me_2P$, $C_4H_2{}^tBu_2P$, C_4Me_4P, $C_4H_2Me_2As$) are synthesized either by reaction of $Cp^*{}_2Sm(Et_2O)_x$ ($x = 0$, 1) with $(C_4H_2Me_2P)_2$, $(C_4H_2{}^tBu_2P)_2$, $(C_4Me_4P)_2$, $(C_4H_2Me_2As)_2$, or with Tl-$[C_4Me_4P]$ (equation 18).[63]



(18)

Tris(indenyl)lanthanide complexes of all rare earth metals can be prepared analogously from the lanthanide trichlorides with alkali or magnesium indenyl salts.[6] All five-membered rings are η^5-bonded to the metal. They form base adducts with THF and pyridine, with (S)-(−)-nicotine,[61] and with bridging chloride or LiCl (Figure 27).[64]

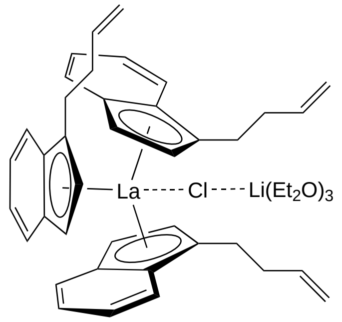


Figure 27 $(1\text{-}C_4H_7\text{-}4,7\text{-}Me_2C_9H_4)_3La(\mu\text{-}Cl)Li(Et_2O)_3$

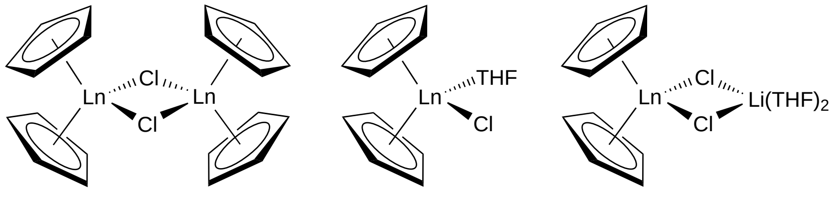
7.2 Bis(cyclopentadienyl) Complexes

The organometallic chemistry of the rare earths deals mainly with bis(cyclopentadienyl) derivatives due to the easy available bis(cyclopentadienyl) rare earth chlorides and other halides via reaction of the rare earth trichlorides with two equivalents of a cyclopentadienyl alkali salt. Bis(cyclopentadienyl)lanthanide chlorides are formed as chloride-bridged dimers (Figure 28a), as monomers stabilized by a donor molecule like THF (Figure 28b) or as *ate* complexes with alkali halides (Figure 28c).

A lot of corresponding derivatives are known derived of substituted cyclopentadienyl ligands, for example, $(C_5H_4Me)_2LnCl$, $(C_5H_4{}^tBu)_2LnCl$, $(C_5HMe_4)_2LnCl$, $Cp^*{}_2$-LnCl, $(Me_3SiC_5H_4)_2LnCl$, $[(Me_3Si)_2C_5H_3]_2LnCl$, or $(PhCH_2C_5H_4)_2LnCl(THF)$ (Ln = Gd, Er). Bis(cyclopentadienyl) ytterbium and samarium halides can be prepared by oxidation of $Cp_2Ln(II)$, for example, $Cp_2YbX(THF)_n$ (X = Cl, $n = 0.5$; X = Br or I, $n = 1$) oxidation of $Cp_2Yb(DME)$ with C_2Cl_6 or $(CH_2X)_2$ (X = Br or I) in THF, and $(Cp_2YbX)_2$ analogously from unsolvated Cp_2Yb in petroleum ether.[6]

Hydrofluorination of $[(Me_3Si)_2C_5H_3]_3Ln$ or Cp_3Ln in THF with 1 equiv. of Me_3NHF gave $[\{(Me_3Si)_2C_5H_3\}_2LnF]_2$ (Ln = La, Nd, Sm, Gd) or $[Cp_2LnF(THF)]_2$ (Ln = Y, Yb),



(a) (b) (c)

Figure 28 (a) $Cp_2Ln(\mu\text{-}Cl)_2LnCp_2$, (b) $Cp_2LnCl(THF)$, and (c) $Cp_2Ln(\mu\text{-}Cl)_2Li(THF)_2$

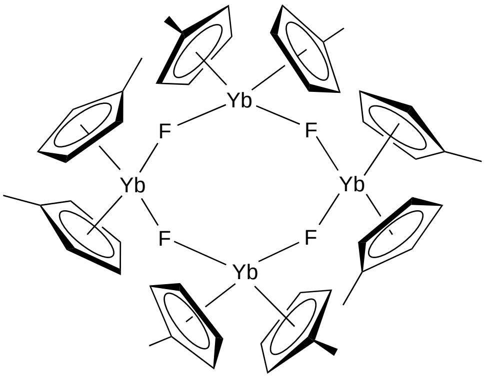


Figure 29 $[(C_5H_4Me)_2YbF]_4$

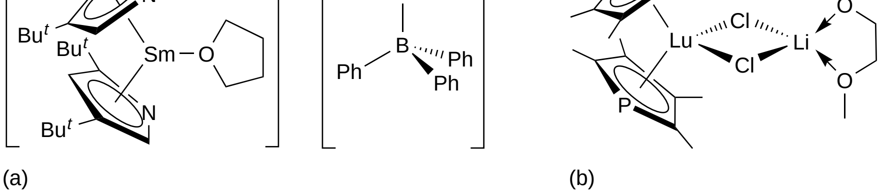
correspondingly. Oxidation of Cp_2Yb and $(C_5H_4Me)_2Yb$ with perfluoro(methylcyclohexane) or perfluorodecalin in DME gave unsolvated $(Cp_2YbF)_3$ and $[(C_5H_4Me)_2YbF]_4$, while in THF, the oxidation of $(C_5H_4Me)_2Yb$ provided the dimeric $[(C_5H_4Me)_2YbF(THF)]_2$. $(Cp_2YbF)_3$ is a trimer with formal eight-coordination for ytterbium and a planar $(YbF)_3$ ring, whereas $[(C_5H_4Me)_2YbF]_4$ is an eight-coordinate tetramer having a puckered $(YbF)_4$ unit (Figure 29).[65] The organosamarium fluoride $[(C_5H_4{}^tBu)_2Sm(\mu\text{-}F)]_3$ was generated by oxidation of $(C_5H_4{}^tBu)_2Sm(THF)_2$ with Me_3SnF.

$[(Me_3Si)_2C_5H_3]_2YbI(THF)$ was synthesized by the reaction of two equivalents of $Na[(Me_3Si)_2C_5H_3]$ with $YbI_3(THF)_2$.[66] Related complexes $[(Me_3Si)_2(C_5H_3]_2LnI(THF)$ (Ln = La, Sm, Y, Er, Lu) were prepared by treatment of $[\{(Me_3Si)_2C_5H_3\}_2LnCl]_2$ with excess of NaI in dry THF, or by reaction of a mixture of $LnCl_3$ and NaI with two equiv. of $Na[(Me_3Si)_2C_5H_3]$ in THF.

Lanthanide (+)-neomenthylcyclopentadienyl complexes $[Cp^R{}_2Ln(\mu\text{-}Cl)]_2$ (Ln = Sm, Yb, Y, Lu; Cp^R = (+)-neomenthylcyclopentadienyl) and $Cp^RLnX_2(THF)_3$ (X = Cl, Ln = Sm, Gd, Yb, Y, Lu; X = I, Ln = Sm, Yb) are available from $LnCl_3$ and the appropriate alkali metal (+)-neomenthylcyclopentadienyl complexes as chloride-bridged dimers. $Cp^RSmI_2(THF)_3$ is pseudo-octahedral with the two iodine atoms taking the trans positions.

$Cp^*{}_2Y(\mu\text{-}Cl)YCp^*{}_2Cl$ reacts with oxygen-containing substrates to form monomeric adducts $Cp^*{}_2YCl(L)$ (L = THF, benzophenone, methylmethacrylate, ε-caprolactone, hexamethylphosphoramide, ε-caprolactam, 1-methyl-2-pyrrolidinone, N,N'-dimethylpropyleneurea). A bis-adduct, $Cp^*{}_2YCl(\varepsilon\text{-caprolactam})_2$ was isolated when an excess of ε-caprolactam was used.[67]

Oxidation of $Cp^*{}_2Sm$ with $AgBPh_4$ in toluene yields $[Cp^*{}_2Sm][BPh_4]$, which in the solid state consists of a bent $Cp^*{}_2Sm$ unit oriented toward two of the Ph rings of the $[BPh_4]^-$ anion. Analogous Nd and Tm derivatives were prepared reacting $Cp^*{}_2Ln(\eta^3\text{-}CH_2CH{=}CH_2)$ (Ln = Nd, Tm) with $[Et_3NH][BPh_4]$ in benzene. $[(C_5H_4{}^tBu)_2Yb(THF)_2][BPh_4]$ has been synthesized from $(C_5H_4{}^tBu)_2Yb(THF)_2$ and $AgBPh_4$ followed by crystallization from THF. Related cationic organolanthanide compounds $[(C_5H_4R)_2Sm(THF)_2][BPh_4]$ (R = ^{t}Bu, $SiMe_3$), $[Pyr^*{}_2Sm(THF)][BPh_4]$ ($Pyr^* = NC_4H_2{}^tBu_2$-2,5) (Figure 30a), $[Cp^*{}_2Ln(THF)_2][BPh_4]$ (Ln = Y, Yb), and $[(C_5Me_4Et)_2Ln(THF)_2][BPh_4]$ (Ln = Y, Sm) have been synthesized by oxidation of the divalent metallocenes



(a) (b)

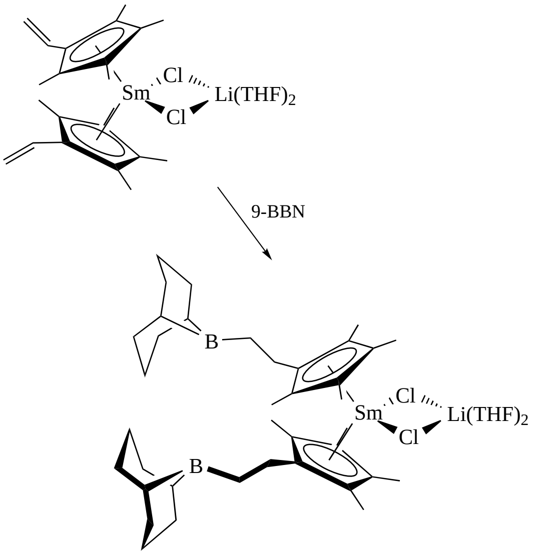
Figure 30 (a) $[Pyr^*{}_2Sm(THF)][BPh_4]$, (b) $(C_4Me_4P)_2Lu(\mu\text{-}Cl)_2Li(DME)$

with $AgBPh_4$ or by protolysis of the lanthanide alkyls $Cp^*_2YMe(THF)$, $Cp^*_2YbCH(SiMe_3)_2$, and $(C_5Me_4Et)_2$-$LnCH(SiMe_3)_2$ (Ln = Y, Sm), respectively, by $[Et_3NH]$-$[BPh_4]$. Bis(phospholyl) chloride complexes of Y and Lu can be prepared as DME (Figure 30b) or Et_2O adducts.

Phosphinoethyl substituted cyclopentadienyl complexes $[CpCH_2CH_2PR_2]_2LnX$ (Ln = Y, Lu; R = Me, Cy, ^{t}Bu, Ph; X = Cl, CF_3SO_3) show a distorted trigonal bipyramid with two axial phosphino groups and two equatorial cyclopentadienyl moieties, and the third equatorial site being occupied by the halide or triflate ligand (Figure 31).[68]

The lanthanum complex $[(MeOCH_2CH_2C_5H_4)_2La(\mu$-$Cl)]_2$ with ether-functionalized Cp ligands is a chlorine-bridged dimer. Optically active metallocene complexes of Y, Sm, and Lu containing cyclopentadienyl ligands with chiral nonracemic N- or O-substituted side chains, for example, (*S*)-(2-methoxypropyl)cyclopentadienyl, (*S*)-[2-(dimethylamino)propyl]cyclopentadienyl, and (*S*)-[2-(dimethylamino)-1-(phenylethyl)]cyclopentadienyl were prepared by reaction of the potassium salts of those cyclopentadienyl systems with the trichlorides of Y, Sm, and Lu in a 2:1 molar ratio: $[(S)$-η^5:η^1-$C_5H_4(CH_2CH(Me)OMe)]_2LnCl$ (Ln = Y, Sm), $\{(S)$-η^5:η^1-$C_5H_4[CH_2CH(Me)NMe_2]\}_2$-LnCl (Ln = Y, Sm), and $\{(S)$-η^5:η^1-$C_5H_4[CH(Ph)CH_2$-$NMe_2]\}_2LnCl$ (Ln = Y, Sm, Lu). The mixed chiral sandwich complexes $[(\eta^5$-Cp*$)\{(S)$-η^5:η^1-$C_5H_4[CH_2CH(Me)$-$NMe_2]\}LnCl]$ (Ln = Y, Lu) and $[(\eta^5$-Cp*$)\{(S)$-η^5:η^1-$C_5H_4[CH(Ph)CH_2NMe_2]\}LnCl]$ (Ln = Y, Lu) were prepared by successive reaction of $LnCl_3$ with one equiv. of the potassium salt of the chiral nonracemic cyclopentadienyl ligand and one equiv. of Cp*Na. In all the cases, the N- and O-donor functions are coordinated by the metals (Figure 32). An intramolecular coordination of the oxygen atom has also been found in the chiral lanthanocene iodides $[(S)$-$Cp']_2LnI$ (Ln = La, Sm; Cp′ = $C_5H_4CH_2CHMeOCH_2Ph$).

Lanthanide complexes with vinyl-substituted cyclopentadienyl ligands $(CH_2{=}CHC_5Me_4)_2Ln(\mu$-$Cl)_2Li(Et_2O)_2$ (Ln = Y, Sm, Lu),[69] $[(CH_2{=}CHCH_2CH_2C_5Me_4)_2Ln(\mu$-$Cl)]_2$ (Ln = Y, Sm, Lu), and $(CH_2{=}CHCH_2CH_2C_5Me_4)_2$-LnCl(THF) (Ln = Y, Sm) were prepared by exchange reactions with the lithium and sodium salts of the appropriate Cp-ligands.[70] $(CH_2{=}CHC_5Me_4)_2Sm(\mu$-$Cl)_2Li(Et_2O)_2$ could be hydroborated with 9-BBN affording $(C_8H_{14}BCH_2$-$CH_2C_5Me_4)_2Sm(\mu$-$Cl)_2Li(THF)_2$ (equation 19).[69]



(19)

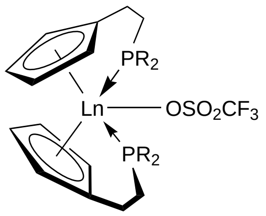


Figure 31 $[C_5H_4CH_2CH_2PR_2]_2LnOSO_2CF_3$

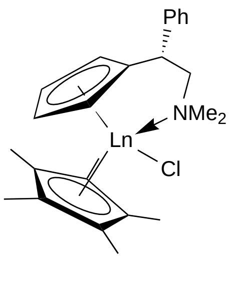

Figure 32 $[(Cp^*)\{(S)$-η^5:η^1-$C_5H_4(CHPhCH_2NMe_2)\}LnCl]$

Many bis(cyclopentadienyl)lanthanide oxides, hydroxides, alkoxides, and carboxylates have been prepared mainly by protonolysis of tris(cyclopentadienyl)lanthanides and bis(cyclopentadienyl)lanthanide alkyls, or by alkali halide abstraction from bis(cyclopentadienyl)lanthanide chlorides and water, alcohols, acids, or the corresponding alkali metal salts, respectively;[6] for example, dinuclear $[Cp_2Yb(\mu$-$OCH_2CH_2CH_2CH_2CH_3)]_2$ (Figure 33a) and $[Cp_2Ln(\mu$-$OCH_2CH_2CHMe_2)]_2$ (Ln = Dy, Yb), $[Cp_2Ln(\mu$-$OPr)]_2$, monomeric $Cp_2Ln(THF)(OR^F)$ [Ln = Nd, Sm, Yb; R^F = 2,4,6-tris(trifluoromethyl)phenyl] (Figure 33b), $Cp_2Yb(\alpha$-naphthol)(THF) were prepared by reacting of Cp_3Ln with respective alcohols or phenols. Monomeric organolanthanide acetates $[(C_5Me_4{}^tBu)_2LnO_2CCH_3]$ (Ln = La, Lu) (Figure 33c) are prepared from $[(C_5Me_4{}^tBu)_2LnCl(THF)]$ (Ln = La, Lu) and NaO_2CCH_3.

Another approach to bis(cyclopentadienyl)lanthanide alkoxides is the cleavage of ethers by bis(cyclopentadienyl) lanthanide hydrides. Dialkyl ethers, ROR′, are cleaved by $(Cp^*_2LnH)_2$ (Ln = Y, La, Ce) to form Cp^*_2LnOR, Cp^*_2LnOR', R′H, and RH. The extent to which either of the C–O bonds of asymmetrically substituted dialkyl ethers ROR′

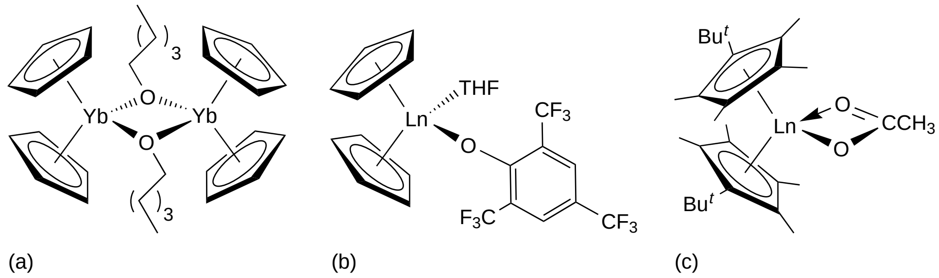

Figure 33 (a) $[Cp_2Yb(\mu\text{-}OCH_2CH_2CH_2CH_2CH_3)]_2$, (b) $Cp_2Ln(THF)(OR^F)$, (c) $[(C_5Me_4{}^tBu)_2LnO_2CCH_3]$

is attacked strongly depends on the alkyl substituents but is relatively insensitive to the nature of the metal. Ring opening is observed when THF or 1,4-dioxane reacted with hydrides to give Cp^*_2YOBu and $(Cp^*_2Y)_2(\mu\text{-}OCH_2CH_2O)(THF)_2$, respectively. NMR studies in solution of the lanthanocene complexes containing a chiral alkoxide ligand, for example, $[Cp_2Ln(\mu\text{-}OCHRCHR^1NR^2R^3)]_2$ ($R = H$, $R^1 = Et$, R^2, $R^3 = Me$ and Ln = Pr, Nd, Sm, Yb, Lu) indicate an additional coordination of nitrogen to the lanthanide at room temperature for the Pr, Nd, and Sm complexes (Figure 34).

Reaction of two equiv. of $Li_2(C_5R_4SiMe_2NCH_2CH_2X)$ ($C_5R_4 = C_5Me_4$, $C_5H_3{}^tBu$; X = OMe, NMe_2) with $LnCl_3$ (Ln = Y, Lu) yields C_2-symmetric complexes $Li[(\eta^5{:}\eta^1\text{-}C_5R_4SiMe_2NCH_2CH_2X)_2Ln]$ (Figure 35). In the case of $Li[Y(\eta^5{:}\eta^1\text{-}C_5H_3{}^tBuSiMe_2NCH_2CH_2X)_2]$, a mixture of the two diastereomers in relative ratios depending on the reaction time are formed. The (R, S)-diastereomer is the kinetic

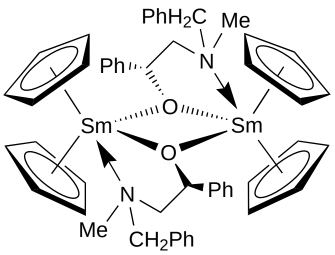

Figure 34 $[Cp_2Sm\{\mu\text{-}OCHPhCH_2NMeCH_2Ph\}]_2$

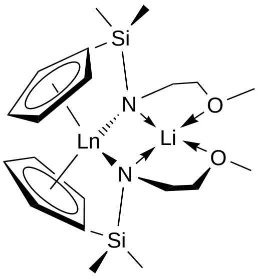

Figure 35 $Li[(\eta^5{:}\eta^1\text{-}C_5H_4SiMe_2NCH_2CH_2OMe)_2Ln]$

product that rearranges to the thermodynamically preferred C_2-symmetric (R, R)-diastereomer in donor solvents such as THF.

Lanthanidocene silylamide complexes $(C_5HMe_4)_2YN(SiHMe_2)_2$, $Cp^*_2YN(SiHMe_2)_2$, and $(C_5HPh_4)_2LaN(SiHMe_2)_2$ were obtained by a silylamine elimination from $Ln[N(SiHMe_2)_2]_3(THF)_2$ (Ln = Y, La) and the respective cyclopentadienes. Deprotonation of tetraphenylcyclopentadiene was possible only in the case of La. The spectroscopic and structural data for these complexes revealed a strong agostic interaction (*see Agostic Bonding*) between the electron-deficient metal centers and the SiH moiety of the bis(dimethylsilyl)amide ligand (Figure 36a).[71] Amidolanthanidocenes $(C_5H_4Me)_2LnNC_5H_{10}$ (Ln = Yb, Er, Y; NC_5H_{10} = piperidine) (Figure 36b) were prepared reacting $LnCl_3$ with NaC_5H_4Me, followed by treatment with $LiNC_5H_{10}$. The amidinate derivatives

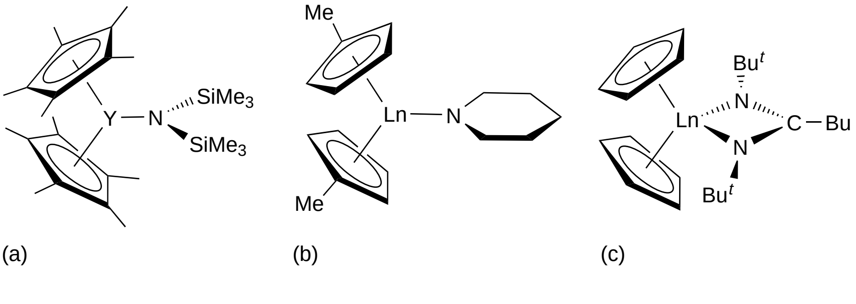

Figure 36 (a) $Cp^*_2YN(SiHMe_2)_2$, (b) $(C_5H_4Me)_2LnNC_5H_{10}$, (c) $Cp_2Ln[{}^tBuNCBuN{}^tBu]$

$Cp_2Ln[^tBuNC(Bu)N^tBu]$ (Ln = Er, Y, Gd) (Figure 36c) were prepared by reaction of Cp_2LnBu (generated in situ) with N,N'-di-*tert*-butylcarbodiimide that proceeds via monoinsertion of carbodiimide into the Ln–C σ-bond. The structurally characterized yttrium compound is a good catalyst for the cyclotrimerization of phenylisocyanate.[72]

Protonolysis of Cp_3Ln (Ln = Dy or Yb) with thiols, HSR (R = Pr or Bu) in THF yields dimeric thiolates $[Cp_2Ln(\mu\text{-}SR)]_2$ (R = Pr; Ln = Dy or Yb; R = Bu; Ln = Dy or Yb). $[Cp_2Yb(\mu\text{-}SBu)]_2$ has a planar Yb_2S_2 unit with the Bu groups antipositioned relative to the Yb_2S_2 ring (Figure 37a). Elemental Te readily inserts into the Sc–C bond of $Cp^*{}_2ScCH_2SiMe_3$ and $Cp^*{}_2ScCH_2Ph$ yielding the corresponding tellurates $Cp^*{}_2ScTeR$ (R = CH_2SiMe_3, CH_2Ph). The phosphide complex $Cp_2Lu[\mu\text{-}PPh_2]_2Li(TMEDA)$ (Figure 37b) was obtained from Ph_2PH and $Cp_2Lu(\mu\text{-}Me)_2Li(TMEDA)$[6] and the reaction of $[1,3\text{-}(Me_3Si)_2C_5H_3]_2YCl$ with $KPHSi^tBu_3$ yields $[1,3\text{-}(Me_3Si)_2C_5H_3]_2YPHSi^tBu_3$.[73]

Bimetallic complexes $Cp_2(THF)LuRu(CO)_2Cp$ (Figure 38a), $[1,3\text{-}(Me_3Si)_2C_5H_3]_2(THF)LuRu(CO)_2Cp$, and $Cp^*{}_2LuRu(CO)_2Cp$ were prepared by reaction of $Na[CpRu(CO)_2]$ with the respective cyclopentadienyllutetium halides in THF. An X-ray structural study of $(THF)Cp_2LuRu(CO)_2Cp$ revealed a direct Lu–Ru bond. Lanthanide–tungsten complexes $Cp^*{}_2Ln(C_5H_4)W(H)_2Cp$ (Ln = Y, Sm) (Figure 38b) were prepared reacting $(Cp^*{}_2LnH)_2$ with Cp_2WH_2.

Bis(indenyl)lanthanide complexes are also described. According to X-ray crystallographic investigations $(C_4H_7OCH_2C_9H_6)_2LnCl$ (Ln = Nd, Sm, Dy, Ho, Er, Yb) (Figure 39) are unsolvated nine-coordinate monomeric complexes with a

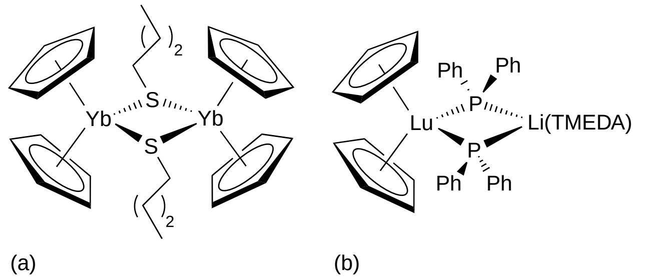

Figure 37 (a) $[Cp_2Yb(\mu\text{-}SBu)]_2$, (b) $Cp_2Lu[\mu\text{-}PPh_2]_2Li(TMEDA)$

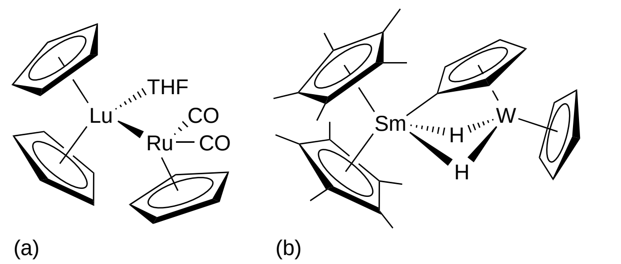

Figure 38 (a) $(THF)Cp_2LuRu(CO)_2Cp$, (b) $Cp^*{}_2Sm(C_5H_4)W(H)_2Cp$

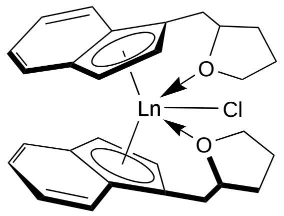

Figure 39 $(C_4H_7OCH_2C_9H_6)LnCl$

trans arrangement of both the side arm and indenyl rings in the solid state.[74]

Similar structures were found for $(CH_3OCH_2CH_2C_9H_6)_2LnCl$ (Ln = Y, La, Nd, Gd, Ho, Lu). Neutral monomeric bis(indenyl) complexes containing alkenyl-functionalized ligands, for example, $(Ind')_2LnCl(THF)$ (Ln = Gd, Er; Ind′ = 1-Allyl-2,4,7-trimethyl-1H-indene) and $(Ind'')_2LnCl(THF)$ [Ln = Y, Lu; Ind″ = 1-(3-buten-1-yl)-4,7-dimethyl-1H-indene] were prepared by reaction of $LnCl_3$ with the lithium salts of the corresponding indenyl ligand. However, the trichlorides of the comparatively large Sm and La ions react with different molar amounts of Ind″Li in THF exclusively with formation of the tris(indenyl) complexes Ind''_3Sm and $Ind'_3La(\mu\text{-}Cl)Li(Et_2O)_3$, respectively. Single-crystal X-ray structural analyses show that the alkenyl groups of the indenyl side chains are not coordinated to the lanthanide atoms.[64]

7.3 *Ansa*-bis(cyclopentadienyl) Complexes

ansa-Lanthanidocene complexes are very important catalysts for a number of organic reactions such as hydrogenation (*see Hydrogenation*), hydrosilylation (*see Hydrosilation*), -amination, and -phosphination of unsaturated compounds, as well as for the polymerization of olefins and for ring-opening polymerization of cyclic esters. The nature of the *ansa*-metallocene ligands impacts dramatically activity and stereoselectivity of the Ln-based catalysts.

rac-, C_1-, and *meso*-*ansa*- Metallocene complexes (*see Metallocene Complexes*) of Y and Sm, for example, *rac*-$Me_2Si[2,4\text{-}(Me_3Si)_2C_5H_2]_2SmCl_2Li(THF)_2$, C_1-$Me_2Si[2,4\text{-}(Me_3Si)_2C_5H_2][3,4\text{-}(Me_3Si)_2C_5H_2]SmCl_2Li\text{-}(THF)_2$, C_1-$Ph_2Si[2,4\text{-}(Me_3Si)_2C_5H_2][3,4\text{-}(Me_3Si)_2C_5H_2]SmCl_2Li(THF)_2$, *meso*-$[1,2\text{-}(Me_2Si)(Me_2SiOSiMe_2)](4-{}^tBuC_5H_2)_2SmCl_2Li(THF)_2$, *rac*-$Me_2Si[2,4\text{-}(Me_3Si)_2C_5H_2]_2YCl_2Li(THF)_2$, C_1-$Me_2Si[2,4\text{-}(Me_3Si)_2C_5H_2][3,4\text{-}(Me_3Si)_2C_5H_2]YCl_2Li(THF)_2$, *meso*-$[1,2\text{-}(Me_2Si)(Me_2SiOSiMe_2)](4\text{-}Me_3SiC_5H_2)_2YCl(THF)$ were prepared and structurally characterized. Their structures differ with respect to the bridging group and the position of the substituents on the cyclopentadienyl rings. The alkyl complexes C_1-$Me_2Si[2,4\text{-}(Me_3Si)_2C_5H_2][3,4\text{-}(Me_3Si)_2C_5H_2]SmCH(SiMe_3)_2$ (Figure 40) and C_1-$Me_2Si[2,4\text{-}(Me_3Si)_2C_5H_2][3,4\text{-}(Me_3Si)_2C_5H_2]YCH(SiMe_3)_2$ polymerize ethylene, giving high molecular weight polyethylenes.[75]

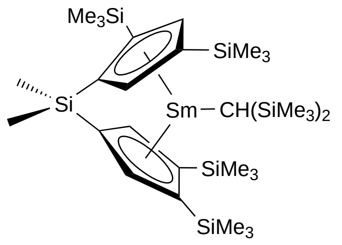

Figure 40 C_1-$Me_2Si[2,4-(Me_3Si)_2C_5H_2][3,4-(Me_3Si)_2C_5H_2]$-$SmCH(SiMe_3)_2$

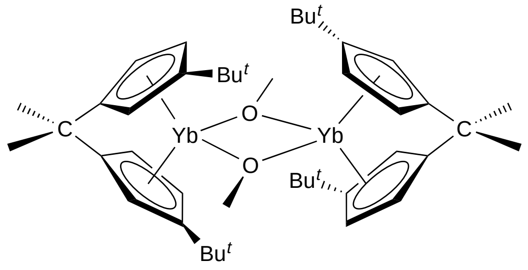

Figure 42 [*meso*-$Me_2C(3\text{-}^tBuC_5H_3)_2Yb(\mu_2\text{-}OMe)]_2$

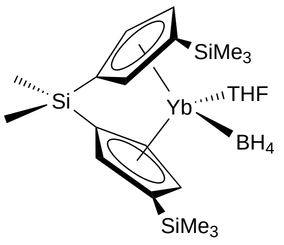

Figure 41 *meso*-$Me_2Si(3\text{-}Me_3SiC_5H_3)_2YbBH_4(THF)$

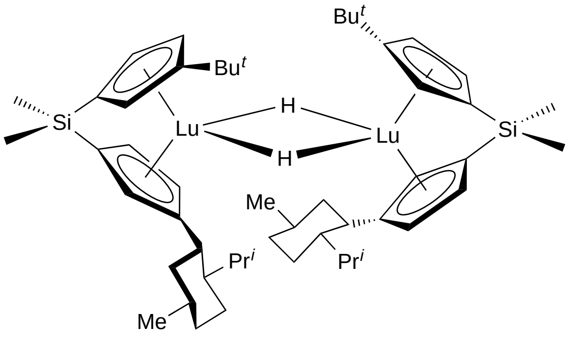

Figure 43 {[(*R*, *S*)-$Me_2Si(C_5H_3{}^tBu)(C_5H_3$-(+)-*neo*-Men)]LuH}$_2$

The *ansa*-ytterbocene(III) *meso*-$Me_2Si(3\text{-}Me_3SiC_5H_3)_2$-YbCl(THF) undergoes desolvation during recrystallization from toluene yielding [*meso*-$Me_2Si(3\text{-}Me_3SiC_5H_3)_2Yb(\mu_2\text{-}Cl)]_2$. Treatment with $LiBH_4$ in Et_2O results in *meso*-$Me_2Si(3\text{-}Me_3SiC_5H_3)_2YbBH_4(THF)$ (Figure 41), in which ytterbium coordinates to three H atoms of the $BH_4{}^-$ anion.

Reaction of $\{Me_2Si[C_5H_2\text{-}2,4\text{-}{}^iPr_2]_2\}Li_2$ with $ScCl_3$ and YCl_3 yields *rac*-$Me_2Si[C_5H_2\text{-}2,4\text{-}{}^iPr_2]_2ScCl[LiCl(THF)_2]$, *meso*-$Me_2Si[C_5H_2\text{-}2,4\text{-}{}^iPr_2]_2Sc(\mu_2\text{-}Cl)]_2$, *rac*-$Me_2Si[C_5H_2\text{-}2,4\text{-}{}^iPr_2]_2YCl[LiCl(THF)_2]$, and *meso*-$Me_2Si[C_5H_2\text{-}2,4\text{-}{}^iPr_2]_2Y(\mu_2\text{-}Cl)]_2$ in approximately 3:1 racemic:meso ratios. Treatment of the Sc compounds with allylmagnesium bromide affords the allyl complexes *rac*- and *meso*-$Me_2Si[C_5H_2\text{-}2,4\text{-}{}^iPr_2]_2Sc(\eta^3\text{-}C_3H_5)$. Diastereomerically pure rac-compounds or pure meso dimers undergo spontaneous isomerization upon dissolution in THF-d_8 with reversion back to a 3:1 racemic:meso ratio. The complexes *rac*-$Me_2C(3\text{-}{}^tBuC_5H_3)_2Yb(\mu_2\text{-}Cl)_2Li(OEt_2)_2$ and the monosolvate *meso*-$Me_2Si(3\text{-}Me_3SiC_5H_3)_2YbCl(THF)$ were prepared reacting $Me_2E(3\text{-}Me_3EC_5H_3)_2Li_2$ (E = C, Si) with $YbCl_3$, respectively. The reaction between $Me_2C(3-{}^tBuC_5H_3)_2Li_2$ and YbI_2 in DME proceeds with solvent cleavage to form the dimeric methoxide complex [*meso*-$Me_2C(3\text{-}{}^tBuC_5H_3)_2Yb(\mu_2\text{-}OMe)]_2$ (Figure 42).

ansa-Metallocene complexes (*R*, *S*)-$Me_2Si({}^tBuC_5H_3)$ [(+)-*neo*-Men-Cp]$Ln(\mu\text{-}Cl)_2Li(OEt_2)_2$ (Ln = Y, Lu; (+)-*neo*-Men = (+)-*neo*-menthyl) were synthesized by reaction of the corresponding lanthanide trichlorides with the dilithium salt of the ligand and were isolated isomerically pure by crystallization from Et_2O. Alkylation of the (*R*, *S*)-epimers with $LiCH(SiMe_3)_2$ proceeds with retention of configuration at the lanthanide center, affording chiral hydrocarbyl complexes in high yield. Reaction of the Lu-hydrocarbyl with H_2 affords diastereomerically pure {(*R*, *S*)-$Me_2Si({}^tBuC_5H_3)$[(+)-*neo*-Men-Cp]LuH}$_2$ (Figure 43), an active catalyst for asymmetric olefin hydrogenation (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).

Disiloxane-bridged metallocenes $\{O(Me_2SiC_5H_4)_2\}PrCl$-(THF) and $[\{O(Me_2SiC_5H_4)_2\}YbCl]_2$ (Figure 44a) were prepared from $LnCl_3$ (Ln = Pr or Yb) and $K_2[O(Me_2SiC_5H_4)_2]$ in THF. $[Me_2Si(C_5H_4)_2Yb(\mu\text{-}Br)]_2$ and $[Me_2Si(C_5H_4)_2Yb$-$(\mu\text{-}Cl)]_2$ are also dimers, like $[Me(R)Si(C_5H_4)(C_5Me_4)$-$LnCl]_2$ (R = Et, Ph; Ln = Y, La, Sm, Lu) and $[Me(Et)Si$-$(C_5H_4)(C_5Me_4)SmCl]_2$. Metallocenes with two cyclopentadienyl rings tethered by a 2,6-bis(methylene)pyridyl unit $[\{2,6\text{-}C_5H_3N(CH_2C_5H_4)_2\}Ln(\mu\text{-}O_2SOCF_3)]_2$ (Figure 44b) (Ln = Nd, Y, Yb) are also dimers with each triflate ligand bridging two Ln ions.[76]

$[MeO(CH_2)_5(Me)Si(C_5Me_4)_2]YCH(SiMe_3)_2$, containing a donor functionality in the Si bridge, exhibits low catalytic activity in such reactions as olefin hydrogenation, presumably because of the competition between the substrate (weak donor) and the donor functionality of the ansa ligand for the empty coordination site at the metal center. In contrast, for aminoalkene hydroamination/cyclization in which a strong amine donor is the substrate, catalytic activity is significantly enhanced while diastereoselectivity is essentially unchanged compared to nonfunctionalized analogs.

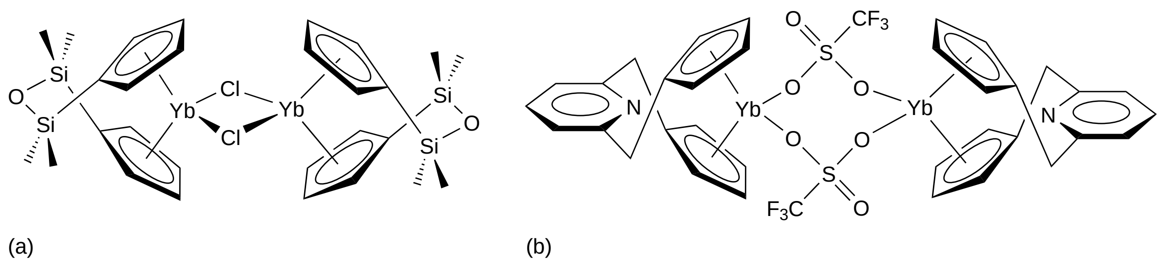

Figure 44 (a) $[\{O(Me_2SiC_5H_4)_2\}YbCl]_2$, (b) $[\{2,6\text{-}C_5H_3N(CH_2C_5H_4)_2\}Yb(\mu\text{-}O_2SOCF_3)]_2$

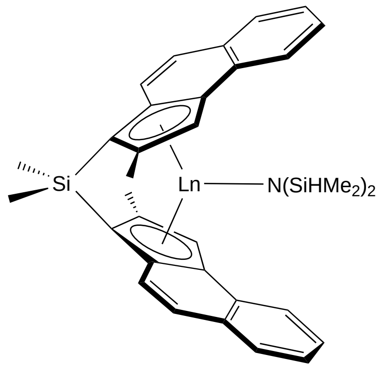

Figure 45 *rac*-$Me_2Si(2\text{-Me-Benz-Ind})_2LnN(SiHMe_2)_2$

Brintzinger-type, indenyl-derived metallocene complexes *rac*-$Me_2Si(2\text{-Me-Benz-Ind})_2LnN(SiHMe_2)_2$ (Figure 45) and *rac*-$Me_2Si(2\text{-Me-}C_9H_5)_2LnN(SiHMe_2)_2$ (Ln = Y, Lu) have been prepared by silylamine elimination of $Ln[N(SiHMe_2)_2]_3$-$(THF)_2$ and linked, substituted indene systems, and isolated in racemic yields as high as 72%.[77]

1,2-Bis(indenyl)ethane-derived *ansa*-lanthanidocenes [*rac*- and *meso*-$(CH_2)_2(\eta^5\text{-}C_9H_6\text{-}1)_2LnCl][LiCl(Et_2O)_2]$ (Ln = Yb, Lu) were synthesized from dilithiated 1,2-bis(indenyl)ethane with either $YbCl_3$ or $LuCl_3$ in THF followed by solvent exchange with Et_2O. In the Yb case, the major diastereomer formed is meso, while in the case of Lu, the rac diastereomer predominated.

1,1′- (3-Oxapentamethylene)-bridged bis(indenyl) *ansa*-lanthanidocenes $[O(CH_2CH_2C_9H_6)_2]LnCl(THF)$ (Ln = Y, Pr, Nd, Dy, Yb, Lu) were obtained as a rac/meso mixture by the reaction of $LnCl_3$ with $O(CH_2CH_2C_9H_6)_2K_2$ in THF. Direct amidation or alkylation of the rac/meso mixtures in toluene provided solely pure racemic *ansa*-lanthanidocene amides $[O(CH_2CH_2C_9H_6)_2]LnN(SiMe_3)_2$ (Ln = Y, Pr, Nd, Yb, Lu) and pure racemic *ansa*-lanthanidocene hydrocarbyls $[O(CH_2CH_2C_9H_6)_2]LnCH_2SiMe_3$ (Ln = Dy, Yb), correspondingly. The amide and hydrocarbyl complexes are efficient single-component catalysts for MMA polymerization.[78]

Me_2Si-bridged cyclopentadienyl/indenyl (donor-functionalized)-*ansa*-metallocenes $\{Me_2Si(C_5H_2\text{-}3,5\text{-}^tBuMe)$-$[1\text{-}C_9H_5\text{-}3\text{-}(CH_2)_2NMe_2]\}LnCl$ (Ln = Y, Sm, Lu) are monomeric and solvent free with intramolecular coordination of the donor function to the metal as shown by X-ray crystallography of the Lu derivative (Figure 46).

A C_s-symmetric yttrocene complex, *ansa*-$Me_2Si(\eta^3\text{-}Flu)(\eta^5\text{-}C_5Me_4)YCl_2Li(OEt_2)_2$ (Flu = $C_{13}H_8$, fluorenyl), was prepared from YCl_3 and the dilithium salt of *ansa*-$Me_2Si(FluH)(C_5Me_4H)$. Treatment with $NaN(SiMe_3)_2$ yields the corresponding bis(trimethylsilyl)amide derivative *ansa*-$Me_2Si(Flu)(\eta^5\text{-}C_5Me_4)YN(SiMe_3)_2$ (Figure 47). In both complexes, the five-membered ring of the fluorenyl ligand is slipped from η^5 toward an η^3 coordination mode.

Lanthanide complexes with an unsymmetric cyclopentadienyl-fluorenyl ligand $[Me_2C(\eta^5\text{-}Flu)(\eta^5\text{-}Cp)]Ln(\eta^5\text{-}Cp)$-$(FluH)CMe_2$ (Figure 48a) (Ln = Y, La, Nd) were prepared by amine elimination from $Ln[N(SiMe_3)_2]_3$ and (CpH–CMe_2–FluH). These ansa complexes feature very ‘open’ Cp(centroid)–Ln–Flu(centroid) bite angles (Ln = La,

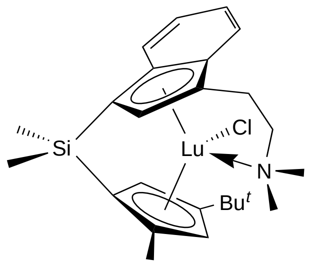

Figure 46 $\{Me_2Si(C_5H_2\text{-}3,5\text{-}^tBuMe)[1\text{-}C_9H_5\text{-}3\text{-}(CH_2)_2NMe_2]\}^-$ LuCl

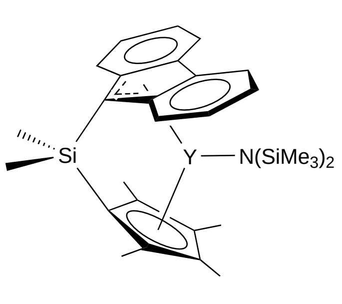

Figure 47 *ansa*-$Me_2Si(\eta^3\text{-}Flu)(\eta^5\text{-}C_5Me_4)YN(SiMe_3)_2$

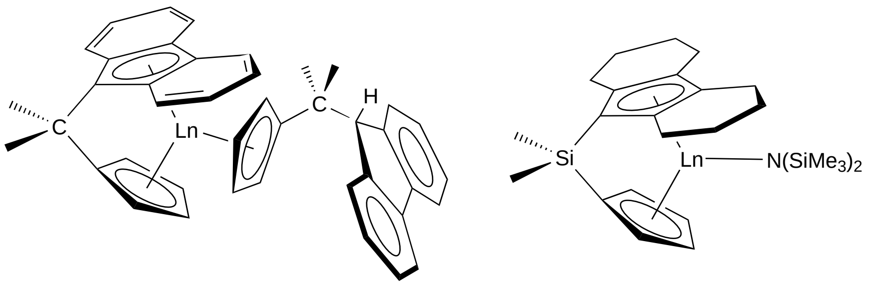

(a) (b)

Figure 48 (a) $[Me_2C(\eta^5\text{-Flu})(\eta^5\text{-}C_5H_4)]Ln(\eta^5\text{-}C_5H_4)(FluH)CMe_2$, (b) $Me_2Si(OHF)(C_5H_3R)LnN(SiMe_3)_2$

103°; Nd, 105°).[79] The related Lu complex $[Ph_2C(\eta^5\text{-Flu})(\eta^5\text{-}Cp)]LuN(SiMe_3)_2$ exhibits intramolecular ß–C–Si agostic interaction with Lu. The complex was used as stereospecific catalyst in polymerization of MMA producing richly syndiotactic PMMA and in ring-opening polymerization of ε-caprolactone and δ-valerolactone producing polymers with moderate polydispersity.[80] Chiral C_1-symmetric *ansa*-metallocenes $Me_2Si(OHF)(C_5H_3R)LnN(SiMe_3)_2$ (Figure 48b) (OHF = η^5-octahydrofluorenyl; R* = (−)-menthyl; Ln = Sm,Y, Lu) exhibit catalytic activity for hydroamination/cyclization of aminoalkenes (≤67% enantioselectivities) and for the hydrophosphination/cyclization of phosphinoalkenes (≤96% diastereoselectivities).[81]

ansa-Metallocenes $(\eta^5{:}\eta^5\text{-}C_{24}H_{16})LnI(THF)$ (Figure 49) (Ln = Dy, Er, Tm, Lu) were prepared by in situ reactions of two equiv. of potassium acenaphthylenide $K^+\ C_{12}H_8^-$ with LnI_3. Dimerization of two acenaphthylene radical anions produces a *rac-ansa*-metallocene structure with the Lu atom in a distorted tetrahedral geometry with two η^5-coordinated five-membered rings of the acenaphthylene ligands, the iodine and the THF.[82]

Tris(peralkylcyclopentadienyl)samarium complexes containing two rings bridged by a Me_2Si group were synthesized reacting SmI_3 first with $Me_2Si(C_5Me_4K)_2$ in THF followed by the reaction with KC_5Me_4R (R = Me, Et, ^{n}Pr, ^{i}Pr). When the second stage is carried out in toluene the solvent-free complexes $Me_2Si(C_5Me_4)_2SmCp^*$ (Figure 50a), $Me_2Si(C_5Me_4)_2Sm(C_5Me_4Et)$, $Me_2Si(C_5Me_4)_2Sm(C_5Me_4{}^n Pr)$, and $Me_2Si(C_5Me_4)_2Sm(C_5Me_4\text{-}{}^i Pr)$ were isolated. In contrast to the reactivity of Cp^*_3Sm,

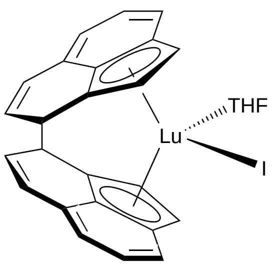

Figure 49 $(\eta^5{:}\eta^5\text{-}C_{24}H_{16})LuI(THF)$

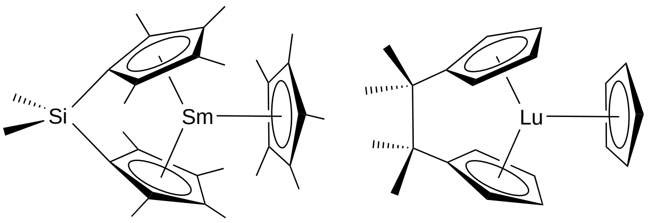


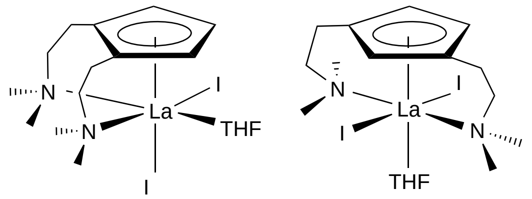
(a) (b)

Figure 50 (a) $Me_2Si(C_5Me_4)_2SmCp^*$, (b) $Me_4C_2(C_5H_4)_2LuCp(THF)$

the complexes obtained do not cleave THF, do not reduce 1,3,5,7-C_8H_8 or $Ph_3P{=}Se$, and do not polymerize ethylene. Tris(cyclopentadienyl) compounds with two Cp rings linked by a tetramethylethano unit $Me_4C_2(C_5H_4)_2LnCp(THF)$ (Figure 50b) (Ln = Nd, Sm, Gd, Yb) were prepared by reaction of $Me_4C_2(C_5H_4MgCl)_2$ with $LnCl_3$ followed by CpNa in THF.

7.4 Mono(cyclopentadienyl) Complexes

Monomeric half-sandwich complexes (*see Half-sandwich Complexes*) bearing double-N-functionalized cyclopentadienyl ligands $[C_5H_3(CH_2CH_2NMe_2)_2\text{-}1,2]LaI_2(THF)$ (Figure 51a) and $[C_5H_3(CH_2CH_2NMe_2)_2\text{-}1,3]LaI_2(THF)$ (Figure 51b), were prepared reacting LaI_3 with $K[1,2\text{-}C_5H_3(CH_2CH_2NMe_2)_2]$ and $K[1,3\text{-}C_5H_3(CH_2CH_2NMe_2)_2]$.



(a) (b)

Figure 51 (a) $[C_5H_3(CH_2CH_2NMe_2)_2\text{-}1,2]LaI_2(THF)$,
(b) $[C_5H_3(CH_2CH_2NMe_2)_2\text{-}1,3]LaI_2(THF)$

In both complexes, the La atoms have a distorted octahedral geometry. However, different coordination requirements of the tridentate 1,2- and 1,3-substituted cyclopentadienyl ligands cause different positions of the iodine atoms and the THF molecule around the metal.[83]

The (+)-neomenthylcyclopentadienyllanthanide complexes $Cp^RLnX_2(THF)_3$ [X = Cl, Ln = Sm, Gd, Yb, Y, Lu; X = I, Ln = Sm, Yb; Cp^R = (+)-neomenthylcyclopentadienyl] were prepared by reaction of $LnCl_3$ with appropriate alkali metal cyclopentadienyl derivatives. In the solid state, the monomeric $Cp^RSmI_2(THF)_3$ adopts a pseudo-octahedral geometry with the two iodine atoms taking trans positions. A similar structure is found for $(Ind)GdCl_2(THF)_3$.

Half-sandwich cyclopentadienyl lanthanide complexes $\{[(\eta^5\text{-}C_5H_4{}^t\text{Bu})Ln(THF)]_2(\mu_2\text{-Cl})_2(\mu_3\text{-Cl})_3Na(THF)\}_n$ (Ln = Nd, Sm, Gd, Yb) are available from the reaction of $LnCl_3$ with $NaC_5H_4{}^t\text{Bu}$ in THF. The Sm complex reacts with Na_2Se_5 yielding hexanuclear $[Na(THF)_6]_2[(\eta^5\text{-}C_5H_4{}^t\text{Bu})_6Sm_6(\mu_6\text{-Se})(\mu\text{-}Se_2)_6]$ (Figure 52).[84] Earlier described clusters containing monocyclopentadienylsamarium units are $[Cp_{12}Sm_{12}(\mu_3\text{-Cl})_{24}]$, $[(Cp^*Sm)_6Se_{11}]$, and $[(Cp^*Sm)_6Se_{11}]$.

The reaction of $Sm(OAr)_3(THF)$ (Ar = 2,6-$^t Bu_2C_6H_3$) with one equiv. of LiCp* produces $Cp^*Sm(OAr)_2$-(THF), which reveals a three-legged piano stool (*see Piano Stool Structure*) geometry. The monocyclopentadienyl yttrium complex containing a diamide ligand, $CpY\{ArN(CH_2)_3NAr\}(THF)$ (Ar = 2,6-$^i Pr_2C_6H_3$) (Figure 53) was obtained from alkali metal salts of the ligand and cyclopentadiene.[85]

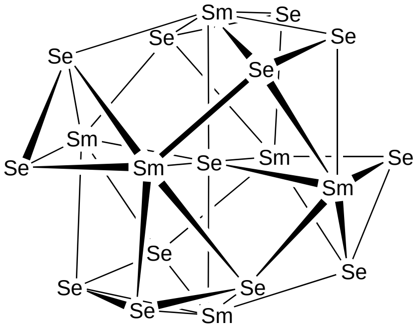


Figure 52 Structure of $[Na(THF)_6]_2[(\eta^5\text{-}C_5H_4{}^t\text{Bu})_6Sm_6(\mu_6\text{-Se})(\mu\text{-}Se_2)_6]$ (Cp ligands are omitted)

Besides the *ansa*-metallocene complexes with so-called *constrained geometry ligands* are used as effective catalysts in a number of important organic reactions. Constrained geometry ligands combine alkoxido-, amido- or other functions attached to the cyclopentadienyl ring. A variety of linkers between the Cp ring and the covalently bonded function, which both rigidly coordinate to the metal, enables the shaping of the free coordination sphere of the metal thus permitting a fine tuning of complex reactivity.[25,86] For alkyl lanthanide complexes supported by constrained geometry ligands see paragraph 2.3.

Reaction of $Y[N(SiMe_3)_2]_3$ with $Me_2Si(C_5Me_4H)$ (N(H)-^{t}Bu) at 100° C results in elimination of 2 equiv. of $HN(SiMe_3)_2$ and attachment of the Cp-amido ligand to yttrium. Later this synthetic approach was used for the preparation of related amide and alkyl complexes, for example, $[Me_2Si(\eta^5\text{-}C_5Me_4)(N{}^t\text{Bu})]LnE(SiMe_3)_2$ (Ln = Sm, Nd, Yb, Lu; E = CH, N) (Figure 54). They are significantly more active than the corresponding complexes $Cp^*_2LnE(SiMe_3)_2$ as precatalysts for aminoalkene hydroamination/cyclization.

Yttrium alkyl complexes $Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^1\text{-}NCMe_2\text{-}R)Y(CH_2SiMe_3)(THF)$ (R = Me, Et) and $Me_2Si(\eta^5\text{-Ind})(\eta^1\text{-}N{}^t\text{Bu})Y(CH_2SiMe_3)(THF)$ were prepared in high yields from $Y(CH_2SiMe_3)_3(THF)_2$ and amino-functionalized cyclopentadienes or indene, respectively. According to single-crystal X-ray diffraction, $Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^1\text{-}NCMe_2Et)Y(CH_2SiMe_3)(THF)$ has a three-legged piano stool geometry. Reaction of $Y(CH_2SiMe_3)_3(THF)_2$ with the tridentate linked amido-cyclopentadienyl ligands $(C_5Me_4H)SiMe_2NHR$ (R = CH_2CH_2OMe, $CH_2CH_2NMe_2$, $CH_2CH_2CH_2OMe$, $CMe_2\text{-}CH_2OMe$), which contain an additional donor functionality, results in the cleavage of the silicon-cyclopentadienyl bond and formation of $(C_5Me_4H)\{N(SiMe_2CH_2SiMe_3)(R)\}Y(CH_2\text{-}SiMe_3)(THF)_n$ (n = 0, 1) (Figure 55a). The dimeric hydrido complexes $[Me_2Si(C_5Me_4)(\eta^1\text{-}NCMe_2R)Y(\mu\text{-H})(THF)]_2$ were synthesized by hydrogenolysis of the corresponding alkyl derivatives. They polymerize ethylene, whereas styrene and 1-hexene were cleanly converted into the monoinsertion products. Styrene derivatives react with the hydrido complexes to give, for example, $Me_2Si(C_5Me_4)(\eta^1\text{-}NCMe_2R)Y(CH_2C_6H_4{}^t\text{Bu})(THF)$ (Figure 55b). The insertion product of 1-hexene initiates the polymerization of styrene

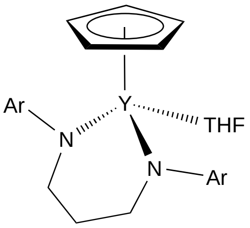

Figure 53 $CpY\{ArN(CH_2)_3NAr\}(THF)$

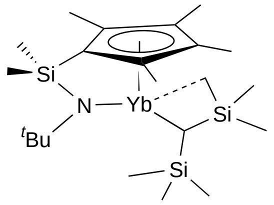

Figure 54 $[Me_2Si(\eta^5\text{-}C_5Me_4)(N{}^t\text{Bu})]YbN(SiMe_3)_2$

yielding atactic polystyrene with a narrow molecular weight distribution and microstructures enriched in syndiotacticity.[87]

Oxirane-ring opening of butylglycidyl ether with cyclopentadienylsodium or indenylsodium affords cyclopentadienyl- and indenyl-substituted alcohols $RHCH_2CH(OH)CH_2OBu$ ($R = C_5H_4$ or $3\text{-}C_9H_6$), which deprotonate with $Ln[N(SiMe_3)_2]_3$ to give corresponding lanthanide complexes $\{[(\eta^5\text{-}R)CH_2CH(\mu_2\text{-}\eta^1\text{-}O)CH_2OBu]LnN(SiMe_3)_2\}_2$ ($R = C_5H_4$, Ln = La, Pr, Er, Lu; $R = 1\text{-}C_9H_6$, Ln = La) (Figure 56). The coordination spheres of the metal atoms in these complexes involve simultaneously the η^5-cyclopentadienyl (indenyl), bridging alkoxide, and terminal amide ligands.[88]

Deprotonation of a CpH/OH ligand with $Y[N(SiMe_3)_2]_3$ yields the neutral chloride complex $[\eta^5{:}\eta^1\text{-}C_5H_4CH_2\{3,5\text{-}C_6H_3(CF_3)_2\}_2CO]_2YCl(THF)$, which is further converted to amide, alkoxide, or alkyl derivatives by reacting with one equiv. of $NaN(SiMe_3)_2$, $LiOC_6H_3{}^tBu_2\text{-}2,6$, and $LiCH(SiMe_3)_2$ respectively. The molecular structure of

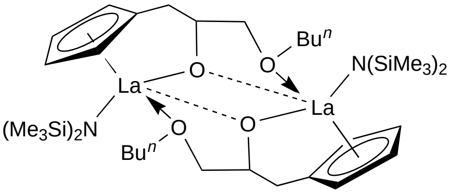

Figure 56 $\{[\eta^5\text{-}C_5H_4CH_2CH(\mu_2\text{-}\eta^1\text{-}O)CH_2OBu]La\text{-}N(SiMe_3)_2\}_2$

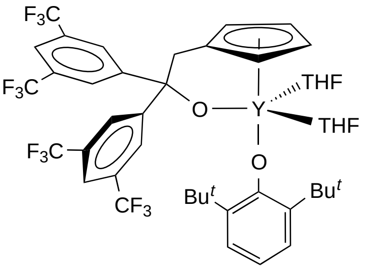

Figure 57 $[\eta^5{:}\eta^1\text{-}C_5H_4CH_2\{3,5\text{-}C_6H_3(CF_3)_2\}_2CO]Y(OC_6H_3\text{-}{}^tBu_2)(THF)_2$

the amide[89] and phenoxide (Figure 57) derivatives were established by X-ray crystallography.[90]

Lanthanide(II) complexes $Me_2Si(C_5Me_4)(PAr)Ln(THF)_3$ (Ln = Sm, Yb; $Ar = C_6H_2{}^tBu_3\text{-}2,4,6$) were prepared by reaction of SmI_2 and YbI_2, respectively, with $K_2[Me_2Si(C_5Me_4)(PHAr)]$. Oxidation of the Sm complex with benzophenone or ICH_2CH_2I in THF afforded $[Me_2Si(C_5Me_4)(PAr)Sm(THF)]_2(\mu\text{-}\eta^2\text{-}OCPh_2)$ (Figure 58a) and $[Me_2Si(C_5Me_4)(PAr)Sm(\mu\text{-}I)(THF)]_2$ (Figure 58b), respectively.[91]

7.5 Lanthanide Complexes with Carboranyl Ligands

A number of organolanthanide complexes with carboranes either bonded to the lanthanide metals via one carbon atom or with an open side as Cp analogs have been

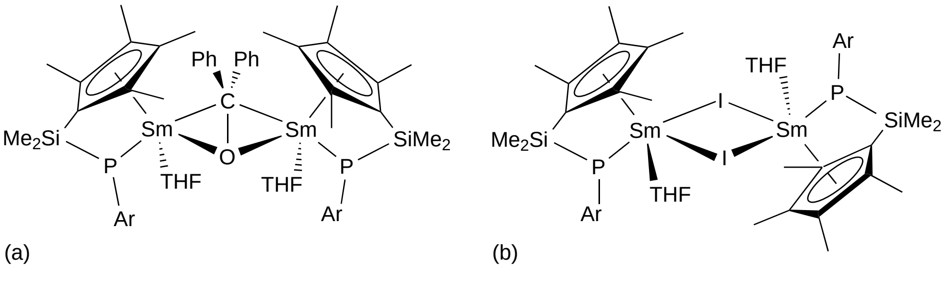

Figure 58 (a) $[Me_2Si(C_5Me_4)(PAr)Sm(THF)]_2(\mu\text{-}\eta^2\text{-}OCPh_2)$, (b) $[Me_2Si(C_5Me_4)(PAr)Sm(\mu\text{-}I)(THF)]_2$

described (see ***Boron, Metallocarboranes***). The dimethylsilyl bridged carboranyl/indenyl ligand $Me_2Si(Ind)(C_2B_{10}H_{11})$ can be reduced to the monoanion $[Me_2Si(Ind)(C_2B_{10}H_{11})]^-$, the dianion $[Me_2Si(Ind)(C_2B_{10}H_{10})]^{2-}$, and the trianion $[Me_2Si(Ind)(C_2B_{10}H_{10})]^{3-}$ by treatment with NaH or K in THF. Reaction of $LnCl_3$ with one equiv. of $[Me_2Si(Ind)(C_2B_{10}H_{11})]Na$ in THF yields $[Me_2Si(\eta^5\text{-}Ind)(C_2B_{10}H_{11})]LnCl_2(THF)_3$ (Ln = Nd, Er). They further react with another equiv. of $[Me_2Si(Ind)(C_2B_{10}H_{11})]Na$ to afford $[Me_2Si(\eta^5\text{-}Ind)(C_2B_{10}H_{11})]_2LnCl(THF)_2$ (Ln = Ce, Nd, Sm, Er). $[Me_2Si(Ind)(C_2B_{10}H_{10})]K_3$ reacts with $ErCl_3$ forming $\eta^5{:}\eta^6\text{-}[Me_2Si(Ind)(C_2B_{10}H_{11})]Er(THF)_2$ (Figure 59).

The related Me_2C-bridged ligand $Me_2C(C_9H_7)(C_2B_{10}H_{11})$ can be converted only into the monoanion $[Me_2C(Ind)(C_2B_{10}H_{11})]^-$ and the dianion $[Me_2C(Ind)(C_2B_{10}H_{10})]^{2-}$ by treatment with one or two equiv. of BuLi, respectively. Reaction of $LnCl_3$ with one or two equiv. of the monoanionic salt yields $[Me_2C(\eta^5\text{-}Ind)(C_2B_{10}H_{11})]GdCl_2(THF)_2$

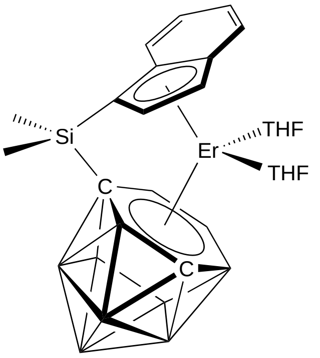

Figure 59 $[Me_2Si(Ind)(C_2B_{10}H_{11})]Er(THF)_2$

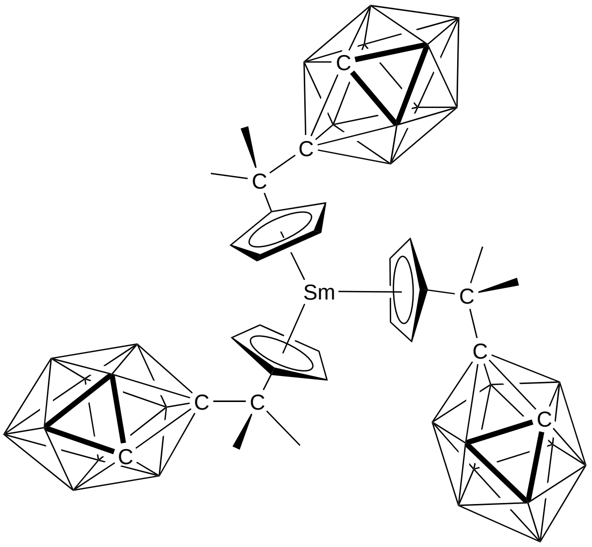

Figure 60 $[Me_2C(\eta^5\text{-}C_5H_4)(C_2B_{10}H_{11})]_3Sm$

and $[Me_2C(\eta^5\text{-}Ind)(C_2B_{10}H_{11})]_2LnCl(THF)(OEt_2)$, respectively (Ln = Y, Yb).[92] Using $[Me_2C(C_5H_5)(C_2B_{10}H_{11})]Na$, neutral $[Me_2C(\eta^5\text{-}C_5H_4)(C_2B_{10}H_{11})]_3Sm$ (Figure 60) can be isolated besides $[Me_2C(\eta^5\text{-}C_5H_4)(C_2B_{10}H_{11})]SmCl_2(THF)_3$ and $[Me_2C(\eta^5\text{-}C_5H_4)(C_2B_{10}H_{11})]_2SmCl(THF)_2$.[93]

The first organolanthanide compound containing an η^7-carboranyl ligand, $[\{[Me_2C(\eta^5\text{-}C_5H_4)(\eta^7\text{-}C_2B_{10}H_{11})]Er\}_2\text{-}\{Na_4(THF)_9\}]_n$ (Figure 61), was prepared by treatment of $[Me_2C(\eta^5\text{-}C_5H_4)(C_2B_{10}H_{11})]ErCl_2(THF)_3$ or $[Me_2C(\eta^5\text{-}C_5H_4)(\eta^6\text{-}C_2B_{10}H_{11})]Er(THF)_2$ with excess of Na in THF.

Silylamine elimination reactions of the boron-bridged ligand $^iPr_2NB(C_9H_7)(C_2B_{10}H_{11})$ incorporating indenyl and carboranyl moieties and $Ln[N(SiHMe_2)_2]_3$ resulted in the formation of $[^iPr_2NB(\eta^5\text{-}C_9H_6)(\eta^1\text{-}C_2B_{10}H_{10})]Ln\text{-}N(SiHMe_2)_2(THF)_2$ (Ln = Nd, Er, Y) (Figure 62).[94]

Treatment of $1,2\text{-}(PhCH_2)_2\text{-}1,2\text{-}C_2B_{10}H_{10}$ with excess Na or Li in THF followed by reaction with $LnCl_3$ in the presence of excess alkali metal gave the 13-vertex closo-metallacarboranes $\{[(PhCH_2)_2C_2B_{10}H_{10}]Ln(THF)\}_2\text{-}\{Na(THF)_3\}_2$ (Ln = Dy, Y, Er) or $[\{(PhCH_2)_2C_2B_{10}H_{10}\}\text{-}Ln(THF)]_2[Li(THF)_4]_2$ (Figure 63) (Ln = Y, Er), respectively. The yttrium complexes were the first examples of d^0 metallacarboranes incorporating an η^7-carboranyl ligand. Density functional calculations indicate that the metal-carborane bonding is well delocalized and can be described as

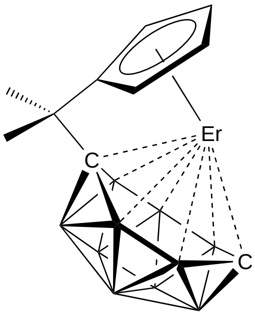

Figure 61 Structure of the dianionic fragment $[Me_2C(\eta^5\text{-}C_5H_4)\text{-}(\eta^7\text{-}C_2B_{10}H_{11})]Er$

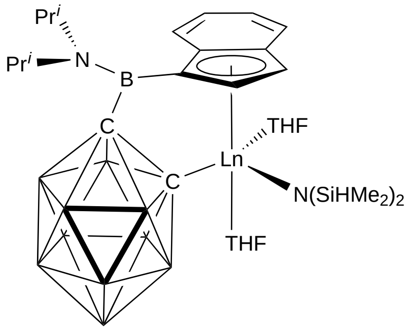

Figure 62 $[^iPr_2NB(\eta^5\text{-}C_9H_6)(\eta^1\text{-}C_2B_{10}H_{10})]LnN(SiHMe_2)_2\text{-}(THF)_2$

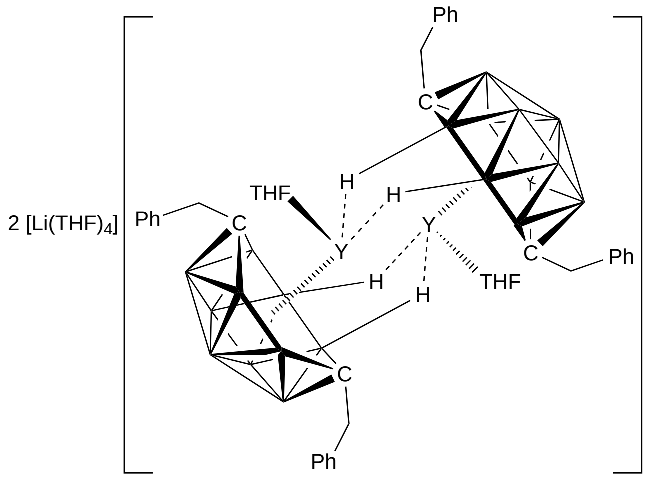

Figure 63 $[\{(PhCH_2)_2C_2B_{10}H_{10}\}Y(THF)]_2[Li(THF)_4]_2$

the orbital interactions between the metal's five d orbitals and the cage's five symmetry-adapted frontier orbitals. It is anticipated that only the d^0/f^n transition metal ion with the proper size is capable of being η^7-bound to an *arachno*-carboranyl ligand.[95]

Treatment of the sodium salt of the 'carbons-adjacent' *nido*-carborane anion $[\{\mu\text{-}1,2\text{-}[o\text{-}C_6H_4(CH_2)_2]\text{-}1,2\text{-}C_2B_{10}H_{10}\}_2Na_4(THF)_6]_n$ with two equiv. of $LnCl_3$ gave $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-}C_6H_4(CH_2)_2]\text{-}1,2\text{-}C_2B_{10}H_{10}\}]LnCl(THF)_3$ (Ln = Nd, Er, Y). Further reactions with $NaBH_4$ and NaC_5H_5 resulted in $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-}C_6H_4(CH_2)_2]\text{-}1,2\text{-}C_2B_{10}H_{10}\}]Nd[(\mu\text{-}H)_3\text{-}BH](THF)_3$ (Figure 64) and $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-}C_6H_4(CH_2)_2]\text{-}1,2\text{-}C_2B_{10}H_{10}\}]Y(\eta^5\text{-}C_5H_5)(THF)$, respectively.[96]

The erbacarborane sandwich complex $2,2',4,4'\text{-}(Me_3Si)_4\text{-}3,6'\text{-}[(\mu\text{-}H)_2K(THF)_2]\text{-}1,1'\text{-}$*commo*-$Er(\eta^5\text{-}2,4\text{-}C_2B_4H_4)_2$ (Figure 65) results from the reaction of $1,2\text{-}(Me_3Si)_2\text{-}1,2\text{-}C_2B_4H_4$ with $ErCl_3$ and potassium in a 2:1:4 molar ratio, in the absence of an outside electron-transfer agent.[97]

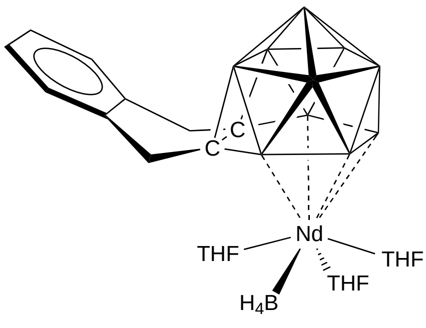

Figure 64 $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-}C_6H_4(CH_2)_2]\text{-}1,2\text{-}C_2B_{10}H_{10}\}]$ $Nd[(\mu\text{-}H)_3BH](THF)_3$

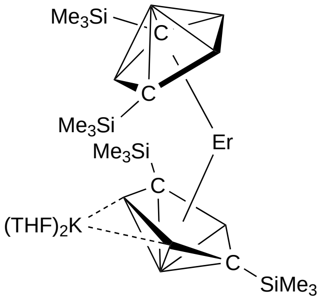

Figure 65 $2,2',4,4'\text{-}(Me_3Si)_4\text{-}3,6'\text{-}[(\mu\text{-}H)_2K(THF)_2]\text{-}1,1'\text{-}$*commo*-$Er(\eta^5\text{-}2,4\text{-}C_2B_4H_4)_2$

8 ARENE COMPLEXES

A comprehensive review covers the whole literature on arene complexes of the rare earth elements up to 2002.[98]

8.1 Complexes with Neutral Arene Ligands

Chloroaluminate complexes of the general formula $Ln(\eta^6\text{-}Arene)(\eta^2\text{-}AlCl_4)_3$ (equation 20) were prepared by reacting $AlCl_3$ with $LnCl_3$ in the corresponding aromatic solvent. In some cases, the reactions proceed only with addition of aluminum powder. The first compound of this type, $Sm(\eta^6\text{-}C_6Me_6)(AlCl_4)_3$, was reported in 1986.

$$3AlCl_3 + LnCl_3 \xrightarrow{\text{Arene}} Ln(\eta^6\text{-Arene})(\eta^2\text{-}AlCl_4)_3 \qquad (20)$$

Arene	**Lanthanide**
Benzene	La, Nd, Sm, Yb
Toluene	Sm, Nd, Gd ($[AlBr_4]^-$)
m-Xylene	Pr, Er
Mesitylene	Nd
Hexamethylbenzene	Nd, Sm, Gd, Yb

The molecular structure of $Sm(\eta^6\text{-}C_6Me_6)(AlCl_4)_3$ shows a distorted pentagonal bipyramid with the η^6-arene occupying an apical site. $Nd(\eta^6\text{-}C_6H_5Me)(AlCl_3Me)_3$ has been prepared by reaction of $Nd(\eta^6\text{-}C_6H_5Me)(AlCl_4)_3$ with $AlMe_3$. $(\eta^6\text{-}C_6H_6)Sm(AlCl_4)_2$ and $(\eta^6\text{-}C_6H_3Me_3)Sm(AlCl_4)_2$ were prepared by reduction of $SmCl_3$ with Na/Hg in the presence of $AlCl_3$ and the corresponding aromatic ligand. Single-crystal X-ray diffraction showed the Sm atom pentagonal-bipyramidal coordinated by the π-aromatic ligand and six Cl atoms. Analogoues Yb(II) chloroaluminates $(\eta^6\text{-}C_6H_6)_2Yb(AlCl_4)_2$ and $(\eta^6\text{-}C_6H_3Me_3)Yb(AlCl_4)_2$ have been synthesized by the same synthetic approach.

Abstraction of methide from the ß-diketiminato supported organoscandium complex $[LScMe_2]_2$ using $[Ph_3C][B(C_6F_5)_4]$ in arene solvents gives solvent separated ion pairs in which the arenes (C_6H_5Br, C_6H_6, C_6H_5Me, $1,3,5\text{-}Me_3C_6H_3$) are coordinated to the cationic scandium center in an η^6-fashion. Although the aromatic fragment in the bromobenzene

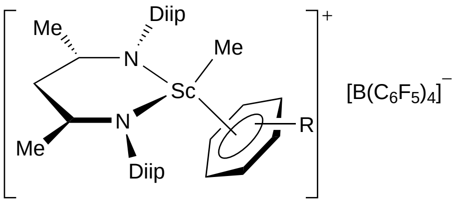

Figure 66 $[LSc(Me)(C_6H_5Br)][B(C_6F_5)_4]$ (Diip = 2,6-diisopropylphenyl, R = Br)

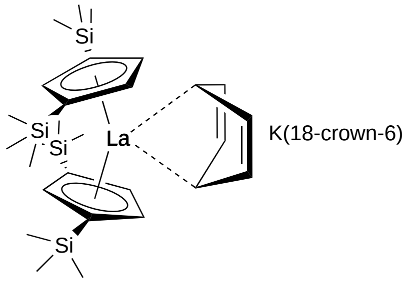

Figure 68 $[K([18]\text{-crown-6})][La\{\eta^5\text{-}C_5H_3(SiMe_3)_2\text{-}1,3\}_2(C_6H_6)]$

derivative $[LSc(Me)(C_6H_5Br)][B(C_6F_5)_4]$ (Figure 66) is η^6-bonded, steric interactions invoke significant ring tilting.[99]

The reaction of $Nd[N(SiMe_3)_2]_3$ with $(C_6F_5)_2NH$ in PhMe yields $[(\eta\text{-PhMe})Nd[N(C_6F_5)_2]_3]$ in which the Nd atom is η^6-bonded to a toluene solvent molecule.

η^6-Arene coordination between lanthanide ions and phenyl groups of certain phenolate and thiolate ligands have been detected in some unsolvated lanthanide complexes, for example, $Ln(SAr)_2$ (Ln = Eu, Yb; Ar = 2,6-$Trip_2C_6H_3$; Trip = 2,4,6-i-$Pr_3C_6H_2$), $[Eu_2(OAr)(\mu\text{-}OAr)_3]$ (OAr = 2,6-diphenylphenolate), and $Ln_2(O\text{-}2,6\text{-}(Me_2CH)_2C_6H_3)_6$ (Ln = Nd, Sm, Er), $[Sc(OArH)_3]$ (OAr = 2, 6-diphenylphenolate).[100] The reactions of the lanthanide metal powders with $Hg(C_6F_5)_2$ and 2,6-diphenylphenol in THF afford the lanthanide(III) phenoxides $Ln(2,6\text{-}OC_6H_3Ph_2)_3$ (Ln = Nd, Sm, Er, Yb, Lu) and the corresponding THF solvates. In the unsolvated compound $Yb(2,6\text{-}OC_6H_3Ph_2)_3$, one phenyl substituent is in a geometrically favorable position that allows this ring to engage in a novel π-interaction with the central ytterbium atom (Figure 67).

Reaction of 3 equiv. of 2,6-diisopropylaniline with $Sm[N(SiMe_3)_2]_3$ affords dimeric $[Sm(NHAr)_3]_2$, in which each metal center is engaged in an η^6-arene interaction with the aryl ring of an amide ligand attached to an adjacent samarium. IR spectroscopy indicates that the π-arene interactions are maintained in solution.[101]

8.2 Complexes with Anionic Arenes and Heterocyclic Aromatic Ligands

Treatment of Cp''_3Ln [Cp'' = 1,3-bis(trimethylsilyl) cyclopentadienide; Ln = La, Ce, Pr, Nd] with 2 equiv. of 18-crown-6 and 2 equiv. of potassium in benzene affords lanthanide complexes with C_6H_6 dianions. The molecular structure of the isomorphous La, Ce, and Nd salts $[K([18]\text{-crown-6})][Ln\{\eta^5\text{-}C_5H_3(SiMe_3)_2\text{-}1,3\}_2(C_6H_6)]$ (Ln = La, Ce, Pr, Nd) shows a tight ion pair with a boat-shaped C_6H_6 dianion bridging the K and the Ln atoms (Figure 68).

Phenylation of Y and Ho complexes $(LnL)_2(\mu\text{-}Cl)_2$ (Ln = Y, Ho; L = *syn*-$PhP[CH_2(SiMe_2)N(SiMe_2)CH_2]_2$-PPh) with PhLi in Et_2O/toluene results with coupling of two phenyl anions in binuclear compounds $[(L)Ln]_2(\mu\text{-}\eta^6\text{:}\eta^6\text{-}Ph_2)$ with a bridging diphenyl dianion. In these complexes, the Ln atoms are bonded to opposite sides of different rings of the biphenyl ligand, which retains its planarity (Figure 69).

In contrast, $(YbL)_2(\mu\text{-}Cl)_2$ reacts with PhLi yielding the paramagnetic monophenyl compound (L)YbPh.[102] Reduction of (L)LnCl(THF) (Ln = Y, Lu; L = *syn*-PhP $[CH_2(SiMe_2)N(SiMe_2)CH_2]_2PPh$) with KC_8 in toluene/diethyl ether in the presence of naphthalene or 1-methylnaphthalene generates the dinuclear naphthalene-bridged species $[(L)Ln]_2(\mu\text{-}C_{10}H_7R)$ (R = H, Me; Ln = Y, Lu), in which each Ln atom has η^4-coordination to opposite sides of the dianionic naphthalene ligand. Similarly, reaction of anthracene with (L)LnCl(THF) (Ln = Y, Lu) in the presence of KC_8 yields $[(L)Ln]_2(\mu\text{-}C_{14}H_{10})$ (Ln = Y, Lu).[103] Related

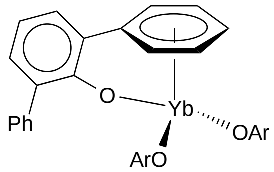

Figure 67 $Yb(2,6\text{-}OC_6H_3Ph_2)_3$ (Ar = 2,6-$OC_6H_3Ph_2$)

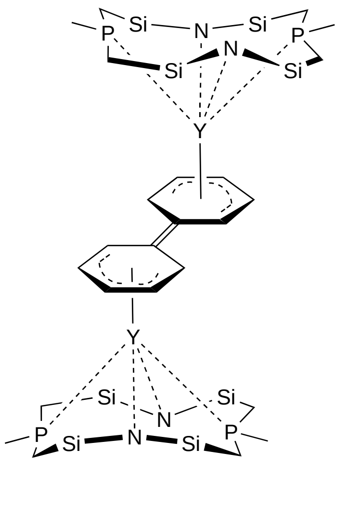

Figure 69 $[(syn\text{-}PhP[CH_2(SiMe_2)N(SiMe_2)CH_2]_2PPh)Y]_2(\mu\text{-}\eta^6\text{:}\eta^6\text{-}Ph_2)$ (Ph and Me groups are omitted)

lanthanide(III) complexes with a bridging naphthalene dianion $[(THF)_3LnI_2]_2(\mu\text{-}C_{10}H_8)$ (Ln = La, Ce, Pr, Nd) were synthesized by reaction of $LnI_3(THF)_3$ with equimolar amounts of Li metal and excess of $C_{10}H_8$ in THF. $[(DME)_2LnI]_2(\mu\text{-}C_{10}H_8)$ (Ln = Eu, Yb) were prepared in the same manner using LnI_2 in DME. The X-ray structure determination of the La and Eu complexes show two $LaI_2(THF)_3$ and $EuI(DME)_2$ moieties, respectively, bridged by η^4 bonded nonplanar naphthalene molecules. In contrast, reaction of TmI_2 with two equivalents of $Li[C_{10}H_8]$ in DME yields a binuclear Tm(III) complex with one bridging and two terminal naphthalene dianions $[Tm(DME)]_2(\eta^2\text{-}C_{10}H_8)_2(\mu^2\text{-}\eta^4{:}\eta^4\text{-}C_{10}H_8)$ (Figure 70).

Mononuclear lanthanide(III) complexes with terminal naphthalene dianions $CpLn(\eta^2\text{-}C_{10}H_8)(DME)$ (Ln = Y, Gd, Er, Tm, Lu) have been prepared by the reaction of $CpLnCl_2(THF)_3$ with $Na[C_{10}H_8]$ in DME (Figure 71a). The molecular structure of the yttrium and lutetium compound revealed that one naphthalene ring is bent, while the second one, which is not coordinated by the metal is planar. Two structurally related complexes of La(III) and Sm(III) with a bridging anthracene dianion $(Cp^*{}_2Ln)_2(\mu\text{-}\eta^3{:}\eta^3\text{-}C_{14}H_{10})$ (Ln = La, Sm) were prepared by reaction of $(Cp^*{}_2La)(\mu\text{-}Cl)_2K(DME)_2$ with disodium anthracenide and by direct reduction of anthracene with decamethylsamarocene in toluene, correspondingly. The molecules contain two $Cp^*{}_2Ln$ moieties, which are η^3-coordinated to two aromatic rings from opposite sides of the anthracene ligand (Figure 71b), which, in contrast to the complexes mentioned above, maintains its planarity. Bent anthracene dianions have also been found in $CpLu(\eta^2\text{-}C_{14}H_{10})(THF)_2$, $[Na^+(diglyme)_2][Cp_2Lu(\eta^2\text{-}C_{14}H_{10})]$, and $(DME)_2TmI(\eta^2\text{-}C_{14}H_{10})$.

2,3-benzanthracene and pyrene readily react with $Cp^*{}_2Sm$ to give $(Cp^*{}_2Sm)_2(\mu\text{-}\eta^3{:}\eta^3\text{-Arene})$ (Arene = $C_{18}H_{12}$ and $C_{16}H_{10}$, respectively). In the benzanthracene derivative, two $Cp^*{}_2Sm$ fragments are coordinated at opposite edges of the nearly planar arene ligand and are located on the opposite faces of its plane in the manner similar to that in $(Cp^*{}_2Sm)_2(\mu\text{-}\eta^3{:}\eta^3\text{-}C_{14}H_{10})$. In contrast, the metallocene moieties in $(Cp^*{}_2Sm)_2(\mu\text{-}\eta^3{:}\eta^3\text{-pyren})$ are coordinated at the neighboring edges of the pyrene ligand above and below its plane. Reaction of $(Cp^*LaCl)(\mu\text{-}Cl)_2Li(THF)_2$ with pyrene in toluene in the presence of potassium yields $(Cp^*LaCl)_3(\mu^3\text{-}C_{16}H_{10})(THF)$. All three Cp*LaCl moieties are located above one plane of the pyrene ligand and bridged by Cl atoms. Two La atoms are η^6-bonded to the arene ligand, whereas the third one is coordinated by one THF and has only two short La–C(pyrene) contacts (Figure 72).

Complexes of the lanthanides with heterocyclic aromatic ligands have been also reported, for example, $(Cp^*{}_2La)_2(\mu\text{-Arene})$ (Arene = 2, 3-dimethylquinoxaline or phenazine). Phenazine is reduced by $Cp^*{}_2Sm$ yielding $(Cp^*{}_2Sm)_2(\mu\text{-}\eta^3{:}\eta^3\text{-}C_{12}H_8N_2)$ (Figure 73a), in which the samarocene fragments are in transoid orientation with respect to the $(C_{12}H_8N_2)^{2-}$ dianion. Three short contacts between the samarium atoms and the phenazine ligand suggest an allylic type of bonding. Reduction of acridine with $Cp^*{}_2Sm$, independent of the reagents ratio, results in dimerization of two arene ligands via C–C bond formation. An ytterbium complex containing the antiaromatic 2,2′-bipyridyl ligand has been prepared by reduction of 2,2′-bipyridine with $Yb(C_{10}H_8)(THF)_2$ as the cyclic trimer $[Yb(\mu^2\text{-}N_2C_{10}H_8)(THF)_2]_3$ in which the Yb atoms are bridged by 2,2′-bipy ligands (Figure 73b).

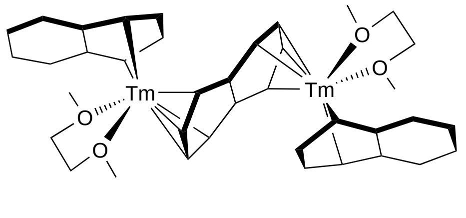

Figure 70 $[Tm(DME)]_2(\eta^2\text{-}C_{10}H_8)_2(\mu^2\text{-}\eta^4{:}\eta^4\text{-}C_{10}H_8)$

8.3 Boratabenzene Complexes

Lithium 1-aminoboratabenzenes react with lanthanide trihalides in toluene to give the stepped ladder dimers $[(3,5\text{-}Me_2C_5H_3BNMe_2)_2Y(\mu\text{-}Cl)_2Li]_2$ (Figure 74a), $[(3,5\text{-}Me_2C_5H_3BNMe_2)_2Lu(\mu\text{-}Cl)_2Li]_2$, and the mononuclear complexes $YCl[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]_2$, $LuCl[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]_2$, and $ScCl(3,5\text{-}Me_2C_5H_3BN{}^iPr_2)_2$ (Figure 74b). The same reactions in THF or THP yield solvated complexes $(3,5\text{-}Me_2C_5H_3BNMe_2)_2Sm(\mu\text{-}Cl)_2Li(THF)$, $(3,5\text{-}Me_2C_5H_3BNMe_2)_2Y(\mu\text{-}Cl)_2Li(THP)$, $(3,5\text{-}Me_2C_5H_3BN{}^iPr_2)_2Y(\mu\text{-}Cl)_2Li(THF)_2$, $(3,5\text{-}Me_2C_5H_3BN{}^iPr_2)_2Sm(\mu\text{-}Cl)_2Li(THF)_2$, and the *ansa* complexes $[(3,5\text{-}Me_2C_5H_3BNMeCH_2)_2]Lu(\mu\text{-}Cl)_2Li(THF)_2$ and $[(3,5\text{-}Me_2C_5H_3BNMeCH_2)_2]Lu(\mu\text{-}Cl)_2Li(THP)_2$.[104]

Reaction of yttrium trichloride with lithium 1-methylboratabenzene in toluene affords donor-free dinuclear $[(C_5H_5BMe)_2Y(\mu\text{-}Cl)]_2$. Bis(boratabenzene)scandium complexes $[ScCl(C_5H_5BMe)_2]_2$, $[ScCl(3,5\text{-}Me_2C_5H_3BNMe_2)_2]_2$, and $ScCl[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]_2$ were synthesized from solvent-free Li boratabenzenes and $ScCl_3$ in toluene. $[ScCl(C_5H_5BMe)_2]_2$ (Figure 75a) possesses a double chloro-bridged dinuclear structure with four facially coordinated boratabenzene ligands. In contrast, in $[ScCl(3,5\text{-}Me_2C_5H_3BNMe_2)_2]_2$, each Sc atom binds to one boratabenzene in an unprecedented N–B–C-2 coordination mode and facially to the second boratabenzene ligand (Figure 75b). $ScCl[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]_2$ is mononuclear because of the bulkiness of its boratabenzene ligands. The

reaction of $C_5H_5B{-}PMe_3$ with $Ph_3Sc(THF)_2$ provides $(C_5H_5B{-}Ph)ScPh_2(THF)$.

9 CYCLOHEPTATRIENYL COMPLEXES

Only one cycloheptatrienyl complex of the lanthanides is known until now. Reaction of $Nd(BH_4)_3(THF)_2$ with $K(C_7H_9)$ yields $(THF)(BH_4)_2Nd(\mu\text{-}\eta^7{:}\eta^7\text{-}C_7H_7)Nd(BH_4)(THF)_3$ (Figure 76). The X-ray structure determination shows a unique reverse-sandwich structure with both Nd atoms η^7 coordinated to the planar ligand.

10 CYCLOOCTATETRAENYL COMPLEXES

10.1 Mono(cyclooctatetraenyl) Complexes

Cyclooctatetraenyl lanthanide(III) halides of the type $[(COT)Ln(\mu\text{-}Cl)(THF)_2]_2$ (Figure 77a) are the most important precursors for the preparation of other half-sandwich (*see Half-sandwich Complexes*) and mixed sandwich complexes with cyclooctatetraenyl ligands. These complexes are readily accessible by reacting anhydrous lanthanide trichlorides with $K_2[COT]$ in a molar ratio of 1:1. The compounds consist of centrosymmetric, chloro-bridged dimers with η^8-coordinated cyclooctatetraenyl ligands. The use of the sterically demanding 1,4-bis(trimethylsilyl)cyclooctatetraenyl ligand allows the synthesis of a related series of organolanthanide halides $[Ln\{(1,4\text{-}(Me_3Si)_2C_8H_6)\}(\mu\text{-}Cl)(THF)]_2$ (Ln = Y, Sm, Ho, Lu). The anionic complex $[Li(diglyme)_2][(1,4\text{-}(Me_2SiC_6H_4NMe_2\text{-}o)_2C_8H_6)_2Sm_2(\mu\text{-}Cl)_3]$ (Figure 77b) has a triple chlorine bridge between two Sm atoms.

Mononuclear iodo complexes $(COT)LnI(THF)_n$ (Ln = La, Ce, Pr, $n = 3$; Ln = Nd, $n = 2$; Ln = Sm, $n = 1$) can be prepared either by reaction of LnI_3 with $K_2[COT]$ in THF (Ln = Nd, Sm), or directly from metal powders, iodine, and COT (Ln = La, Ce, Pr, Nd, Sm) in THF. The Tm complex $(COT)TmI(THF)_2$ is formed by reduction of COT with TmI_2 in THF. An improved solubility in polar organic solvents was also found for the corresponding mono(cyclooctatetraenyl)lanthanide triflates $[(COT)Ln(\mu\text{-}O_3SCF_3)(THF)_2]_2$. Mono(cyclooctatetraenyl) lanthanide complexes $(COT)Ln(BH_4)(THF)_n$ can be prepared from $Ln(BH_4)_3(THF)_3$ and $K_2[COT]$. $(COT)Nd(BH_4)(THF)_2$ looses one THF upon recrystallization forming the dimer $[(COT)Nd(\mu\text{-}BH_4)(THF)]_2$. Protonation of $(COT)Nd(BH_4)(THF)_2$ with $[NHEt_3][BPh_4]$ provides a convenient access to the cationic mono(cyclooctatetraenyl) neodymium(III) complex $[(COT)Nd(THF)_4][BPh_4]$. Its X-ray crystal structure reveals the presence of discrete cation–anion pairs in the solid state with the Nd ions being in a slightly distorted square-pyramidal coordination environment. Replacement of the THF ligands in $[(COT)Nd(THF)_4][BPh_4]$ with HMPA yields $[(COT)Nd(HMPA)_3][BPh_4]$.

Mono(cyclooctatetraenyl)lanthanide(III) complexes containing additional group 16 donor ligands $[(COT)Ln(\mu\text{-}OR)(THF)]_2$ (Ln = Y, Lu, R = Ph, 2,6-$C_6H_3Me_2$; Ln = Dy, R = $(CH_2)_3CH{=}CH_2$; Ln = Nd, R = Et) were prepared from $[(COT)Ln(\mu\text{-}Cl)(THF)_2]_2$ or $(COT)Ln(BH_4)(THF)_n$ and NaOR. Three representatives, $[(COT)Y(\mu\text{-}OPh)(THF)]_2$ (Figure 78a), $[(COT)Nd(\mu\text{-}OEt)(THF)]_2$, and $[(COT)Dy\{\mu\text{-}O(CH_2)_3CH{=}CH_2\}(THF)]_2$ have been structurally characterized. Other sterically more demanding alkoxides and

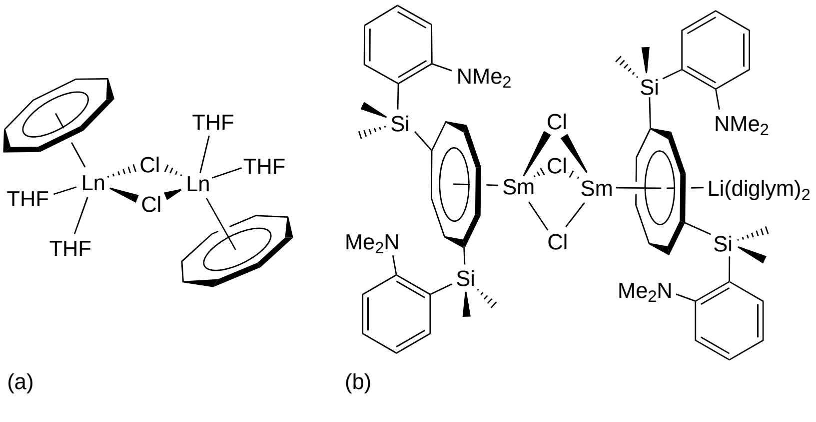

Figure 77 (a) $[(COT)Ln(\mu\text{-}Cl)(THF)_2]_2$, (b) $[Li(diglyme)_2][1,4\text{-}(Me_2SiC_6H_4NMe_2\text{-}o)_2(C_8H_6)_2Sm_2(\mu\text{-}Cl)_3]$

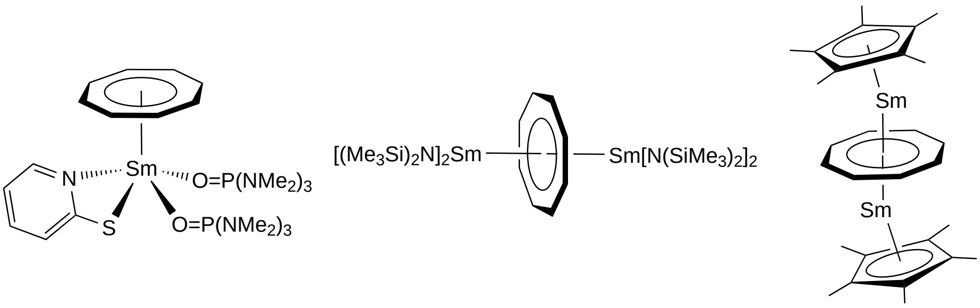
Figure 78 (a) [(COT)Y(μ-OPh)(THF)]$_2$, (b) {[Zr$_2$(O^{i}Pr)$_9$]Sm}$_2$(COT)

siloxides are (COT)Ln(OC^{t}Bu$_3$)(THF), (COT)Ln(OSiPh$_3$)-(THF) (Ln = Y, Lu), Ln[1,4-(Me$_3$Si)$_2$C$_8$H$_6$](OC$_6$H$_2$-2,6-^{t}Bu$_2$-4-Me)(THF) (Ln = Sc, Y), [{1,4-(Me$_3$Si)$_2$C$_8$H$_6$}-Sm(μ-OAr)]$_2$ (Ar = C$_6$H$_2$(^{t}Bu)$_2$-2,6,-Me-4), and {[Zr$_2$-(O^{i}Pr)$_9$]Ln}$_2$(COT) (Ln = Sm, Yb) (Figure 78b).

The preparation of mono(cyclooctatetraenyl)samarium(III) thiolates and selenolates [(COT)Sm(μ-EAr)(THF)$_n$]$_2$ ($n = 1$, EAr = 2,4,6-SC$_6$H$_2$^{i}Pr$_3$; $n = 2$, EAr = SPh, SePh, 2,4,6-SC$_6$H$_2$^{i}Pr$_3$) has been achieved by the reaction of samarium powder with COT in THF in the presence of diaryl disulfides or diselenides. The molecular structure of [(COT)Sm(μ-SePh)(THF)$_2$]$_2$ reveals a dimeric molecule with phenylselenolate bridges. Monomeric organosamarium thiolates have been prepared in the same manner with use of either sterically demanding or potentially chelating thiolate ligands, for example, (COT)Sm(SC$_5$H$_4$N)[OP(NMe$_2$)$_3$]$_2$ (Figure 79a) or [Na(THF)$_2$][(COT)Nd(S-^{t}Bu)$_2$]. A number of lanthanide mono(cyclooctatetraenyl)/amide complexes (COT)Ln[N(SiMe$_3$)$_2$](THF) (Ln = Y, Gd, Er, Lu) has been synthesized by the reactions of [(COT)Ln(μ-Cl)(THF)$_2$]$_2$ with two equiv. of NaN(SiMe$_3$)$_2$. An unusual 'inverse sandwich complex' is obtained when the same reaction is carried out with [(COT)Sm(μ-Cl)(THF)$_2$]$_2$. [Sm{N(SiMe$_3$)$_2$}$_2$]$_2$(μ-COT) shows two Sm{N(SiMe$_3$)$_2$}$_2$ units symmetrically bridged by the cyclooctatetraenyl ligand (Figure 79b). A closely related 'inverse sandwich complex' of divalent samarium (μ-COT)[Sm{N(SiMe$_3$)$_2$}(THF)$_2$]$_2$ has a planar (COT)$^{2-}$ ring, sandwiched between two [{(Me$_3$Si)$_2$N}Sm(THF)$_2$]$^+$ cations. This structure is similar to that of the pentamethylcyclopentadienyl derivative [Cp*Ln(THF)$_2$]$_2$(μ-COT) (Ln = Sm, Eu, Yb), prepared by the reaction of [Cp*Ln(μ-I)(THF)$_2$]$_2$ (Ln = Sm, Eu, Yb) with one equiv. of K$_2$[C$_8$H$_8$] in toluene. Dissolvation of those complexes at 30 to 50° C under vacuum yields [Cp*Ln]$_2$(μ-η^8:η^8-COT) (Figure 79c).

The reaction of (COT)LnCl(THF)$_n$ compounds with the lithium, sodium, or potassium salts of C$_5$H$_6$,

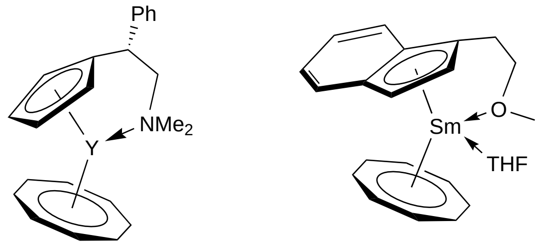


(a) (b) (c)

Figure 79 (a) (COT)Sm(SC$_5$H$_4$N)[OP(NMe$_2$)$_3$]$_2$, (b) [Sm{N(SiMe$_3$)$_2$}$_2$]$_2$ (μ-COT), (c) [Cp*Sm]$_2$(μ-COT)

$C_5H_2Me_4$, C_5HMe_5, C_5HMe_4Et, $C_5H_3(SiMe_3)_2$, C_5HPh_5, $C_5H_5CH_2Ph$, $C_5H_5C_5H_9$, or indene produces a number of mixed cyclopentadienyl(cyclooctatetraenyl)lanthanide complexes, such as (COT)Ln(C_5Me_4R)(THF)$_n$, (COT)Ln(Cp*), (COT)Pr(C_5Ph_5), (COT)Gd($C_6H_5CH_2C_5H_4$)(DME), [(COT)Nd(μ-η^8-COT)K(THF)(η^3-$C_6H_5CH_2$-μ^2-η^5-C_5H_4)-Nd(THF)$_2$(η^8-COT)], (COT)Ln($C_5H_9C_5H_4$)(THF)$_2$, (COT)-Gd($C_5H_9C_5H_4$)(THF), and (Ind)Ln(COT)(THF)$_2$.

Mixed chiral cyclooctatetraenyl cyclopentadienyl lanthanide complexes (COT)Sm{(*S*)-η^5:η^1-$C_5H_4CH_2CHMeO$-Me}, (COT)Ln{(*S*)-η^5:η^1-$C_5H_4CH_2CHMeNMe_2$}, (COT)-Ln{(*S*)-η^5:η^1-$C_5H_4CHPhCH_2NMe_2$} (Figure 80a), and achiral (COT)Ln(η^5:η^1-$C_5H_4CH_2CH_2NMe_2$) (Ln = Sm, Lu), which bear O- and N-donor-functionalized Cp-ligands, have been synthesized by reactions of [(COT)Ln(μ-Cl)(THF)]$_2$ (Ln = Sm, Lu) with respective cyclopentadienyl potassium salts.[105] Mixed COT/indenyl complexes with donor-functionalized indenyl ligands (η^5:η^1-$MeOCH_2CH_2C_9H_6$)Ln(COT)(THF)$_n$ (Figure 80b) (Ln = La, Nd, $n = 0$; Sm, Dy, Er, $n = 1$) and (η^5:η^1-$C_4H_7OCH_2C_9H_6$)-Ln(COT)(THF) (Ln = La, Nd, Sm, Dy, Er) were synthesized by the reactions of $LnCl_3$ with equimolar amounts of K_2[COT], followed by treatment with the corresponding potassium salt of ether-substituted indenide.[106]

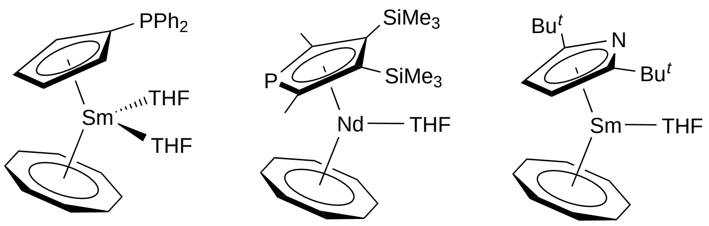


(a) (b)

Figure 80 (a) (COT)Y{(*S*)-η^5:η^1-$C_5H_4CHPhCH_2NMe_2$}, (b) (η^5:η^1-$MeOCH_2CH_2C_9H_6$)Sm(COT)(THF)

Reactions of K[$C_5Me_4PMe_2$], Li[$C_5H_4PPh_2$], and K[$C_5Me_4PPh_2$] with [(COT)Sm(μ-Cl)(THF)$_2$]$_2$ yield a series of COT complexes (COT)Sm($C_5R_4PR'_2$)(THF)$_n$ (Figure 81a) (R = H or Me; R′ = Me or Ph; $n = 0$ or 2). They react with CpRh(CO)$_2$ affording phosphido-bridged bimetallic samarium(III)-rhodium(I) complexes (COT)Sm(μ-$C_5R_4PR'_2$)Rh(Cp)(CO) (R = H or Me; R′ = Me or Ph). 3,4-Dimethyl-2,5-bis(trimethylsilyl)phospholyl (Dsp) derivatives (COT)Sm(Dsp) and (COT)Nd(Dsp)(THF) (Figure 81b) have also been prepared.[107] COT/pyrolyl complexes (COT)Ln(η^5-pyr*)(THF)$_n$ (Figure 81c) (Ln = Sm, $n = 1$; Ln = Tm, Lu, $n = 0$) were prepared from [(COT)Ln(μ-Cl)(THF)]$_2$ and Na(pyr*) (pyr* = $NC_4H_2{}^tBu_2$-2,5).

Polydentate nitrogen ligands are very suited to stabilize mono(cyclooctatetraene) lanthanide(III) complexes. These include silylated benzamidinates [$RC_6H_4C(NSiMe_3)_2$]Ln-(COT)(THF) (Ln = Y, Ce, Pr, Nd, Sm, Tm, Lu; R = H, MeO, CF_3) (Figure 82a) and diiminophosphinates



(a) (b) (c)

Figure 82 (a) [$RC_6H_4C(NSiMe_3)_2$]Sm(COT)(THF), (b) [$Ph_2P(NSiMe_3)_2$]Sm(COT)(THF), (c) [$HB(C_3N_2Me_2)_3$]Lu(COT)

$[Ph_2P(NSiMe_3)_2]Ln(COT)(THF)$ (Ln = Y, Ce, Pr, Nd, Sm) (Figure 82b), as well as tridentate pyrazolylborates $[HB(C_3N_2R_2)_3]Ln(COT)$ (Ln = Ce, Pr, Nd, Sm, Lu; R = H, Me) (Figure 82c).

Complexes of the type $[1,4\text{-}(Me_3Si)_2C_8H_6]Ln(DAD)$ (Ln = Sm, Yb; DAD = 1,4-diazadiene) have been prepared in a 'one-pot' reaction by treatment of elemental samarium or ytterbium with equimolar amounts of 1,4-bis(trimethylsilyl)cyclooctatriene and substituted 1,4-diazadiene ligands. ^1H and ^{171}Yb NMR data revealed that the Sm derivatives contain Sm^{3+} ions and coordinated DAD radical anions, while, in the case of Yb, the neutral DAD ligand is coordinated to divalent ytterbium. The ^{171}Yb NMR spectrum of $[1,4\text{-}(Me_3Si)_2C_8H_6]Yb[PhN{=}C(Me)C(Me){=}NPh]$ shows a single resonance at $\delta 224.3$ ppm, which is consistent with the presence of an Yb^{2+} complex. Recently a series of half-sandwich complexes containing the same ligand in combination with aminotroponiminates have been prepared and characterized (Figure 83).**[108]**

10.2 Bis(cyclooctatetraenyl) Complexes

Shortly after the synthesis of uranocene (*see Uranocene*), the first lanthanide complexes containing the cyclooctatetraenyl dianion, $K[Ln(COT)_2]$, have been prepared by the reaction of $K_2[COT]$ with lanthanide trichlorides (equation 21).

$$2K_2(COT) + LnCl_3 \xrightarrow[-3KCl]{\text{solvent}} [(\text{solvent})K][Ln(\eta^8\text{-}COT)_2] \qquad (21)$$

They are thermally very robust, but decompose almost explosively upon contact with traces of oxygen. X-ray diffraction studies showed $[Li(THF)_4][Ln(COT)_2]$ (Ln = Ce, Sm) consisting of separated ions with the lithium cation being coordinated by four THF molecules. $[Na(THF)_3][Sm(COT)_2]$ (Figure 84a) forms a double sandwich with two COT ligands and the two metal ions arranged as a linear unit. A very similar molecular structure was reported for the solvated potassium salt $[K(diglyme)][Ce(COT)_2]$. The X-ray structure of $[(COT)Er(\mu\text{-}COT)K(\mu\text{-}COT)Er(\mu\text{-}COT)K(THF)_4]$ (Figure 84b) shows that the stacking of cyclooctatetraene ligands in organolanthanide complexes can be further extended.

Several examples of anionic sandwich complexes containing substituted cyclooctatetraenyl ligands have been reported also, for example, $[Li(THF)_4][Ln\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$ (Ln = Y, Ce, Pr, Nd, Sm). The very bulky 1,3,6-tris(trimethylsilyl)cyclooctatetraenyl ligand as well as functionally substituted cyclooctatetraenyl ligands $1,4\text{-}R_2C_8H_6$ ($R = o\text{-}Me_2NC_6H_4SiMe_2$) were also reported to form anionic sandwich complexes with nearly all rare earth elements. Alkali metal-free sandwich complexes $[Ln(COT)(HMPA)_n]^+[Ln(COT)_2]^-$ (Ln = La, $n = 4$; Ln = Sm, $n = 3$) were obtained by reaction of lanthanide metals with COT in the presence of a catalytic amount of iodine in THF containing HMPA. When a stoichiometric amount of iodine is used in this reaction, $[Sm(COT)(HMPA)_3]^+ (I)^-$ is isolated. Bimetallic complexes containing $[Ln(COT)_2]^-$ anions, for example, $[CoCp_2][Ce\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$ (Figure 85a) and $[Yb(THF)_6][Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]_2$ (Figure 85b) are also known.

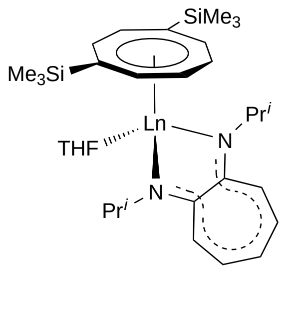

Figure 83 $[1,4\text{-}(Me_3Si)_2C_8H_6]\,Ln[C_7H_5(N^iPr)_2](THF)$

11 ORGANOLANTHANIDES IN THE OXIDATION STATE 0, +1, +2 AND +4

11.1 Organolanthanides in the Oxidation State 0

There are just few examples of authentic lanthanide complexes in the oxidation state zero. Bis(arene) complexes of the lanthanides $(1,3,5\text{-}^tBu_3C_6H_3)_2Ln$ (Ln = Sc, Y, La, Nd, Pr, Sm, Gd, Tb, Dy, Ho, Er, Lu) have been synthesized by cocondensation of metal vapors (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***) with 1,3,5-tri(*tert*-butyl)benzene at 75 K. A sandwich structure with coplanar arene ligands has been proven by X-ray crystal structure analysis of the Gd and Ho complexes (Figure 86a).

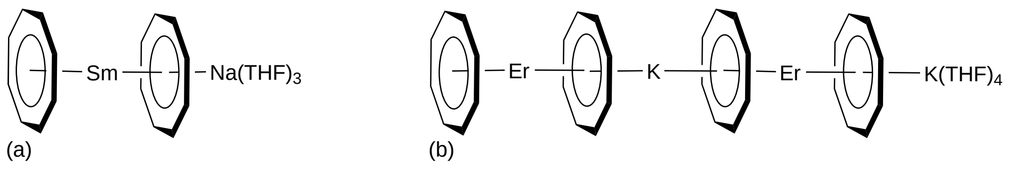

Figure 84 (a) $[Na(THF)_3][Sm(COT)_2]$, (b) $[(COT)Er(\mu\text{-}COT)K(\mu\text{-}COT)Er(\mu\text{-}COT)K(THF)_4]$

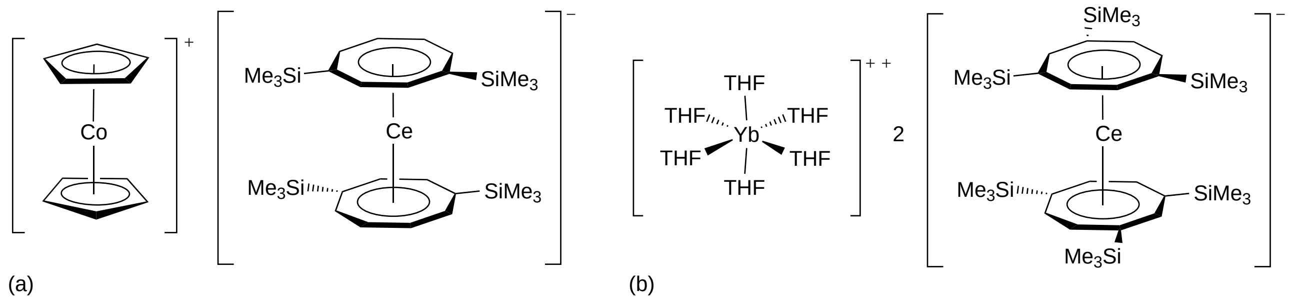

Figure 85 (a) $[CoCp_2][Ce\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$, (b) $[Yb(THF)_6][Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]_2$

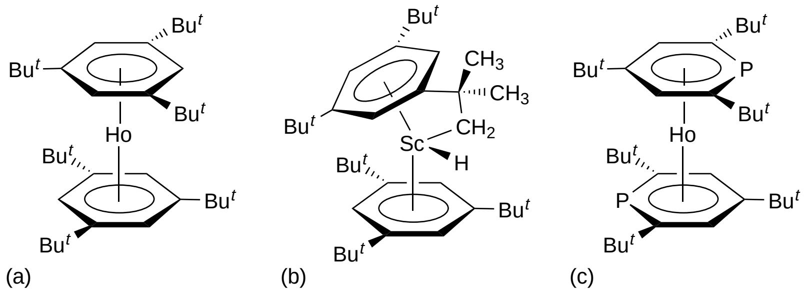

Figure 86 (a) $(^tBu_3C_6H_3)_2Ho$, (b) $(^tBu_3C_6H_3)Sc(H)[(^tBu)_2(CMe_2CH_2)C_6H_3]$, (c) $Ho(PC_5H_2Bu^t_3)_2$

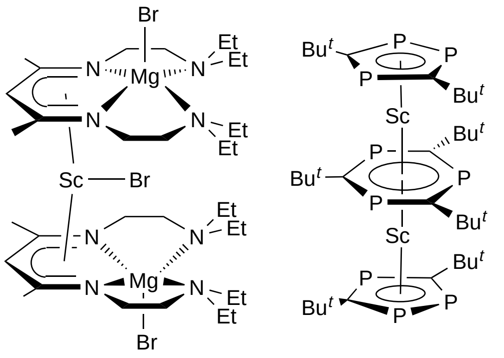
An attempt to prepare the analogues complexes of Ce, Eu, Tm, and Yb failed, what has been explained on the basis of the difference in the promotion energy of $f^ns^2 \rightarrow f^{n-1}d^1s^2$ for different lanthanides. As in chloroaluminate lanthanide(III) complexes with neutral arene ligands, the stability of zerovalent bis(arene)lanthanides increases with increasing number and size of substituents at the aromatic ring. Cocondensation of Sc with tri-*tert*-butylbenzene results in the formation of the bis(arene)scandium complex together with $(\eta^6\text{-}^tBu_3C_6H_3)Sc(H)[(\eta^6{:}\eta^1\text{-}^tBu)_2(CMe_2CH_2)C_6H_3]$ (Figure 86b) via insertion of Sc into the C–H bond of one *tert*-butyl substituent. Cocondensation of Ho vapor with 2,4,6-tri-*tert*-butylphosphorin yields $Ho(\eta^6\text{-}PC_5H_2Bu^t_3\text{-}2,4,6)_2$ (Figure 86c), which sublimes with 90% recovery at 160°C/10^{-5} mbar.



(**134**) (**135**)

Figure 87 (a) $[(Et_2NCH_2CH_2NCMeCHCMeNCH_2CH_2NEt_2)MgBr]_2ScBr$, (b) $(^tBu_2C_2P_3)Sc(\mu\text{-}^tBu_3C_3P_3)Sc(^tBu_2C_2P_3)$

11.2 Organolanthanides in the Oxidation State 1

Organometallic compounds of the 4f-elements in the oxidation state +1 are not reported until now. There are only two examples of monovalent scandium complexes. Thus, the ß-diketiminato derivative of scandium, $LScBr_2$ ($L = Et_2NCH_2CH_2NC(Me)CHC(Me)NCH_2CH_2NEt_2$) reacts with $(C_3H_5)MgBr$ yielding $(LMgBr)_2ScBr$ (Figure 87a). X-ray structure, liquid and solid-state NMR, EPR-, UV-vis-spectroscopy, and magnetic measurements support a formal oxidation state of Sc(I) having no unpaired electrons.[109] Cocondensation of Sc vapor with 2,2-dimethylpropylidynephosphine, $Me_3CC{\equiv}P$, affords the triple-decker sandwich complex $(\eta^5\text{-}^tBu_2C_2P_3)Sc(\mu\text{-}\eta^6{:}\eta^6\text{-}^tBu_3C_3P_3)Sc(\eta^5\text{-}^tBu_2C_2P_3)$, which was characterized by X-ray crystallography (Figure 87b).

11.3 Organolanthanides in the Oxidation State 2

Organometallic compounds of the lanthanides in the oxidation state Ln(II) were first reported in the early 1980s

and was limited to only Sm, Eu, and Yb. In 1997, the first divalent thulium complex (*see* ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***) was reported by Bochkarev *et al*. Since then, divalent Nd and Dy derivatives have been prepared and structurally characterized. The chemistry of those compounds is increasing because of their unique reactivity, which is associated with the reducing properties of the divalent lanthanide ions.

11.3.1 Divalent Alkyl Lanthanide Complexes

The reaction between LnI_2 (Ln = Eu, Yb) and $K[C(SiMe_3)_3]$ in benzene yields solvent-free monomeric $Ln[C(SiMe_3)_3]_2$. The Yb derivative reacts with Et_2O or iodomethane yielding $[Yb\{C(SiMe_3)_3\}(\mu\text{-OEt})(OEt_2)]_2$ and $[Yb\{C(SiMe_3)_3\}I]_2$, respectively, which are dimeric in the solid state. The Yb analogs of Grignard reagents, $Yb[C(SiMe_3)_2(SiMe_2X)]I(OEt_2)$ (X = Me, CH=CH$_2$, Ph, or OMe) were prepared from Yb metal and RI [R = $[C(SiMe_3)_2(SiMe_2X)]$, X = Me, CH=CH$_2$, or CH$_2$CH$_2$-OEt]. The alkylytterbium iodides crystallize from Et_2O as solvated iodide-bridged dimers in which the coordination at Yb is four when X = Me but is increased to five by chelation from the group X when X = OMe (Figure 88a). A redistribution yielding R_2Yb and YbI_2 is not observed when X = Me, but it takes place readily when X = Ph, CH=CH$_2$, or OMe. Reaction of $SmI_2(THF)_2$ with two equiv. of $K[C(SiMe_3)_2(SiMe_2OMe)]$ in THF results in the formation of $Sm[C(SiMe_3)_2(SiMe_2OMe)]_2(THF)$ (Figure 88b).

The ether-solvated bis(trimethylsilyl)methyl derivative $Yb\{CH(SiMe_3)_2\}_2(OEt_2)_2$ is prepared from YbI_2 and $Na[CH(SiMe_3)_2]$, the three-coordinate ytterbium(II) alkyl complex $[K(Yb\{CH(SiMe_3)_2\}_3)]_n$ from YbI_2 and three equiv. of $K[CH(SiMe_3)_2]$ in benzene, and the red *ate* complex $[Li(THF)_4][Yb\{CH(SiMe_3)_2\}_3]$ by the reaction of LiR, YbI_2, and two equiv. of $K[CH(SiMe_3)_2]$ in Et_2O in the presence of a small amount of THF. $[K(Yb\{CH(SiMe_3)_2\}_3)]_\infty$ consists in the solid state of double chains of $[(Yb\{CH(SiMe_3)_2\}_3)]^-$ anions linked by K^+ cations (Figure 89a), whereas $[Li(THF)_4][Yb\{CH(SiMe_3)_2\}_3]$ has an ionic structure with isolated $[Li(THF)_4]^+$ cations and $[Yb\{CH(SiMe_3)_2\}_3]^-$ anions (Figure 89b).[110] The mixed alkyl/alkoxy complexes $[Yb\{CH(SiMe_3)_2\}(OEt)(L)_n]$ (L = Et_2O, $n = 2$; L = THF, $n = 3$) were prepared from $[Yb(OEt)_2(L)_n]$ and $K[CH(SiMe_3)_2]$.

Only two crystallographically characterized aryl derivatives of divalent lanthanides are reported. Reaction of Eu

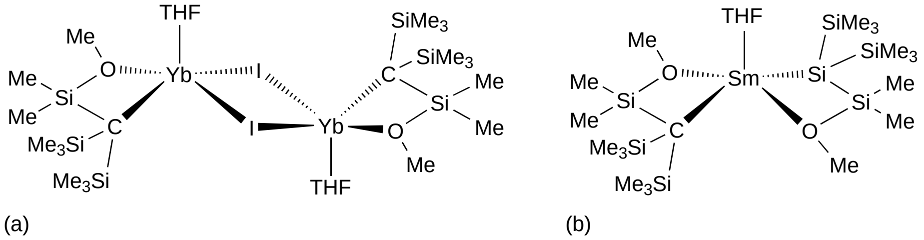


Figure 88 (a) $[YbC(SiMe_3)_2(SiMe_2OMe)(THF)]_2(\mu\text{-}I)_2$, (b) $Sm[C(SiMe_3)_2(SiMe_2OMe)]_2(THF)$

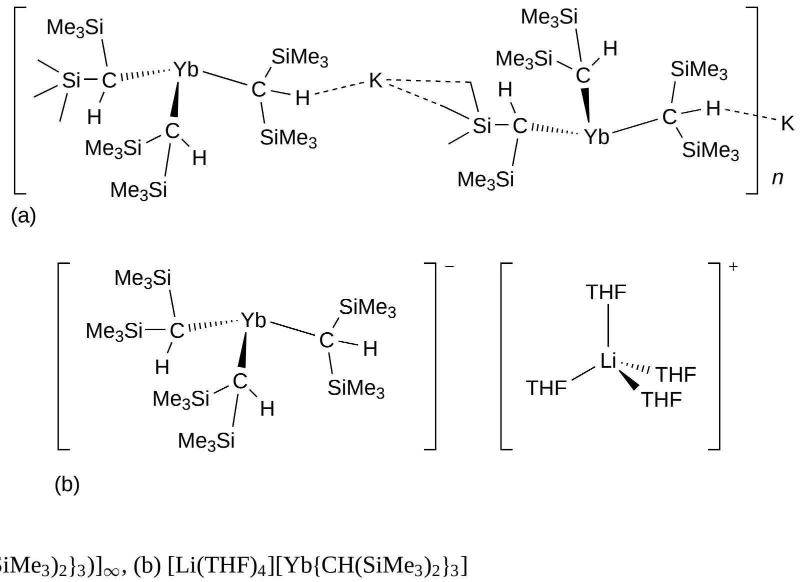

Figure 89 (a) $[K(Yb\{CH(SiMe_3)_2\}_3)]_\infty$, (b) $[Li(THF)_4][Yb\{CH(SiMe_3)_2\}_3]$

metal with $Hg(C_6F_5)_2$ in THF, followed by crystallization from THF/light petroleum affords $Eu(C_6F_5)_2(THF)_5$, which reveals axial C_6F_5 and equatorial THF ligands bonded to a pentagonal-bipyramidal Eu center (Figure 90a).[111] *m*-Terphenyl derivatives $Yb(Dpp)I(THF)_3$ and $Eu(Dpp)_2(THF)_2$ (Dpp = 2, 6-$Ph_2C_6H_3$) were obtained from reactions of DppI with lanthanides in THF.[112] In $Yb(Dpp)I(THF)_3$ (Figure 90b), the metal is bonded to the *ipso*-carbon atom of the terphenyl group, to the terminal iodo substituent, and to three THF molecules. $Eu(Dpp)_2(THF)_2$ shows an Eu center in a distorted tetrahedral coordination environment.

$(Ph_3Ge)_2Eu(DME)_3$ (Figure 91a) was synthesized by reacting Ph_3GeH with $C_{10}H_8$ $Eu(THF)_2$ in DME. The Eu atom is located in the center of the hexagonal bipyramid with axially positioned germyl ligands. Six oxygen atoms of the DME ligands form an equatorial plane. The interrelated stannyl derivative $(Ph_3Sn)_2Yb(THF)_4$ was prepared by reaction of Yb with either Ph_3SnCl, $PhSnCl_3$, or $Ph_3SnSnPh_3$. According to X-ray data, Sn is covalently bonded to Yb. Ph_2SnCl_2 reacts with Yb with formation of $[Yb_2Cl_2(DME)_6]^{2+}$ and $[(Ph_3Sn)_3Sn]^-$ ions (Figure 91b). In the solid state, it consists of $[(Ph_3Sn)_3Sn]^-$ anions separated by $[Yb_2Cl_2(DME)_6]^{2+}$ cations with μ_2-bridging chlorine atoms. A Sn–Sn bond formation also takes place when Sm or Yb reacts with Me_3SnCl in THF yielding $[(Me_3Sn)_3Sn]^-$ anions. However, in these cases, complexes with direct Ln–Sn bonds $[(Me_3Sn)_3Sn]_2Ln(THF)_4$ (Ln = Sm, Yb) were isolated. According to X-ray crystallography, both molecules have a distorted octahedral structure in which the central Ln (Ln = Sm, Yb) atom is bonded to four oxygen atoms of THF in equatorial positions and two tin atoms of the $(Me_3Sn)_3Sn$ groups in axial positions.

$(Ph_3Si)_2Yb(THF)_4$ and $(Ph_3Ge)_2Yb(THF)_4$ (Figure 92a) were synthesized by reaction of Ph_3SiCl or Ph_3GeCl, respectively, with ytterbium in THF. Both compounds have octahedral structures with axial silyl and germyl groups. The reaction between YbI_2 and $K[Sn(CH_2{}^tBu)_3]$ affords diamagnetic $[(^tBuCH_2)_3Sn]_2Yb(THF)_2$ (Figure 92b). Reaction with one equiv. of ArOH or Cp*H results in the formation of mixed-ligand complexes $(ArO)YbSn(CH_2{}^tBu)_3(THF)_2$ and $Cp^*YbSn(CH_2{}^tBu)_3(THF)_2$. $Cp^*YbSi(SiMe_3)_3(THF)_2$ was prepared by the reaction of $Cp^*_2Yb(OEt_2)$ with one equiv. of $Li[Si(SiMe_3)_3](THF)_3$ in toluene.

The reaction of $[(DME)_2YbI]_2(\mu\text{-}C_{10}H_8)$ with PhC≡CH leads to the mixed iodo/ethynyl complex [IYb(μ-C≡CPh) $(DME)_2]_2$ (Figure 93a). According to X-ray diffraction analysis, the molecule consists of two $YbI(DME)_2$ units bridged by two C≡CPh groups. The central cyclic fragment Yb–C–Yb–C is planar. The homoleptic Yb(II)

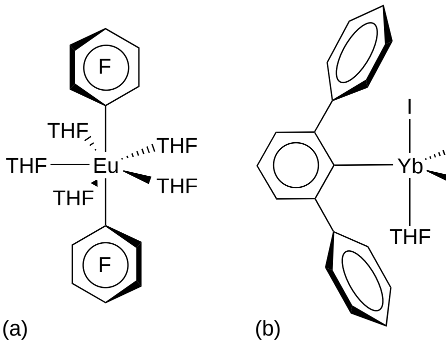

Figure 90 (a) $Eu(C_6F_5)_2(THF)_5$, (b) $Yb(Dpp)I(THF)_3$

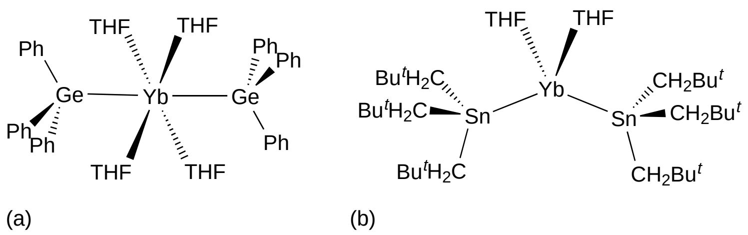

Figure 92 (a) $(Ph_3Ge)_2Yb(THF)_4$, (b) $[(^tBuCH_2)_3Sn]_2Yb(THF)_2$

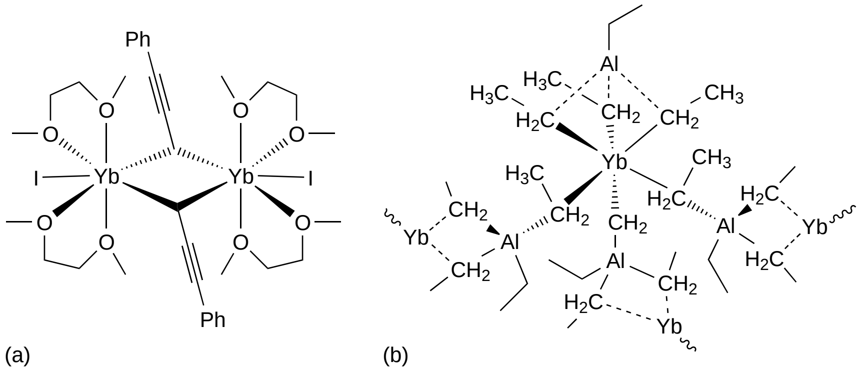

Figure 93 (a) $[Yb(\mu\text{-}C{\equiv}CPh)(I)(DME)_2]_2$, (b) $\{Yb[AlEt_4]_2\}_n$

tetraalkylaluminate complexes $\{Yb[AlR_4]_2\}_n$ were obtained by silylamide elimination from $Yb[N(SiMe_3)_2]_2(THF)_2$ and excess AlR_3 (R = Me, Et, ^{i}Bu). In the solid state, $\{Yb[AlEt_4]_2\}_n$ (Figure 93b) is polymeric, constituted of $[Yb(AlEt_4)]^+$ and $[Yb(AlEt_4)_3]^-$ units, forming an intricacy three-dimensional network. Both fragments are linked by bridging α-C atoms and secondary Yb···H–C agostic interactions combining μ,η^1-,μ,η^2-, and μ,η^3-coordination modes that result in remarkably short Yb···Al (2.809 Å) and a large range of Yb···C (2.649-3.364 Å) distances.[113] The alkylaluminum adducts $Yb[N(SiMe_3)_2]_2(AlR_3)_2$ were prepared from $Yb[N(SiMe_3)_2]_2$ and AlR_3 (R = Me, Et).

11.3.2 Divalent Lanthanidocenes and Related Compounds

A variety of cyclopentadienyl, indenyl, fluorenyl, and other related ligands have been used for the synthesis of divalent lanthanidocenes. Most of the synthetic approaches employ metathetical reactions between lanthanide salts and alkali or alkaline-earth metal salts of the ligands. Till recently, only Ln(II) complexes have been known for Sm, Eu, and Yb.[114] However, the synthetic routes using lanthanide metals are also known. Europium and ytterbium metal dissolved in liquid ammonia react with Cp*H affording $Cp^*_2Ln(NH_3)(THF)$ (Ln = Eu, Yb). Transmetallation of $Tl(C_5D_5)$ or $(C_5H_4PPh_2)Tl$ with Yb metal in DME yields $(C_5D_5)_2Yb(DME)$ and $[(C_5H_4PPh_2)_2Yb(DME)]$, respectively. Diethylene glycol dimethyl ether (DIME) adducts $[(C_5H_4PPh_2)_2Eu(DIME)]$ and $[(C_5H_4PPh_2)_2Yb(DIME)]$ have been prepared analogously in THF, followed by crystallization from DME/DIME.

SmI_2 reacts with one or two equiv. of Cp*K in THF yielding $[Cp^*Sm(\mu\text{-}I)(THF)_2]_2$ and $Cp^*_2Sm(THF)_2$, respectively. $Cp^*_2Sm(THF)_2$ shows a bent metallocene (*see Bent Metallocenes*) structure in which the two Cp* ring centroids and the two oxygen atoms of the THF ligands (Figure 94a) are arranged roughly tetrahedral around Sm. $Cp^*_2Sm(THF)_2$ can be dissolvated at 75°C under high vacuum or under reflux in toluene to form Cp^*_2Sm, which was the

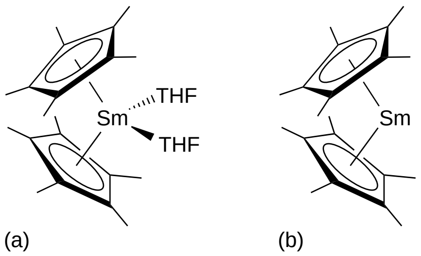

Figure 94 (a) $Cp^*_2Sm(THF)_2$, (b) Cp^*_2Sm

first reported solvent-free bis(cyclopentadienyl) compound of Ln(II). Even in the absence of coordinating solvent molecules it has a bent structure (Figure 94b).

Bis(dihydropyran) and mono(tetrahydropyran) solvates of Cp^*_2Sm have been prepared by displacing THF from $Cp^*_2Sm(THF)_2$• and $Cp^*_2Sm(DME)$ has been obtained as green crystals by the reaction of $SmCl_2$ with NaCp* in DME.

The reaction of LnI_2 with $Na(C_5Me_4{}^iPr)$ in THF yields $(C_5Me_4{}^iPr)_2Ln(THF)$ (Ln = Sm, Yb); base-free ytterbocenes Cp^*_2Yb, $(C_5HMe_4)_2Yb$, and $(C_5H_3{}^tBu_2)_2$-Yb have been prepared by refluxing their Et_2O adducts in toluene,[115] as well as bis(substituted cyclopentadienyl)lanthanide(II) complexes $[(Me_3Si)_2CHC_5H_4]_2Ln$-$(THF)_2$ (Ln = Sm, Eu, Yb), $(Me_2{}^tBuSiC_5H_4)_2Yb(THF)_2$, $(\{Me_2{}^tBuSi\}_2C_5H_3)_2Ln(THF)_2$ (Ln = Sm, Yb), $[(Me_3Si)_2$-$CHC_5H_4]_2Ln$ (Ln = Sm, Eu, Yb), $(Me_2{}^tBuSiC_5H_4)_2Yb$, $(\{Me_2{}^tBuSi\}_2C_5H_3)_2Ln$ (Ln = Sm, Yb), and $Me_2Si(C_5H_3CH\{SiMe_3\}_2)_2Yb(THF)_2$ were synthesized from the appropriate LnI_2 with the respective Na or K cyclopentadienide.[116] Other solvent stabilized lanthanidocenes are $(C_5H_3{}^tBu_2)_2Yb$-(OEt_2), $(C_5H_3{}^tBu_2)_2Sm(DME)$, $(C_5H_3{}^tBu_2)_2Yb(DME)$, and $(C_5H_2{}^tBu_3)_2Ln(L)$ (Ln = Sm, L = THF; Ln = Sm, Yb, L = 2, 6-$Me_2C_6H_3NC$).[117] Octa-isopropyllanthanidocenes, as well as hexa-*tert*-butyllanthanidocenes of Sm, Eu, and Yb show no tendency towards coordination of donor solvent molecules or alkali salts. Deca-isopropyllanthanidocenes have

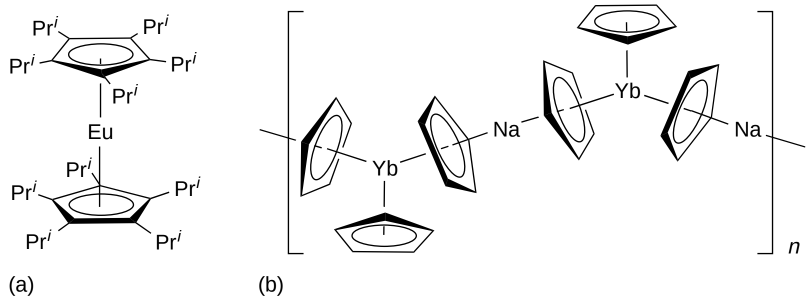

Figure 95 (a) $(C_5{}^iPr_5)_2Eu$, (b) $Na^+[YbCp_3]^-$

been synthesized from Sm, Eu, and Yb and free pentaisopropylcyclopentadienyl radicals (equation 22). The hexa-, octa-, and deca-isopropyleuropocenes show fluorescence in daylight or under UV irradiation. Crystals of $(C_5H_2{}^iPr_3)_2Eu$ and $(C_5H{}^iPr_4)_2Eu$ show bent-sandwich complexes, whereas $(C_5{}^iPr_5)_2Eu$ has an axial symmetry with parallel five-membered rings (Figure 95a).[118] Reduction of Cp_3Yb with $Na^+[C_{10}H_8]^-$ in THF yields $Na^+[YbCp_3]^-$ as a three-dimensional polymer in which μ-η^5:η^5-Cp groups link sodium and ytterbium (Figure 95b).

$$2[C_5(Pr^i)_5]^{\cdot} + Ln \xrightarrow{THF} [C_5(Pr^i)_5]_2Ln \qquad (22)$$
$$Ln = Sm, Eu, Yb$$

Coordinated THF in bis(cyclopentadienyl)lanthanides(II) can be replaced by so-called *Wanzlick-Arduengo carbenes*. $Cp^*{}_2Sm(THF)_2$ reacts with 1,3-diisopropyl-4,5-dimethylimidazoline-2-ylidene, $(C_3N_2Me_2{}^iPr_2)$, or 1,3,4,5-tetramethylimidazolin-2-ylidene, $(C_3N_2Me_4)$, in toluene with formation of $Cp^*{}_2Sm(C_3N_2Me_2{}^iPr_2)$ (Figure 96a),[119] and $Cp^*{}_2Sm(C_3N_2Me_4)_2$, respectively. Related 1,3-dimethylimidazoline-2-ylidene, $(C_3N_2H_2Me_2)$, adducts of divalent lanthanidocenes $(C_5Me_4Et)_2Ln(C_3N_2H_2Me_2)$ (Ln = Sm, Yb), $Cp^*{}_2Yb(C_3N_2H_2Me_2)$ and $(C_5H_3{}^tBu_2)_2Yb(C_3N_2H_2Me_2)$ were prepared analogously. The analogous silylene complex $Cp^*{}_2Sm[SiN{}^tBuCHCHN{}^tBu]$ has been synthesized by reaction of $Cp^*{}_2Sm$ with 1,3-di-*tert*-butyl-2,3-dihydro-1H-1,3,2-diazasilol-2-ylidene in toluene. The silylene ligand is

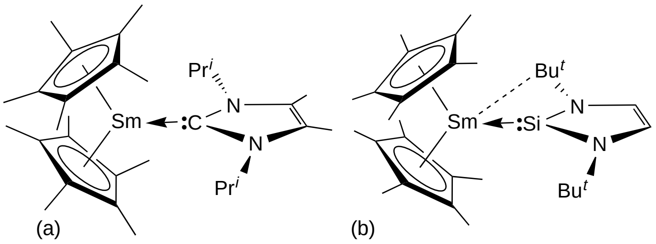

Figure 96 (a) $Cp^*{}_2Sm(C_3N_2Me_2{}^iPr_2)$, (b) $Cp^*{}_2Sm[SiN{}^tBuCH$-$CHN{}^tBu]$

located asymmetrically in the metallocene wedge with one ^{t}Bu group much closer to the metal than the other one (Figure 96b).[120]

Several heterometallic lanthanide(II)/transition metal complexes have been synthesized. $(THF)_2Yb(C_5H_4PPh_2)_2$-$PtMe_2$ was prepared by the reaction of $(C_5H_4PPh_2)_2Yb(THF)$ with (*cis*,*cis*-1,5-cyclooctadiene)dimethylplatinum in toluene. Similar reaction with $W(CO)_6$ in THF yields $[(THF)_3Yb(C_5H_4PPh_2)_2W(CO)_4]$, while $[(THF)Yb(C_5H_4$-$PPh_2)_2(\mu$-$OC)W(CO)_3]$ (Figure 97a) is obtained in toluene. In both molecules, the $(\eta^5$-$C_5H_4PPh_2)_2Yb$ units are bonded to W through the P atoms giving an octahedral *cis*-$W(CO)_4P_2$ arrangement. An isocarbonyl linkage (W–C=O–Yb) is found in $[(THF)Yb(C_5H_4PPh_2)_2(\mu$-$OC)W(CO)_3]$.[121] The reaction of $Cp^*{}_2Yb$ with $(dippe)PtMe_2$ (dippe = $^iPr_2P(CH_2)_2P{}^iPr_2$) results in the formation of $(dippe)Pt(\mu$-$Me)_2YbCp^*{}_2$ with

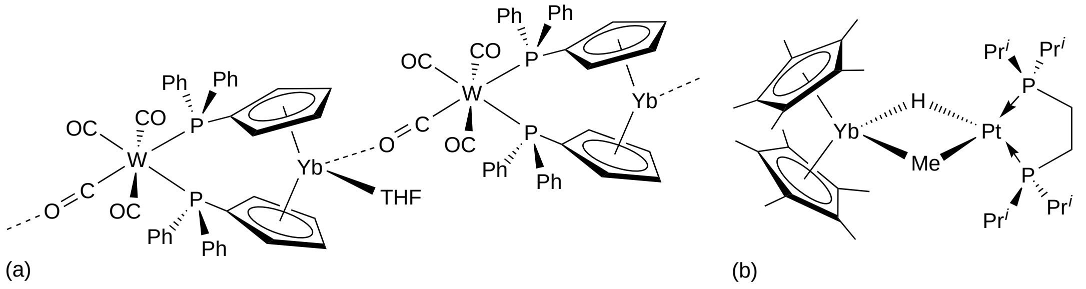

Figure 97 (a) $[(THF)Yb(C_5H_4PPh_2)_2(\mu$-$OC)W(CO)_3]$, (b) $(dippe)Pt(\mu$-$Me)(\mu$-$H)YbCp^*{}_2$

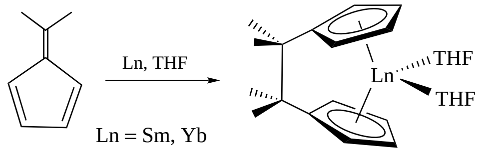
two Me groups bridging Pt and Yb. The solid-state structure of the adduct (dippe)Pt(μ-Me)(μ-H)YbCp*$_2$ (Figure 97b), which has been prepared analogously, showed an asymmetric (μ-Me)(μ-H) bridge between both metal atoms.

Mixed-ligand complexes CpLnCp$'$ are also known, for example, [C$_5$H$_2$(SiMe$_3$)$_3$][C$_5$H$_3$(SiMe$_3$)$_2$]Sm(THF) and (C$_5$H$_3{}^t$Bu$_2$)(Cp*)Yb(THF) as bent sandwiches.

Reduction of dimethylfulvene with activated Sm or Yb in THF results in the formation of *ansa*-lanthanidocene complexes Me$_2$C(C$_5$H$_4$)$_2$Ln(THF)$_2$ (equation 23) and [(C$_5$H$_2{}^t$Bu$_2$-C$_5$H$_2{}^t$Bu$_2$)Yb(THF)]$_2$ (Figure 98), and the analogous Sm derivative are formed by an electron-transfer reaction of Yb and Sm powder with tetra(*tert*-butyl)pentafulvalene in the presence of HgCl$_2$ in THF.



(23)

ansa-Metallocene complexes with oxygen bridged Cp ligands O(CH$_2$CH$_2$C$_5$H$_4$)$_2$Ln(THF)$_2$ (Ln = Sm, Yb) were synthesized by reduction of O(CH$_2$CH$_2$C$_5$H$_4$)$_2$LnCl with Na metal in THF. Divalent samarium complexes with variously substituted Me$_2$Si-bridged *ansa*-bis(cyclopentadienyl) ligands were prepared and structurally characterized, for example, *rac*-Me$_2$Si(2-Me$_3$Si-4-^{t}BuC$_5$H$_2$)$_2$Sm(THF)$_2$ (Figure 99a), *rac*-Me$_2$Si(2-Me$_3$Si-4-^{t}BuMe$_2$SiC$_5$H$_2$)$_2$Sm(THF)$_2$, *meso*-[1,2-(Me$_2$Si)(Me$_2$SiOSiMe$_2$)](3-^{t}BuC$_5$H$_2$)$_2$Sm(THF)$_2$, and the C$_{2v}$ symmetric [1,2-(Me$_2$SiOSiMe$_2$)$_2$](3-^{t}BuC$_5$H$_2$)$_2$Sm-(THF)$_2$ (Figure 99b). They show high activity for the polymerization of ethylene and 1-olefins such as 1-pentene and 1-hexene. *rac*-Me$_2$Si(2-Me$_3$Si-4-^{t}BuMe$_2$SiC$_5$H$_2$)$_2$Sm(THF)$_2$ induces the cyclopolymerization of 1,5-hexadiene yielding poly(methylene-1,3-cyclopentane).

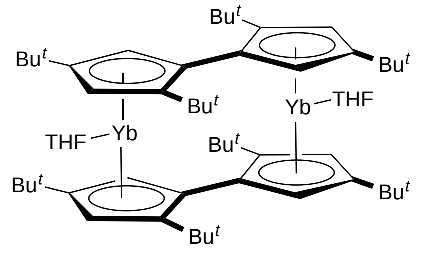


Figure 98 [(C$_5$H$_2{}^t$Bu$_2$-C$_5$H$_2{}^t$Bu$_2$)Yb(THF)]$_2$

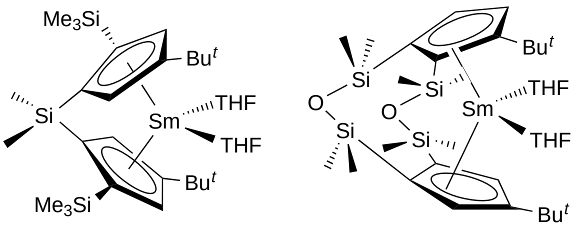
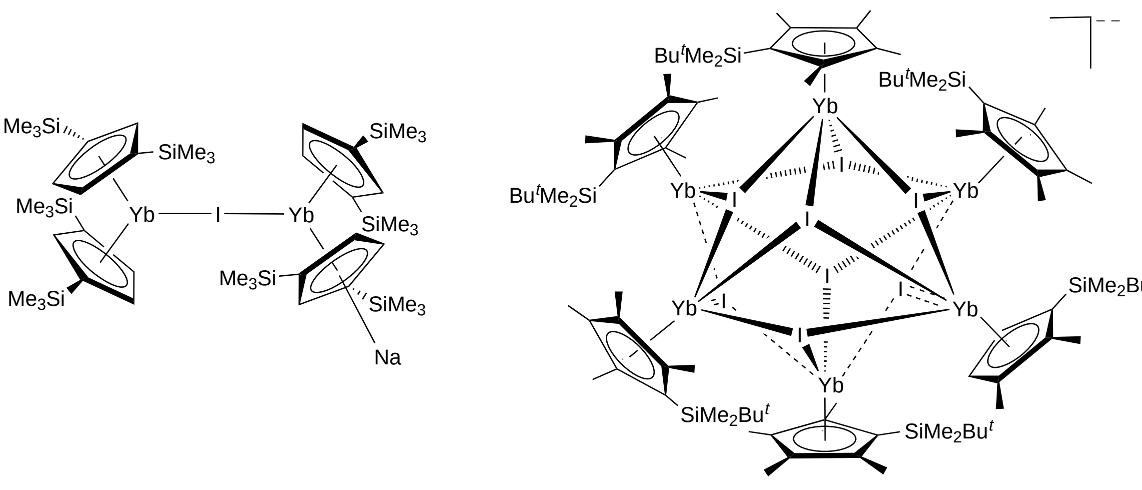


(a) (b)

Figure 99 (a) Me$_2$Si(2-Me$_3$Si-4-^{t}BuC$_5$H$_2$)$_2$Sm(THF)$_2$, (b) [1,2-(Me$_2$SiOSiMe$_2$)$_2$](3-^{t}BuC$_5$H$_2$)$_2$Sm(THF)$_2$

The X-ray crystal structure of [Cp*Sm(μ-I)(THF)$_2$]$_2$ shows two Cp*Sm(THF)$_2$ moieties bridged by iodine via a planar Sm$_2$(μ-I)$_2$ unit, with the Cp* ring on one side of the plane and the THF molecules on the other one. The reaction of YbI$_2$ with two equiv. of Na[C$_5$H$_3$(SiMe$_3$)$_2$] in boiling toluene gives Na{[C$_5$H$_3$(SiMe$_3$)$_2$]$_2$Yb}$_2$(μ-I) (Figure 100a), containing an iodine bridged anion [{C$_5$H$_3$(SiMe$_3$)$_2$}$_2$Yb–I–Yb{C$_5$H$_3$(SiMe$_3$)$_2$}$_2$]$^-$. An unusual cyclic hexanuclear



(a) (b)

Figure 100 (a) Na{[C$_5$H$_3$(SiMe$_3$)$_2$]$_2$Yb}$_2$(μ-I), (b) [Yb$_6${C$_5$Me$_4$(SiMe$_2$Bu^t)}$_6$I$_8$]$^{2-}$

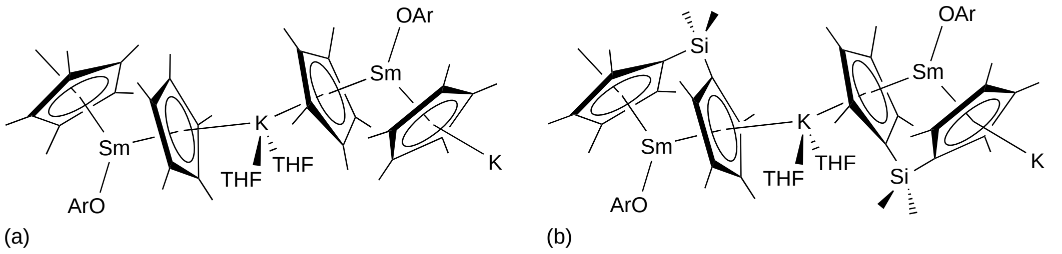


Figure 101 (a) $[Cp^*Sm(OAr)(\mu\text{-}Cp^*)K(THF)_2]_\infty$, (b) $[Me_2Si(C_5Me_4)(\mu\text{-}C_5Me_4)K(THF)_2Sm(OAr)]_\infty$

Yb(II) octaiodo dianion $[Yb_6(\eta^5\text{-}Cp')_6I_8]^{2-}$ has been prepared by reaction of one equivalent of LiCp′ [Cp′ = $C_5Me_4(SiMe_2Bu^t)$] with YbI_2 (Figure 100b).

Reaction of $Cp^*_2Sm(THF)_2$ with one equiv. of ArOH (Ar = $C_6H_2{}^tBu_2$-2,6-R-4, R = H, Me, ^{t}Bu) produces unsolvated dimeric Sm(II) complexes $[Cp^*Sm(\mu\text{-}OAr)]_2$. Addition of four equiv. of HMPA to a THF solution of those complexes affords the corresponding HMPA-coordinated monomeric complexes $Cp^*Sm(OAr)(HMPA)_2$. The reaction with two equiv. of KCp* in THF yields polymeric Sm(II) complexes $[Cp^*Sm(OAr)(\mu\text{-}\eta^5\text{-}Cp^*)K(THF)_2]_\infty$ (Figure 101a) in which the '$Cp^*K(THF)_2$' unit acts as a neutral coordinating ligand. Analogous complexes $[Cp^*Sm(XR)(\mu\text{-}Cp^*)K(THF)_n]_\infty$ ($n = 1$ or 2; XR = $OC_6H_3{}^iPr_2$-2,6, $SC_6H_2{}^iPr_3$-2,4,6, $NHC_6H_2{}^tBu_3$-2,4,6, or $N(SiMe_3)_2$) have been synthesized in the same manner from $Cp^*_2Sm(THF)_2$ and KXR. Using $NaN(SiMe_3)_2$ instead of $KN(SiMe_3)_2$ affords the '$C_5Me_5Na(THF)_3$'-coordinated, 'monomeric' Ln(II) complexes $Cp^*Ln(N(SiMe_3)_2)(\mu\text{-}Cp^*)Na(THF)_3$ (Ln = Sm, Yb). The reaction of $Me_2Si(C_5Me_4)_2Sm(THF)_2$ with one equiv. of KOAr in THF yields $[Me_2Si(C_5Me_4)(\mu\text{-}C_5Me_4)K(THF)_nSm(OAr)]_\infty$ (Figure 101b) (Ar = $C_6H_2{}^tBu_2$-2,6-Me-4, $n = 2$; or $C_6H_3{}^tBu_2$-2,6, $n = 1$), which can be viewed as a C_5Me_4/OAr-ligated Sm(II) species coordinated by the silyl-linked neutral 'C_5Me_4K' ligand.

Reaction of $[Cp^*_2Yb(\mu\text{-}I)(THF)_2]_2$ with $K[N(SiMe_3)_2]$ generates $Cp^*Yb[N(SiMe_3)_2](THF)_2$ that crystallizes from toluene with a distorted piano stool (*see Piano Stool Structure*) geometry[122] and addition of $LnI_2(THF)_2$ (Ln = Sm, Yb) to $[Me_2Si(tacn)C_5Me_4]K$ (tacn = 1,4-diisopropyl-1,4,7-triazacyclononane) in THF yields monomeric solvent-free

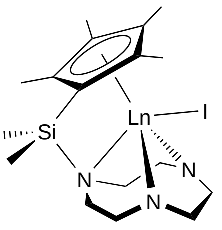

Figure 102 $[Me_2Si(tacn)C_5Me_4]LnI$

$[Me_2Si(tacn)C_5Me_4]SmI$ and $[Me_2Si(tacn)C_5Me_4]YbI$, in which all three N atoms of the triazacycle are coordinated to the metal (Figure 102).[123]

Structurally related Ln(II) alkyl complexes $[Cp^*Ln(CH(SiMe_3)_2)Cp^*K(THF)_2]_\infty$ (Ln = Sm, Eu, Yb) were prepared by reactions of $Cp^*_2Ln(THF)_2$ with one equiv. of $K[CH(SiMe_3)_2]$ in THF. In the presence of $PhSiH_3$, $[Cp^*Ln(SiH_3)Cp^*K(THF)_2]_\infty$ (Ln = Sm, Eu, Yb) are also isolated. $[Cp^*Sm(CH(SiMe_3)_2)Cp^*K(THF)_2]_\infty$ catalyzes the polymerization of ethylene and styrene.[124] Cp^*_2Yb can coordinate saturated hydrocarbons as in $Cp^*_2Yb(\mu\text{-}Me)BeCp^*$ (Figure 103a). The positions of the hydrogens on the bridging methyl group show that this is not a methyl bridge having a three-center-two-electron bond between Yb−C−Be. In contrast, trialkylaluminum forms Sm(III) complexes, for example, $[(C_5Me_4Et)_2Sm(\mu\text{-}Me)_2AlMe_2]_2$ (Figure 103b) in which Sm and Al are bridged by Sm–Me–Al three-center-two-electron bonds.

The use of crown ethers (*see Crown Ethers*) in organolanthanide chemistry often results in formation of solvent

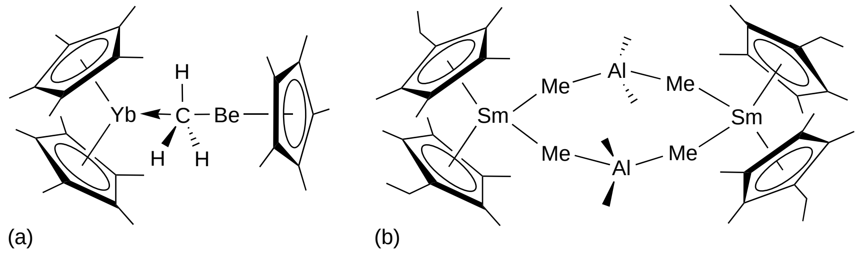

Figure 103 (a) $Cp^*_2Yb(\mu\text{-}Me)BeCp^*$, (b) $[(C_5Me_4Et)_2Sm(\mu\text{-}Me)_2AlMe_2]_2$

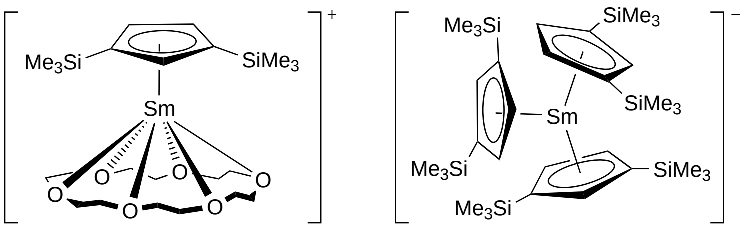

Figure 104 $[\{C_5H_3(SiMe_3)_2\}Sm([18]\text{-crown-6})][Sm\{C_5H_3(SiMe_3)_2\}_3]$

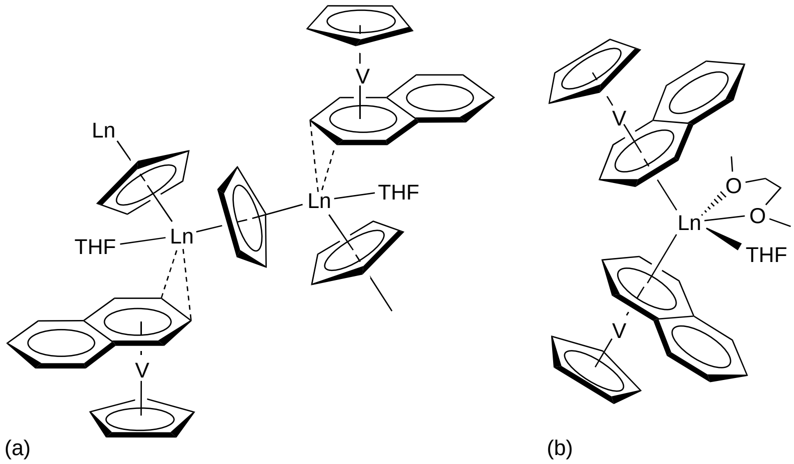

Figure 105 (a) $[CpV(C_{10}H_8)Ln(\mu\text{-}Cp)(THF)]_\infty$, (b) $[CpV(C_{10}H_8)]_2Ln(THF)(DME)$

separated ion pairs, like by treatment of $Ln[C_5H_3(SiMe_3)_2]_2$ (Ln = Sm, Yb) with [18]-crown-6 in benzene, yielding $[\{C_5H_3(SiMe_3)_2\}Sm([18]\text{-crown-6})][Sm\{C_5H_3(SiMe_3)_2\}_3]$ (Figure 104) and $[\{C_5H_3(SiMe_3)_2\}Yb([18]\text{-crown-6})][C_5H_3(SiMe_3)_2]$. Reduction of $[\{C_5H_3(SiMe_3)_2\}Sm([18]\text{-crown-6})][Sm\{C_5H_3(SiMe_3)_2\}_3]$ with K in toluene affords $[K([18]\text{-crown-6})(\eta^2\text{-PhMe})_2][Sm\{C_5H_3(SiMe_3)_2\}_3]$.

Reduction of Cp_2V with an excess of $(C_{10}H_8)Yb(THF)_2$ in THF generates polymeric two-dimensional multidecker complexes $[CpV(C_{10}H_8)Ln(\mu\text{-}Cp)(THF)]_\infty$, which are also formed from the reaction of $YbI_2(THF)_2$ with an equimolar mixture of KCp and $K[CpV(C_{10}H_8)]$ in THF. The analogous Eu derivative has been prepared similarly using EuI_2. The crystals consist of infinite zigzag chains formed by $(\eta^5\text{-}Cp)Ln$ (Ln = Eu, Yb) moieties. Each Ln atom is η^2 coordinated by $(\eta^5\text{-}Cp)V(\eta^6\text{-}C_{10}H_8)$ anions via naphthalene (Figure 105a). Reaction of LnI_2 (Ln = Eu, Sm) with an equimolar mixture of KCp and $K[CpV(C_{10}H_8)]$ in DME forms bimetallic complexes $[CpV(C_{10}H_8)]_2Ln(THF)(DME)$ (Ln = Eu, Sm) containing $CpV(C_{10}H_8)$ units η^6-bonded to the lanthanide (Figure 105b).

A number of mono- and bis(cyclopentadienyl)lanthanide(II) complexes with donor-functionalized Cp ligands has been reported. $(MeOCH_2CH_2C_5H_4)_2Sm$ and $(MeOCH_2CH_2C_5H_4)_2Yb$ were synthesized by the reaction of $K[C_5H_4CH_2CH_2OMe)]$ with LnI_2 (Ln = Sm, Yb). Recrystallization of the Yb complex from THF produces the solvated $(MeOCH_2CH_2C_5H_4)_2Yb(THF)$ with coordination number 9 at Yb. Optically active metallocene complexes of Sm(II) and Yb(II) containing cyclopentadienyl systems with chiral N- or O-substituted side chains as ligands are available by reaction of the Na or K salts of the ligands with LnI_2, for example, $[Ln\{(S)\text{-}\eta^5{:}\eta^1\text{-}C_5H_4(CH_2CHROMe)\}_2]$ (R = Me, Ph; Ln = Sm, Yb), $[Ln\{(S)\text{-}\eta^5{:}\eta^1\text{-}C_5H_4(CH_2CHMeNMe_2)\}_2]$ (Ln = Sm, Yb) (Figure 106a), $[Ln\{(S)\text{-}\eta^5{:}\eta^1\text{-}C_5H_4(CHPhCH_2NMe_2)\}_2]$ (Ln = Sm, Yb), $[C_5H_4(CMe_2CH_2C_5H_4N\text{-}2)]_2Yb$, and $[C_5H_3(SiMe_3)(CMe_2CH_2C_5H_4N\text{-}2)\text{-}3]_2Yb$ (Figure 106b).

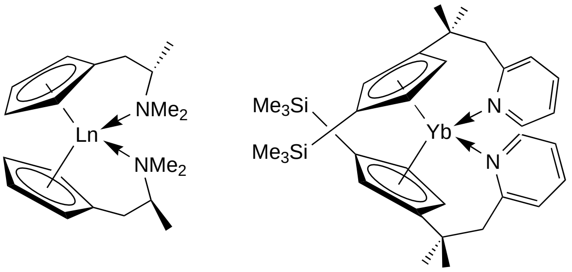

Figure 106 (a) $[Ln(S)\text{-}\eta^5{:}\eta^1\text{-}C_5H_4(CH_2CHMeNMe_2)\}_2]$, (b) $[C_5H_3(SiMe_3)(CMe_2CH_2C_5H_4N\text{-}2)\text{-}3]_2Yb$

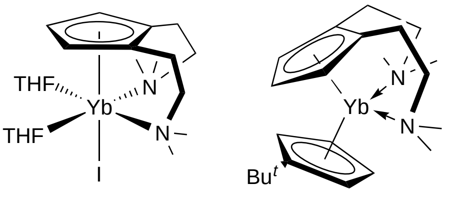

(a) (b)

Figure 107 (a) $(C_5H_3(CH_2CH_2NMe_2)_2$-1,2)YbI(THF)$_2$, (b) $(C_5H_3(CH_2CH_2NMe_2)_2$-1,2)Yb($C_5H_4{}^tBu$)

Analogous reactions of a mixture of the potassium salts of 1,2- and 1.3-bis[(dimethylamino)ethyl]cyclopentadiene with equimolar amounts of YbI_2 in THF allows only the isolation of crystalline (η^5:η^1:η^1-$C_5H_3(CH_2CH_2NMe_2)_2$-1,2)YbI(THF)$_2$ (Figure 107a). The reaction of this half-sandwich complex with KCp* and $NaC_5H_4{}^tBu$ results in the formation of (η^5:η^1:η^1-$C_5H_3(CH_2CH_2NMe_2)_2$-1,2)Yb(η^5-$C_5H_4{}^tBu$) (Figure 107b) and (η^5:η^1:η^1-C_5H_3-$(CH_2CH_2NMe_2)_2$-1,2)Yb(Cp*) respectively.[83]

Linked cyclopentadienyl-anilido or amido lanthanide(II) complexes $Me_2Si(C_5Me_4)$(NPh)Ln(THF)$_n$ (Ln = Yb, $n = 3$; Ln = Sm, $n = 0$–1) are prepared from Ln[N(SiMe$_3$)$_2$]$_2$-(THF)$_2$ with 1 equiv. of (C_5Me_4H)SiMe$_2$NHPh. Recrystallization of $Me_2Si(C_5Me_4)$(NPh)Yb(THF)$_3$ from toluene/hexane yields [$Me_2Si(C_5Me_4)$(NPh)Yb(THF)]$_2$ as a dimer through an 'intermolecular' Yb–Ph π-interaction (Figure 108a). $Me_2Si(C_5Me_4)$(NPh)Yb(THF)$_3$ is oxidized in the presence of azobenzene or fluorenone yielding the Yb(III) complexes $Me_2Si(C_5Me_4)$(NPh)Yb(THF)(μ_2-η^2:η^3-N_2Ph_2)Yb(NPh)(C_5Me_4)SiMe$_2$ and $Me_2Si(C_5Me_4)$-(NPh)Yb(THF)$_2$($OC_{13}H_8$) respectively.[125] A tetranuclear Yb(II) complex with both alkoxy and ether functionalities in the Cp side chain {[(η^5-C_5H_4)CH$_2$CH(μ^3:η^1-O)CH$_2$O^{n}Bu]Yb}$_4$ was synthesized by the reaction of the potassium salt of the corresponding ligand and YbI_2(THF)$_2$. Redox transmetallation reaction of this complex with Me_2Hg yields the Yb(III) complex [(η^5-C_5H_4)CH$_2$CH(η^1-O)CH$_2$O^{n}Bu]YbMe(THF).[126] The dimeric Yb(II) half-sandwich complex [{(η^5-C_5Me_4)SiMe$_2$OSiMe$_2$(η^1-O)}-Yb(THF)]$_2$ (Figure 108b) containing the heterobifunctional tetramethylcyclopentadienyl-silanolate ligand has also been reported.

Half-sandwich (*see Half-sandwich Complexes*) indenyl complexes of Yb(II) have been prepared by reaction of (μ-$C_{10}H_8$)[YbI(DME)$_2$]$_2$ with indene. (Ind)YbI(DME)$_2$, is a monomer in the solid state and stable in DME solution, although it disproportionates in THF yielding (Ind)$_2$Yb(THF)$_2$ and YbI_2(THF)$_2$.[127] The reaction of samarium diiodide with potassium indenide and potassium fluorenide results in the formation of (Ind)$_2$Sm(THF)$_3$ (Figure 109a) and (Flu)$_2$Sm(THF)$_2$ (Figure 109b), respectively. Structural data indicate that, in both compounds, Sm has a more open coordination sphere compared to Cp*$_2$Sm(THF)$_2$.

ansa-Bis(indenyl) complexes (LCH_2CH_2L)Yb(THF)$_2$ (Figure 110a) (L = 1-indenyl and 4,7-dimethylindenyl) have been prepared from (LCH_2CH_2L)Li$_2$ and $YbCl_3$ in Et_2O with subsequent reduction by Na metal in THF. Solvent-free racemic bis(1-(2-dimethylaminoethyl)indenyl) complexes, ($Me_2NCH_2CH_2C_9H_6$)$_2$Sm and ($Me_2NCH_2CH_2C_9H_6$)$_2$Yb, (Figure 110b) have been synthesized by the reaction of ($Me_2NCH_2CH_2C_9H_6$)K with LnI_2 (Ln = Sm, Yb). The nitrogen atoms of both dimethylaminoethyl groups coordinate intramolecularly to Yb.

Fluorenyl complexes of divalent ytterbium [(Flu)$_2$Yb(L)$_n$] (Figure 111a) (L = THF, $n = 2$; L = DME, $n = 1$; L = ^{t}BuNCHCHN^{t}Bu, $n = 1$) have been prepared by reaction of YbI_2(THF)$_2$ with two equiv. of KFlu as well as

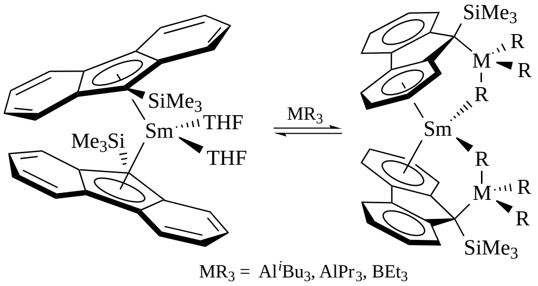
Figure 111 (a) $(Flu)_2Yb(^tBuNCHCHN^tBu)$, (b) *ansa*-$Me_2Si(C_{13}H_8)_2Sm(THF)_4$

by reduction of fluorene with $(C_{10}H_8)Yb(THF)_2$ in THF. The mixed-ligand sandwich complex (Flu)(Cp*)Yb(DME) results from the reaction of $[YbI(DME)_2]_2(C_{10}H_8)$ with Cp*H and KFlu in DME. *ansa*-$Me_2Si(C_{13}H_8)_2Yb(THF)$ and *ansa*-$Me_2Si(C_{13}H_8)_2Sm(THF)_4$ (Figure 111b) were obtained by treatment of the appropriate Ln diiodides with [*ansa*-$Me_2Si(C_{13}H_9)_2]K_2$ in THF.[128]

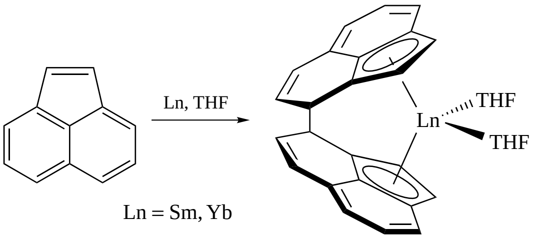
$(Me_3SiC_{13}H_8)_2Sm(THF)_2$ reacts with an excess of AlR_3 (R = Me, Et, Pr, ^{i}Bu) and BEt_3 yielding $(Me_3SiC_{13}H_8\text{-}AlR_3)_2Sm$ and $(Me_3SiC_{13}H_8\text{-}BEt_3)_2Sm$, respectively in a reversible equilibrium (equation 24). In contrast, $(Me_3SiC_{13}H_8)_2Yb(THF)_2$ reacts with an excess of $AlMe_3$ yielding $(Me_3SiC_{13}H_8)(Me_3SiC_{13}H_8\text{-}AlMe_3)Yb$, in which, according to the X-ray crystal structure, only one $AlMe_3$ coordinates to the Yb atom through two Me groups via an agostic interaction. One of the Me_3Si-fluorenyl groups is η^5-coordinated, the other one η^6 (Figure 112). The bis(indenyl) derivative $(^iPrC_9H_6)_2Yb(THF)_2$ shows the same behavior.[129]



(24)

Divalent organolanthanide complexes Ln(COT) (Ln = Eu, Yb) were precipitated with COT from the metal solution in liquid ammonia. $(COT)Yb(py)_3$ (Figure 113a) crystallizes as a 3-legged piano stool. Ionic sandwich complexes like $[(DME)K]_2[Yb(COT)_2]$ (Figure 113b) are available in liquid ammonia by addition of a stoichiometric amount of K, Ln, and COT.

The reductive coupling (*see Reductive Coupling*) of acenaphthylene by activated metallic ytterbium and samarium yields *ansa*-lanthanidocenes $[(\eta^5\text{-}C_{12}H_8)_2Ln(THF)_2]$ (Ln = Yb, Sm) (equation 25).



(25)

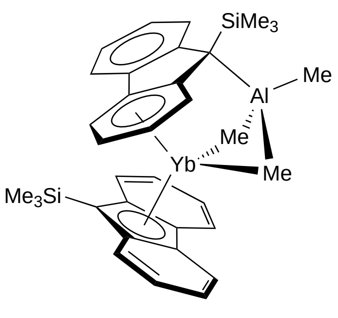


Figure 112 $(Me_3SiC_{13}H_8)(Me_3SiC_{13}H_8\text{-}AlMe_3)Yb$

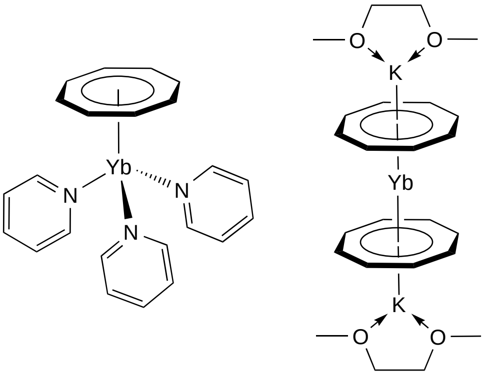

(a) (b)

Figure 113 (a) $(COT)Yb(py)_3$, (b) $[(DME)K]_2[Yb(COT)_2]$

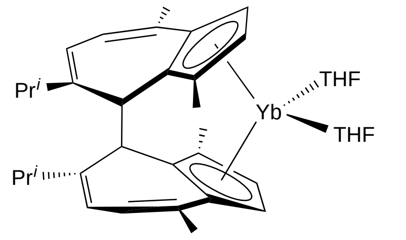

Figure 114 $(Gaz)_2Yb(THF)_2$

According to X-ray crystallography and NMR data, coupling of the radical anions of acenaphthylene in these reaction occurs stereoselectively affording exclusively C_2-symmetric *rac*-*ansa*-lanthanidocenes.[130] The related C_2-symmetric *rac*-*ansa*-ytterbocene complex $(Gaz)_2Yb(THF)_2$ (Gaz = guajazulene) (Figure 114) is isolated when GAZ is reacted with $(C_{10}H_8)Yb(THF)_2$.[131]

The chemistry of the lanthanide(II) complexes with pyrrolyl and pyrazolylborate ligands is unusual and provided surprising structures and unprecedented reactivity including dinitrogen reduction. The reactions of $SmI_2(THF)_2$ and $YbI_2(THF)_2$ with the alkali metal salts of 2,5-dimethylpyrrole led to the formation of divalent mono- and polynuclear complexes, for example, $(\mu\text{-}\eta^1{:}\eta^5\text{-}Me_2C_4H_2N)_3Sm(\mu\text{-}Cl)[Li(THF)_2]_2$ (Figure 115a), $\{[(Na(THF)_2)(\mu\text{-}\eta^1{:}\eta^5\text{-}Me_2C_4H_2N)_3Sm]_2(\mu\text{-}\eta^1{:}\eta^5\text{-}Me_2C_4N)_2\}(THF)_2$, $\{(\mu\text{-}\eta^1{:}\eta^5\text{-}Me_2C_4H_2N)_2Yb(\mu\text{-}Cl)[Li(OEt_2)]\}_2$, and $\{(\mu\text{-}\eta^1{:}\eta^5\text{-}Me_2C_4H_2N)_4[K(THF)]_2Yb\}_n$.[132] The reaction of diphenylbis(2-pyrrolyl)methane with KH and subsequent treatment with $YbI_2(THF)_2$ leads to $[Ph_2C(C_4H_3N)Yb]_8$ (Figure115b) as the major product.[133]

When the similar reaction has been carried out using $SmI_2(THF)_2$, a four-electron dinitrogen reduction is achieved, yielding $[\{[\mu\text{-}Ph_2C(\eta^1{:}\eta^5\text{-}C_4H_3N)_2]Sm\}_4(\mu\text{-}\eta^1{:}\eta^1{:}\eta^2{:}\eta^2\text{-}N_2)]$ (Figure 116).

Reaction of $[Sm\{N(SiMe_3)_2\}_2(THF)_2]$ with one equiv. of 1,1-di(α-pyrrolyl)cyclohexane in THF affords dark red $[\{[1,1\text{-}(\alpha\text{-}C_4H_3N)_2C_6H_{10}]Sm\}_8(THF)_4]$. It reacts rapidly with N_2 to form the dinitrogen complex $\{[(CH_2)_5C(C_4H_3N)_2]\text{-}Sm\}_4(THF)_2(\mu\text{-}N_2)$.[134] $SmCl_3(THF)_3$ reacts with 0.5 equiv. of $(Et_8\text{-calix-pyrrole})[Li(THF)]_4$ yielding $(Et_8\text{-calix-pyrrole})\text{-}Sm_2\{(\mu\text{-}Cl)_2[Li(THF)_2]\}_2$, which, by reduction with $LiAlH_4$,

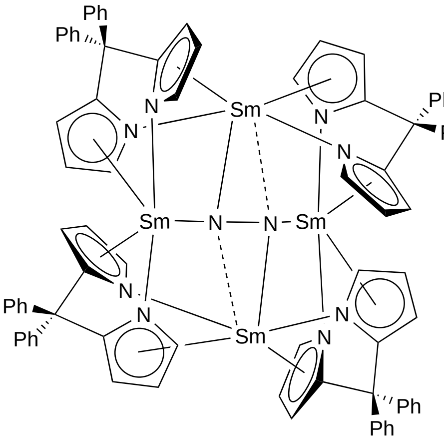

Figure 116 $[\{[\mu\text{-}Ph_2C(C_4H_3N)_2]Sm\}_4(N_2)]$

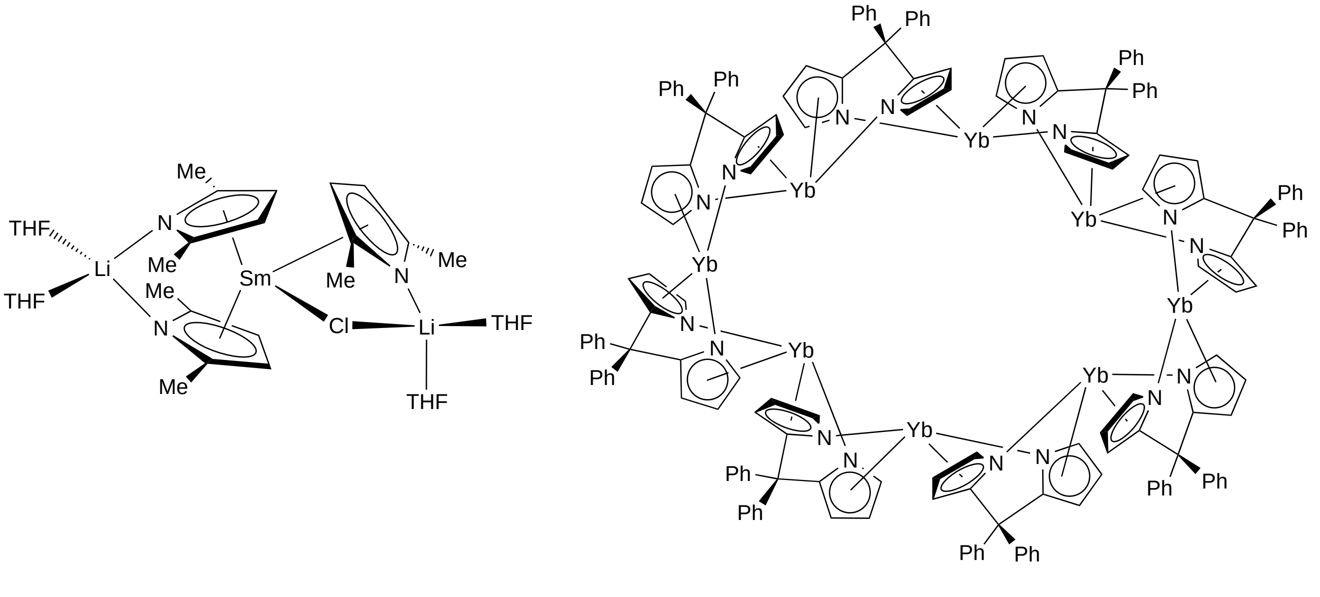

(a) (b)

Figure 115 (a) $(\mu\text{-}Me_2C_4H_2N)_3Sm(\mu\text{-}Cl)[Li(THF)_2]_2$, (b) $[Ph_2C(C_4H_3N)Yb]_8$

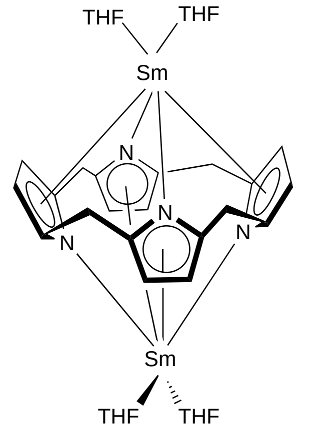

Figure 117 (Et_8-calix-pyrrole)$Sm_2(THF)_4$ (Et-groups are omitted for clarity)

produces either the mixed-valence (Et_8-calix-pyrrole)Sm_2-$(THF)_2(\mu\text{-}Cl)_2[Li(THF)_2]$ or the divalent (Et_8-calix-pyrrole)-$Sm_2(THF)_4$ (Figure 117), depending on the reaction conditions employed.[135]

Use of the sterically demanding hydrotris(3-^{t}Bu-5-Me-pyrazolyl)borate ligand (Tp^{t}Bu,Me) results in monomeric (Tp^{t}Bu,Me)YbI(THF) (Figure 118), which does not disproportionate to Yb(Tp^{t}Bu,Me)$_2$ and YbI_2. Reaction of $[(Tp^tBu,Me)YbH]_2$ with C_5H_6 and $Me_3SiC_5H_5$ gave the corresponding mixed-ligand complexes (Tp^{t}Bu,Me)Yb(C_5H_4R) (R = H, $SiMe_3$). The solid-state structure of the $SiMe_3$-derivative exhibits an unusual distortion; one of the pyrazolyl rings is rotated in a way to bring both pyrazolyl nitrogens in bonding contact with Yb.[136]

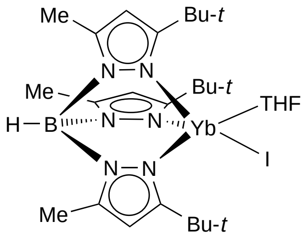

Figure 118 (Tp^{t}Bu,Me)YbI(THF)

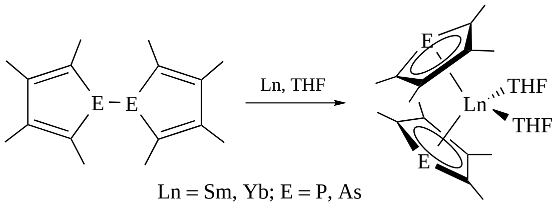
Bis(η^5-phospholyl) or bis(η^5-arsolyl) complexes of Sm or Yb have been prepared from the metal or by metathesis from the metal iodides (equation 26). The coordinated THF molecules can be removed by heating a toluene solution in vacuo, in the case of the 2,3,4,5-tetramethylphospholyl or arsolyl, but not with the 2,5-diphenylphospholyl complexes.



(26)

Related complexes $[Yb(\mu\text{-}Cl)(\eta^5\text{-}C_4Me_4P)(THF)_2]_2$ and $[Yb(\mu\text{-}SPh)(\eta^5\text{-}C_4Me_4P)(THF)_2]_2$ (Figure 119a) were prepared by direct cleavage of the P–Cl or P–S bonds of respective 1-chloro- and 1-phenylthio-2,3,4,5-tetramethylphosphole by ytterbium metal in THF at room temperature. Reaction of bis(η^5-tetramethylphospholyl)ytterbium(II) with $RuH_4(PPh_3)_3$ afforded heterometallic $(THF)_2Yb[\mu\text{-}\eta^5\text{:}\eta^1\text{-}C_4Me_4P]_2Ru(H)_2(PPh_3)_2$ (Figure 119b).

Carboranyl complexes of Ln(II) like $[Me_2Si(C_2B_{10}H_{11})(Cp)]Sm(THF)_2$ are prepared by reaction of SmI_2 with 2 equiv. of $[Me_2Si(C_2B_{10}H_{11})(Cp)]Na$ in THF. In contrast, the reaction with YbI_2 afforded $[Me_2Si(C_2B_{10}H_{11})(Cp)]_2Yb(THF)_2$ (Figure 120a). Treatment of LnI_2 with 1 equiv. of $K_2[(PhCH_2)_2C_2B_{10}H_{10}]$ in THF yields after recrystallization from DME monomeric *exo-nido*-$[(PhCH_2)_2C_2B_{10}H_{10}]Ln(DME)_3$ (Ln = Sm, Yb). Using two equiv. of $Na_2[(PhCH_2)_2C_2B_9H_9]$ results in dimeric complexes [*exo-nido*-$\{(PhCH_2)_2C_2B_9H_9\}Ln(THF)_3]_2$ (Ln = Sm, Yb) (Figure 120b).

Carboranyl/indenyl complexes of Yb(II) are formed by treatment of YbI_2 with $Na[Me_2Si(Ind)(C_2B_{10}H_{11})]$, resulting in $[\{Me_2Si(\eta^5\text{-}Ind)(C_2B_{10}H_{11})\}Yb(\mu\text{-}I)(THF)_2]_2$ (Figure 121a), which reacts with NaH yielding $[Me_2Si(\eta^5\text{-}Ind)(\sigma\text{-}C_2B_{10}H_{10})]Yb(THF)_3$. Treatment with $Na[Me_2Si(Ind)(C_2B_{10}H_{11})]$ in THF gave $[Me_2Si(\eta^5\text{-}Ind)(C_2B_{10}H_{11})]$-$Yb(THF)[Me_2Si(\mu\text{-}\eta^5\text{-}Ind)(\sigma\text{-}C_2B_{10}H_{10})]Na(THF)_3$ (Figure 121b), which is also formed from YbI_2 and two equiv.

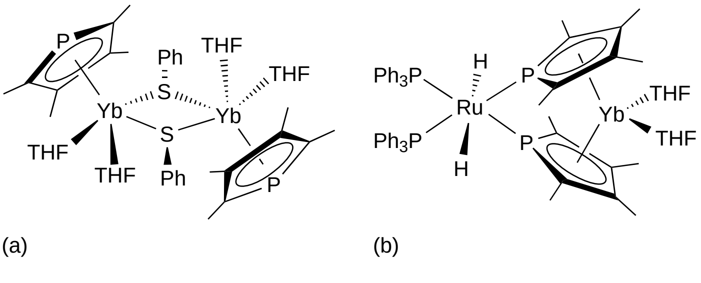


Figure 119 (a) $[Yb(\mu\text{-}SPh)(\eta^5\text{-}C_4Me_4P)(THF)_2]_2$, (b) $(THF)_2Yb[\mu\text{-}C_4Me_4P]_2Ru(H)_2(PPh_3)_2$

Figure 121 (a) $[\{Me_2Si(C_9H_6)(C_2B_{10}H_{11})\}Yb(\mu\text{-}I)(THF)_2]_2$, (b) $[Me_2Si(C_9H_6)(C_2B_{10}H_{11})]Yb(THF)[Me_2Si(C_9H_6)(C_2B_{10}H_{10})]Na(THF)_3$

of $Na[Me_2Si(Ind)(C_2B_{10}H_{11})]$ in THF and reaction with NaH via intermediate $[Me_2Si(\eta^5\text{-Ind})(C_2B_{10}H_{11})]_2Yb(THF)_2$.

Divalent $[1,3\text{-bis(trimethylsilyl)propenyl}]_2Sm(THF)_2$ (Figure 122) and $(1,3\text{-diphenylpropenyl})_2Sm(THF)_2$ were synthesized by the reaction of potassium 1,3-bis(trimethylsilyl)propenide or potassium 1,3-diphenylpropenide with SmI_2.

Organometallic compounds of lanthanide metals other than Sm, Eu, and Yb are very rare until now. But the development of this chemistry became possible after the synthesis of divalent precursors of Tm, Dy, and Nd in the late 1990s, namely of their diiodides (*see* ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***) and by using ligands such as phospholyl or arsolyl, which stabilize divalent lanthanide ions.

The first organothulium(II) compound $(\eta^5\text{-}1,3\text{-}(Me_3Si)_2\text{-}C_5H_3)_2Tm(THF)$ (Figure 123a) was synthesized from $K[C_5H_3(SiMe_3)_2\text{-}1,3]$ and $TmI_2(THF)_3$ in Et_2O or THF in Ar atmosphere. In contrast, DyI_2 and TmI_2 react with $K[C_5H_3(SiMe_3)_2\text{-}1,3]$ under N_2 with reduction of N_2, yielding Ln(III) complexes like $[\{\eta^5\text{-}1,3\text{-}(ME_3Si)_2C_5H_3\}_2Dy]_2(\mu\text{-}N_2)$.[137] $TmI_2(THF)_3$ reacts with K(L) (L = 2, 5-bis(trimethylsilyl)-3,4-dimethylphospholide or -arsolide; 2,5-di-*tert*-butyl-3,4-dimethylphospholide) forming the corresponding $[\eta^5\text{-}PC_4Me_2(SiMe_3)_2]_2Tm(THF)$, $[\eta^5\text{-}AsC_4Me_2(SiMe_3)_2]_2\text{-}Tm(THF)$ (Figure 123b), and $[\eta^5\text{-}PC_4Me_2({}^tBu)_2]_2\text{-}Tm(THF)$.[138]

The first example of a subvalent organolanthanum complex, $[K([18]crown\text{-}6)(\eta^2\text{-}C_6H_6)_2][La\{C_5H_3({}^tBu)_2\text{-}1,3\}_2]_2\text{-}(\mu\text{-}C_6H_6)$ was prepared by reduction of $La[C_5H_3{}^tBu_2]_3$ with K in the presence of 18-crown-6 in benzene. The anion

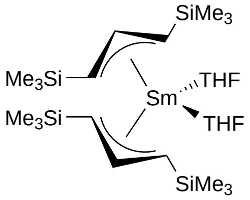

Figure 122 $[1,3\text{-}(Me_3Si)_2C_3H_3]_2Sm(THF)_2$

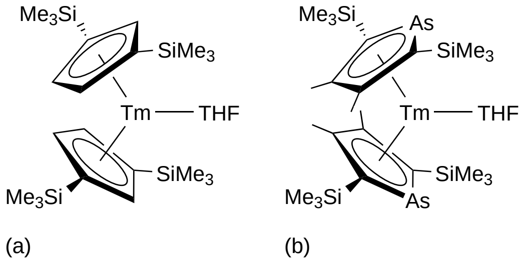

Figure 123 (a) $(1,3\text{-}(Me_3Si)_2C_5H_3)_2Tm(THF)$, (b) $[AsC_4Me_2(SiMe_3)_2]_2Tm(THF)$

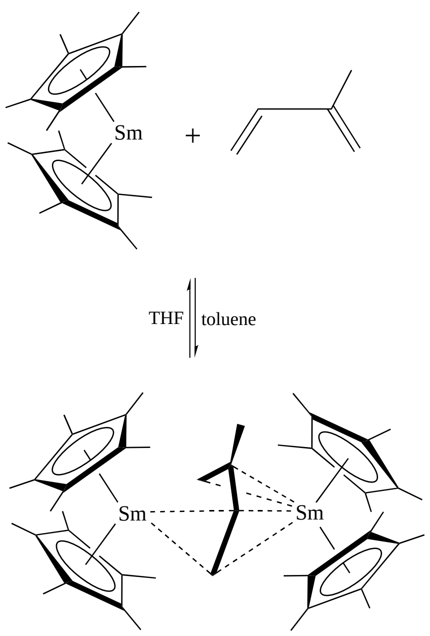
of this compound contains two $[C_5H_3{}^tBu_2]_2La(II)$ moieties bridged by an $\eta^6{:}\eta^6$-benzenide monoanionic ligand (Figure 124). An alternative formulation of the anion with two $[C_5H_3{}^tBu_2]_2La(III)$ moieties bridged by an $[\eta^6\text{-}C_6H_6]^{3-}$ seems less plausible.

11.3.3 Divalent Lanthanidocenes as Reducing Agents

Divalent organolanthanides, especially $Cp^*{}_2Sm(THF)_2$, are widely used as reducing agents.[114] Decamethylsamarocene reduces a number of organic and inorganic substrates by one-electron transfer to give Sm(III) species, for example, as shown in equation (27).[139]



(27)

Divalent ytterbium has a lower reduction potential. Therefore, Yb(II) complexes reduce only substrates with relatively high electron affinity. That could be demonstrated by the isolation of several adducts between heterocyclic nitrogen bases and $Cp^*{}_2Yb$. 1:1-Adducts of the type $Cp^*{}_2Yb(L)$ are formed with pyrazine, quinoxaline, 1,5- and 1,8-naphthyridine, 4,4′-bipyridine, phthalazine, and azobenzene. The adducts are paramagnetic, and their effective magnetic moments are consistent with the formulation $Cp^*{}_2Yb^{3+}$ $(L^{\cdot-})$ $(L^{\cdot-}$ = radical anion), in which spins on the individual units are uncoupled down to 5 K. $Cp^*{}_2Yb$ and pyridazine, phenazine, 2,2′-azopyridine, 2,2′-bipyrimidine, 2,2′-azobenzene, and 2,3-bis(2-pyridino)quinoxaline form $(Cp^*{}_2Yb)_2(\mu\text{-L})$ adducts. The crystal structure of $(Cp^*{}_2Yb)_2(\mu\text{-bipyrimidine})$ shows that two metallocenes are bridged by a planar bipyrimidine ligand. The effective magnetic moment of these 2:1 adducts shows that each $[Cp^*{}_2Yb(III)]$ fragment behaves as an isolated paramagnet; the bridging ligand is a diamagnetic dianion.[140] The 2,2′-bipyridyl and 1,3-diazadiene adducts $Cp^*{}_2Yb(bipy)$

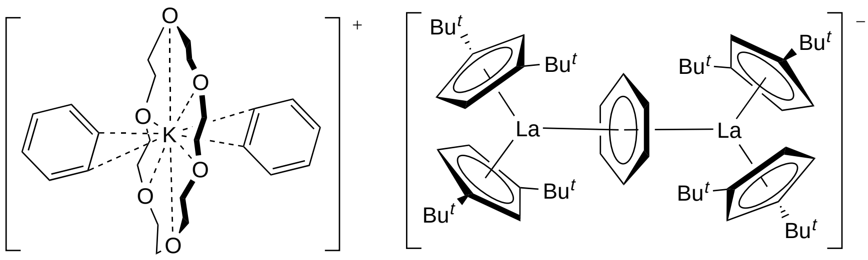


Figure 124 $[K([18]crown\text{-}6)(\eta^2\text{-}C_6H_6)_2][La\{C_5H_3(^tBu)_2\text{-}1,3\}_2]_2(\mu\text{-}C_6H_6)$

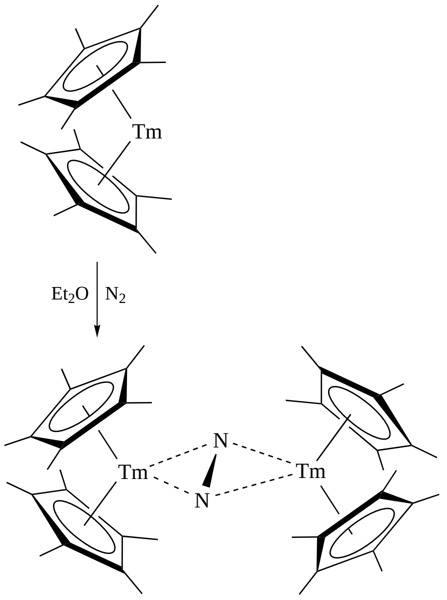
and $Cp_2Yb(DAD)$, respectively, are paramagnetic, containing radical anionic donor ligands.[141]

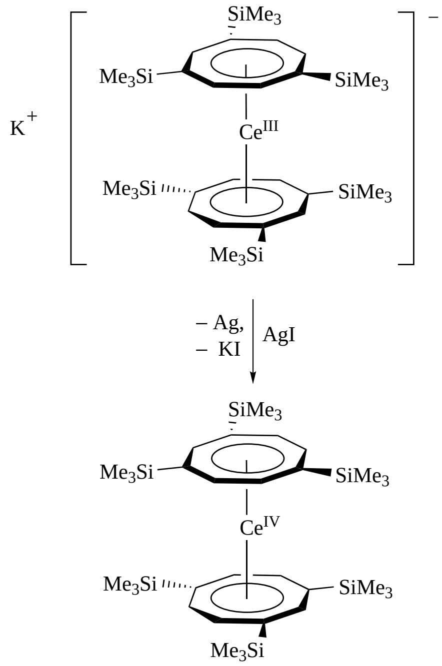
A new era in reductive chemistry of divalent lanthanides began with the synthesis of the first derivatives of divalent Nd, Dy, and Tm. The reaction of TmI_2 with Cp′K [Cp′ = Cp*, $C_5H_3(SiMe_3)_2$, $C_5H_4(SiMe_3)$] in Et_2O under nitrogen results in the formation of the dinitrogen reduction products $[(C_5Me_5)_2Tm]_2N_2$ (equation 28), $\{[C_5H_3(SiMe_3)_2]_2Tm\}_2N_2$, and $\{[C_5H_4(SiMe_3)]_2Tm(THF)\}_2N_2$ respectively.[142]



(28)

11.4 Tetravalent Organocerium Complexes

The most easily accessible tetravalent lanthanide is cerium. However, even Ce(IV) is a powerful oxidizing agent, and organic ligands are easily oxidized by it. Early reports of a Cp_4Ce and a number of other cyclopentadienylcerium(IV) complexes were claimed in the 1970s, but their existence could not be proved. Cerocene, $Ce(COT)_2$, and some related derivatives with substituted cyclooctatetraenyl ligands are available by reaction of $Ce(O^iPr)_4$ with an excess of COT and $AlEt_3$, or by oxidation of $K[Ce(C_8H_7Me)_2]$, $Li[Ce\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$, and $K[Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]$ with AgI (equation 29).



(29)

The X-ray structure analysis shows a soft bend sandwich complex for $Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2$ with an angle ring centroid-Ce-ring centroid of 176.1°. Ab initio calculations (*see Ab Initio Calculations*) on $Ce(COT)_2$, supported by X-ray absorption near-edge structure measurements (XANES), argue against a Ce(IV) complex, but, for a Ce(III) ion with $4f^1$ configuration, coordinated to two $(COT)^{1.5-}$ ligands.

The only one structurally characterized cyclopentadienyl derivative of Ce(IV), Cp_3CeO^tBu was prepared together with $Cp_2Ce(O^tBu)_2$ from $Ce(O^tBu)(NO_3)_3$ and NaCp according to equation (30).

$$Ce(OBu^t)(NO_3)_3(THF)_2 + 3CpNa \longrightarrow Cp_3Ce(OBu^t) + Cp_2Ce(OBu^t) + \text{other products} \quad (30)$$

1 INTRODUCTION

Selenium is the first member of the group 16 elements O, S, Se, Te, and Po that shows some metallic character. Among the several modifications of selenium, three nonmetallic ones contain Se_8 rings, whereas at least two others (gray metallic and amorphous black selenium) are semiconductors. Much of the current interest in the different allotropic modifications of selenium is connected with its extensive use in semiconductor applications, namely, in photocells, in xerography, and in rectifiers. Nanomaterials containing selenium are also becoming important targets. Selenium (and also tellurium) shares with sulfur the tendency to form homonuclear catenation in the element as well as in compound formation. The increasing metallic character in the series O, S, Se, Te, Po is reflected also in the lower electronegativity, in the less acid character of the oxides, and in the lower stability of the oxidation number +VI for selenium compared to sulfur.

Apart from the simple hydrogen chalcogenides of Se and Te (which are more acid and thermally less stable than the corresponding sulfur analogs) the most stable inorganic compounds of selenium (and its higher homologs) are: (1) the various chalcogenides and polychalcogenides with strongly positive counterions such as the alkali metals or the alkaline-earth metals, and those that are more covalently bonded to various transition metals; (2) a large variety of compounds of Se^{II}, Se^{IV}, and Se^{VI} with the electronegative elements O, F, Cl, and Br; (3) a number of homologous compounds belonging to the interesting class of sulfur–nitrogen compounds; and (4) a class of organoselenium compounds with other ligands such as Cl or Br as secondary ligands. All are somewhat less stable than the corresponding sulfur compounds. The tendency to form double bonds is smaller in selenium than sulfur, although the existence of strong Se=O bonds in oxo–halo selenium compounds such as $SeOCl_2$ or $[SeOCl_4]^{2-}$ indicate the ability to form significant (p–d)π bonding, quite in contrast to tellurium.

A well-known feature in the redox chemistry of selenium is its anomalous difficulty in attaining the highest oxidation number +VI. It shares this feature with its neighbors Ge, As, and Br, which immediately follow the 3d metals in the periodic table. The structural aspects and stereochemistry of selenium chemistry are quite diverse. In addition to normal two-valent geometries with bent coordination around the central Se (e.g. H_2 Se, $SeCl_2$, Se_2Cl_2), the following are known: three-coordinate pyramidal Se^{IV} compounds (e.g. H_2SeO_3, $SeCl_3^+$ in $SeCl_4$, polymeric SeO_2); four-coordinate 10-electron systems with ψ-trigonal bipyramidal coordination (e.g. SeF_4); five-coordinate 12-electron systems with ψ-octahedral coordination (e.g. $[SeOCl_4]^{2-}$); and hypervalent octahedral (distorted and undistorted, see below) coordination (e.g. $[SeCl_6]^{2-}$, $[SeBr_6]^{2-}$). The additional ability to form higher coordination with hypervalent bonding (described here as systems of three-center four-electron bonds, as in the hexahaloselenates) leads to many variations of intermolecular aggregation in the solid state, as exemplified by the cubane-like tetranuclear halides $[SeCl_4]_4$ and $[SeBr_4]_4$.

The present account will concentrate on the basic inorganic chemistry of inorganic selenium that will be useful to a reader or researcher exploring this subject for the first time. Thus, the review will describe the diverse range of cations oxo- and halo-compounds that selenium forms.

Other areas of selenium chemistry, such as selenium rings,[1,2] selenides,[3,4] organoselenium compounds,[5–7] and the focus of older, more comprehensive accounts of Se halide chemistry[8,9] will not be covered here. Additionally, the vast environmental chemistry of selenium, for example, its aqueous[10] and sediment[11] speciation,[12] plant uptake,[13,14] nutritional[15] and human health[16,17] aspects, and appearance in coal[18] and coal-derived ash,[19,20] are beyond the scope of this review. The previous reviews on Se-containing ligands,[21–24] biochemistry of selenium,[25] as well as other relevant aspects,[26,27] remain some of the most valuable sources for information on these subjects.

2 POLYATOMIC CATIONS

2.1 Homocyclic Selenium Cations

Several types of homocyclic structures of selenium atoms are known. Neutral selenium rings Se_n with $n = 5-10$ have been studied in the vapor phase by mass spectrometry. In solution, Se_n species with $n = 6-8$ have been observed by HPLC techniques. The crystal structure of Se_6 and three modifications of Se_8 have been determined by X-ray diffraction.[1,2]

It has been found that selenium may be oxidized by several different oxidizing agents to a variety of polyatomic cations. In 1827, Magnus observed that sulfuric acid dissolved selenium to give green or yellow solutions.[28] It has been shown that these solutions contain the polyatomic cations Se_4^{2+} and Se_8^{2+}.[29]

2.1.1 Se_4^{2+} Cation

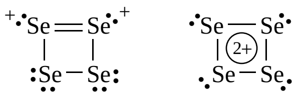
In highly acidic and oxidizing solutions like fluorosulfuric, sulfuric, and disulfuric acids with additional oxidants like selenium dioxide, peroxydisulfuryl difluoride or SbF_5, Se_4^{2+} salts can be prepared (see equations 1–3). The products have been characterized by cryoscopic, conductometric, and spectroscopic experiments.[29,30]

$$4Se + 6H_2S_2O_7 \longrightarrow Se_4^{2+} + SO_2 + 2HS_3O_{10}^- + 5H_2SO_4 \quad (1)$$

$$7Se + SeO_2 + 6H_2SO_4 \longrightarrow 2Se_4^{2+} + 6HSO_4^- + 2H_3O^+ \quad (2)$$

$$4Se + S_2O_6F_2 \longrightarrow Se_4^{2+} + 2SO_3F^- \quad (3)$$

The yellow to orange compounds $Se_4(HS_2O_7)_2$, $Se_4(S_4O_{13})_2$, and $Se_4(Sb_2F_{11})_2$ have been prepared.[31] Crystallographic studies on $Se_4(HS_2O_7)_2$ have shown that the cation Se_4^{2+} has square-planar (D_{4h}) geometry.[32] The structure can be described by valence bond theory[33] in terms of four resonance structures equivalent to (**1a**), or by simple molecular orbital theory in which three of the four π molecular orbitals are filled.[34] The Se_4^{2+} ions are examples of six-π-electron systems, and they are thus examples of inorganic aromatic compounds (**1b**).

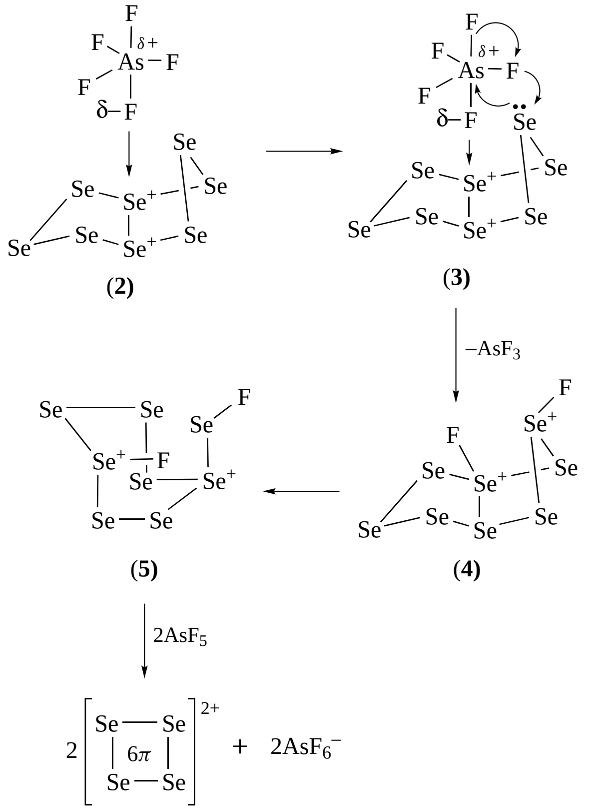


(**1a**) (**1b**)

Their π-bond order is 0.25; accordingly, the overall Se–Se bond length of 2.283 Å in $Se_4(HS_2O_7)_2$[32] is significantly shorter than the Se–Se distance of 2.34 Å in the Se_8 molecule. The intense yellow–orange color of the Se_4^{2+} ion (λ_{max} 410 nm, ε8000) is to be expected from the dipole-allowed excitation of an electron from the highest filled π-orbital which is of symmetry e_g and almost nonbonding, to the lowest empty π-orbital (b_{2u}). The square-planar arrangement is also consistent with magnetic circular dichroism of the Se_4^{2+} ion in solution.[35]

In crystals of $Se_4(Sb_2F_4)(Sb_2F_5)(SbF_6)_5$, prepared from Se and SbF_5 in liquid SO_2, and in $Se_4(AlCl_4)_2$,[36,37] the Se_4^{2+} ion has crystallographic inversion symmetry with average Se–Se distances of 2.260 and 2.286 Å.

Selenium can also be oxidized by arsenic pentafluoride to $Se_4(AsF_6)_2$ (equation 4) and by antimony pentafluoride to $Se_4(Sb_2F_{11})_2$ (equation 5) by heating the reactants in SO_2 for several days[31,38] With a trace of halogen (Cl_2, Br_2, I_2) or $AsCl_4AsF_6$, the reaction proceeds quantitatively in minutes.



Scheme 1

They also propose[1] a reaction pathway for the oxidation of Se_8^{2+} to Se_4^{2+} by AsF_5 (Scheme 1).[39]

$$Se_8 + 6AsF_6 \xrightarrow{SO_2,\ 6\,d} 2Se_4(AsF_6)_2 + 2AsF_3 \quad (4)$$

$$Se_8 + 10SbF_5 \xrightarrow{SO_2,\ 12\,h} 2Se_4(Sb_2F_{11})_2 + 2SbF_3 \quad (5)$$

The Se_8^{2+} species may initially form a donor–acceptor adduct with AsF_5 (**2**) by the donation of an electron pair from the axial fluorine in AsF_5 to one of the positively charged three-coordinate selenium atoms. Another selenium atom of the ring donates an electron pair to the slightly positively charged arsenic atom, followed by rearrangement resulting in the formation of $Se_8F_2^{2+}$ (**3** → **4**). This species may rearrange to form (**5**). Finally, two AsF_5 molecules abstract two F^- to form two molecules of Se_4^{2+}(**5** → **6**).

Selenium reacts with an excess of SbF_5 in SO_2 at 363 K to form $(Se_4)_2(Sb_4F_{17})(SbF_6)_3$.[40] Two crystallographically independent Se_4^{2+} units with slight differences of Se–Se bond distances and angles (cation I, Se–Se 2.273, 2.276 Å, angles 90.5°, 89.5°; cation II, Se–Se 2.265, 2.276 Å, angles 90.7°, 89.3°) are found.[36]

None of these cations are stable in aqueous media or in any solvent containing small amounts of water, as they undergo disproportionation (equation 6).

They exist only in solvents with very low basicities, such as $H_2S_2O_7$, HSO_3F, SO_2, and AsF_5, and in the presence of anions such as SO_3F^-, $HS_2O_7^-$, SbF_6^-, $Sb_2F_{11}^-$, AsF_6^-, and $AlCl_4^-$, all of which are very weak bases of very strong corresponding acids.

$$2Se_4^{2+} + 6H_2O \longrightarrow 7Se + SeO_2 + H_3O^+ \qquad (6)$$

2.1.2 *Se_8^{2+} Cation*

Conductivity measurements on solutions of selenium in highly acidic and oxidizing solutions indicate the formation of Se_8^{2+}.[10,12] Solutions of Se_8^{2+} in 100% H_2SO_4 are prepared by heating selenium in the acid at 50–60 °C (equation 7). Green solutions of Se_8^{2+} are also obtained by dissolving selenium in disulfuric acid (equation 8). The solutions are not stable, and further oxidation yields yellow solutions containing Se_4^{2+}. Salts of Se_8^{2+} are also obtained using SbF_5 or AsF_5 as oxidizing agents in an inert solvent such as SO_2 or HF (equation 9).[41,42]

$$8Se + 5H_2SO_4 \longrightarrow Se_8^{2+} + 2H_3O^+ + 4HSO_4^- + SO_2 \qquad (7)$$

$$8Se + 6H_2S_2O_7 \longrightarrow Se_8^{2+} + 2H_2S_3O_{10}^- + 5H_2SO_4 + SO_2 \qquad (8)$$

$$8Se + 3AsF_5 \xrightarrow[-23\,°C]{SO_2(1)} Se_8(AsF_6)_2 + AsF_3 \qquad (9)$$

$$8Se + 5SbF_5 \xrightarrow[0\,°C]{HF} Se_8(Sb_2F_{11})_2 + SbF_3 \qquad (10)$$

Both deep-green compounds undergo instant disproportionations in the presence of moist air (equation 6). Dissolution of $Se_8(AsF_6)_2$ or $Se_8(Sb_2F_{11})_2$ in 100% sulfuric acid, oleum, or fluorosulfuric acid, however, yields stable green solutions with typical absorption maxima at 295, 470, and 685 nm for the Se_8^{2+} cations.[29]

From phase diagram studies on the pseudobinary Se–($SeCl_4$ + $4AlCl_3$) system, the compounds $Se_4(AlCl_4)_2$ and $Se_8(AlCl_4)_2$ have been identified.[43,44] $Se_8(AlCl_4)_2$ alone was prepared from a stoichiometric mixture of Se, $SeCl_4$, and $AlCl_3$

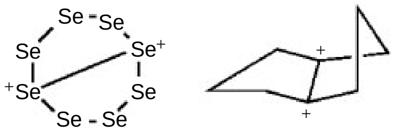


Figure 1 Structure of the bicyclic cation Se_8^{2+}

after fusion at 250 °C for 3 h to produce black prismatic crystals (equation 11). $Se_8(AlCl_4)_2$ can also be prepared by the reaction of Se_2Cl_2 with $AlCl_3$ in SO_2 (equation 12)[45] The structure of $Se_8(AlCl_4)_2$ shows an endo–exo conformation of the eight-membered ring with approximate C_s symmetry (Figure 1).

$$15Se + SeCl_4 + 4AlCl_3 \longrightarrow 2Se_8(AlCl_4)_2 \qquad (11)$$

$$5Se_2Cl_2 + 4AlCl_3 \xrightarrow{SO_2(1)} Se_8(AlCl_4)_2 + 2SeCl_3(AlCl_4) \qquad (12)$$

The bond lengths around the ring vary between 2.29 and 2.36 Å and do not differ significantly from those found in α and β selenium. The most striking difference between the Se_8^{2+} ion and the cyclic Se_8 molecules is the transannular bond, whose length of 2.84 Å is significantly shorter than the van der Waals contact separation of 4.0 Å.

The bond compensates for the removal of two electrons from Se_8 and is accompanied by the folding up of one end of the eight-membered ring. By removing two more electrons, the unknown Se_8^{4+} cation would result (decomposes to Se_4^{2+}). Interestingly, the structure of the isoelectronic Se_4N_4 molecule shows exactly the structure predicted for the hypothetical Se_8^{4+}, with the other end of the ring folding up and with a second transannular Se···Se bond. Thus, Se_8^{2+} appears to be the midpoint between the cage molecule of Se_4N_4 and the crown-shaped ring of Se_8 (Figure 2).[46]

2.1.3 *Se_{10}^{2+} Cation*

The hexafluoroarsenate and hexafluoroantimonate salts $Se_{10}(AsF_6)_2$ and $Se_{10}(SbF_6)_2$, containing the polyatomic

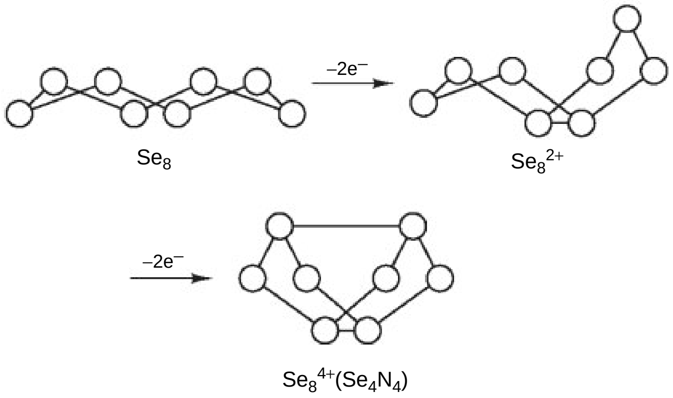

Figure 2 Gradual oxidation of Se_8 to ‘Se_8^{4+}’

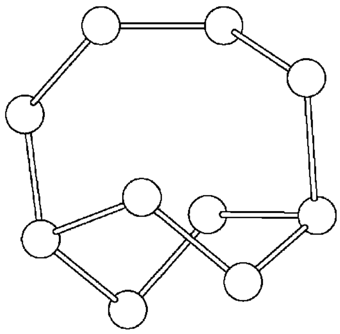

Figure 3 View of the Se_{10}^{2+} cation in $Se_{10}(SbF_6)_2$

cation Se_{10}^{2+}, were prepared by the reaction of excess selenium with AsF_5 or SbF_5 in SO_2 (equation 13) or the reaction of $Se_8(AsF_6)_2$ with elemental selenium in SO_2 (equation 14). $Se_{10}(SbF_6)_2$ can also be prepared similarly by disproportionation of $Se_8(AlCl_4)_2$ on washing with large quantities of SO_2 (equation 15).

$$10Se + MF_5 \longrightarrow Se_{10}(MF_6)_2 + 2MF_3 \qquad (13)$$

$$M = As, Sb$$

$$2Se + Se_8(AsF_6)_2 \longrightarrow Se_{10}(AsF_6)_2 \qquad (14)$$

$$4Se_8(AlCl_4)_2 \longrightarrow 3Se_{10}(AlCl_4)_2 + Se_2Cl_2 + 2AlCl_3 \qquad (15)$$

The structure of $Se_{10}(SbF_6)_2$ shows the cation to be of the bicyclo[4.2.2]decane type with approximate C_2 symmetry (Figure 3).[45] It consists of a six-membered, boat-shaped ring bridged by a chain of four selenium atoms to form an eight-membered ring. The six bonds to the three-coordinate atoms are the longest (2.41–2.44 Å). The adjacent bonds (2.24–2.26 Å) and the unique central bond in the bridging chain (2.35 Å) are shorter. The four short bonds are comparable to those in Se_4^{2+} salts, for example, in $Se_4(HS_2O_7)$ (2.28 Å) which have bond orders of 1.25 according to simple valence bond considerations. Spectrophotometric and potentiometric studies of cationic species of selenium in NaCl–$AlCl_3$ melts have been interpreted as indicating the presence of Se_{12}^{2+} and Se_{16}^{2+},[1,47] but the structures of these cations are unknown.

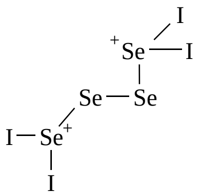
2.2 Derivatives of Selenium Rings

2.2.1 *$Se_4I_4^{2+}$ Cation*

The $Se_4I_4^{2+}$ cation is formed by the reaction of $Se_4(AsF_6)_2$ and I_2 in a 1:2 ratio.

Such solutions were studied by ^{77}Se NMR.[41] The coupling patterns are consistent with a four-membered ring or chain species. Ab initio energy calculations indicate a chain structure (**7**).

$$Se_4(AsF_6)_2 + 2I_2 \xrightarrow{SO_2} Se_4I_4(AsF_6)_2 \qquad (16)$$



(**7**)

2.2.2 *$Se_6I_2^{2+}$ and $(Se_6I^+)_n$ Cations*

The salts $Se_6I_2(AsF_6)_2{\cdot}2SO_2$[48,49] and $(Se_6I)_n{\cdot}nAsF_6$,[49,50] containing stable selenium–iodine cations, have been prepared and characterized by X-ray crystallography. Both $Se_6I_2^{2+}$ and $(Se_6I^+)_n$ are derivatives of the chair form of Se_6, which exists as a metastable allotropic form of selenium.[1] $(Se_6I)_n{\cdot}nAsF_6$ is obtained quantitatively by reacting stoichiometric amounts of Se, I_2, and AsF_5 in SO_2 (equation 17). $Se_6I_2(AsF_6)_2{\cdot}2SO_2$ was prepared from SO_2 solutions (equation 18).

$$12Se + I_2 + 3AsF_5 \xrightarrow[11\,d]{SO_2,\ rt} 2/n(Se_6I)_n{\cdot}nAsF_6 + AsF_3 \qquad (17)$$

$$6Se + I_2 + 3AsF_5 \longrightarrow Se_6I_2(AsF_6)_2{\cdot}2SO_2 + AsF_3 \qquad (18)$$

$$2Se_8(AsF_6)_2 + 2SeI_3AsF_6 \longrightarrow 3Se_6I_2(AsF_6)_2{\cdot}2SO_2 \qquad (19)$$

The centrosymmetric $Se_6I_2^{2+}$ cation (Figure 4) contains hexaselenium rings with a chair conformation similar to Se_6.[48] The Se_6 ring is substituted in the 1,4-positions by two iodine atoms in an endo conformation. The tricoordinate selenium atoms in the $Se_6I_2^{2+}$ cation are positively charged. A Se–Se bond alternation between tri- and dicoordinate selenium atoms is observed, similar to other related rings and to the hexaselenium ring of Se_{10}^{2+}. The Se–I bonds (2.468 Å) are shorter than in SeI_3^+ (2.510 Å), implying $4p_\pi$–$4p_\pi$ and $4p_\pi$–$5p_\pi$ bonding. There are four intracationic I–Se contacts (average 3.714 Å; van der Waals radii 4.15 Å), leading to a distorted cube-like shape of the cation. This interaction must be attractive, otherwise the less sterically hindered *exo* conformation would be preferred.

The $(Se_6I^+)_n$ cation in $(Se_6I)_n{\cdot}nAsF_6$ has a two-dimensional polymeric structure. The geometry of the Se_6I_2

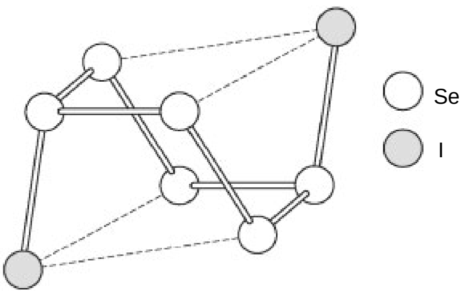


Figure 4 Structure of $Se_6I_2^{2+}$

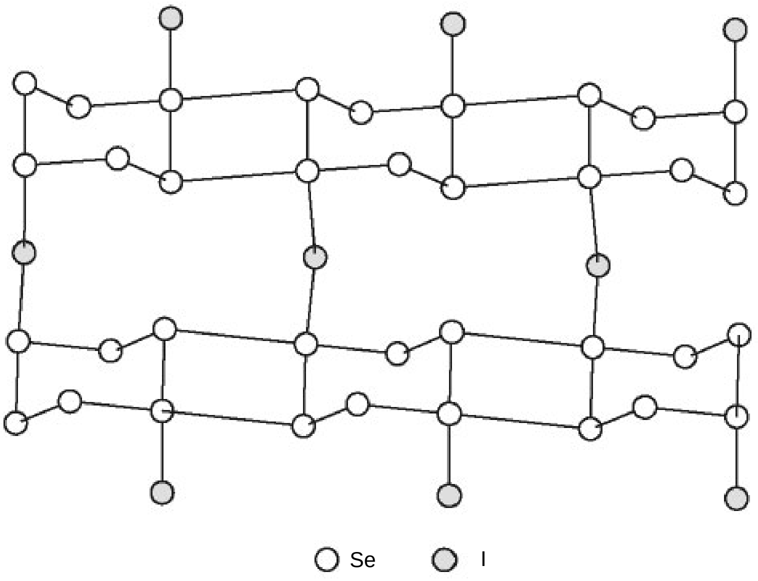

Figure 5 The polymeric $(Se_6I^+)_n$ cation

unit is similar to that in $Se_6I_2{}^{2+}$ (see above), with the iodine atoms bridging the Se_6 rings (Figure 5).[49] The bond alternation within the Se_6 ring is less pronounced than that in $Se_6I_2{}^{2+}$, consistent with the lower charge per ring.

2.2.3 *$Ph_2Se_6{}^{2+}$ Cation*

$Se_4(AsF_6)_2$ reacts with Ph_2Se_2 in liquid SO_2 at room temperature to give bright orange crystals of $Ph_2Se_6(AsF_6)_2\cdot SO_2$.[42] This compound contains a six-membered selenium ring in a boat conformation with two phenyl groups in the 1,4-positions (Figure 6). The six-membered selenium rings Se_6, Se_6I^+, and $Se_6I_2{}^{2+}$ (see above) are all in the chair form. A reaction pathway was proposed (Scheme 2) with an initial trigonal prismatic intermediate or transition state, which rearranges to form the final boat conformation.[42]

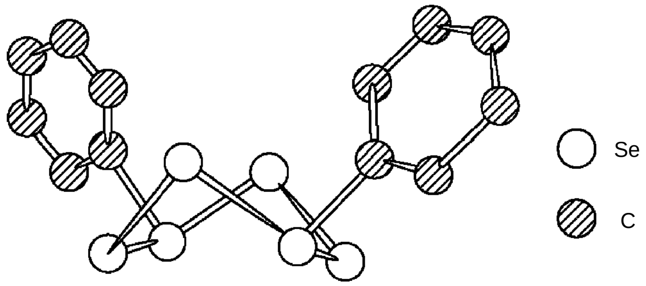

Figure 6 $Ph_2Se_6{}^{2+}$ cation in $Ph_2Se_6(AsF_6)_2\cdot SO_2$

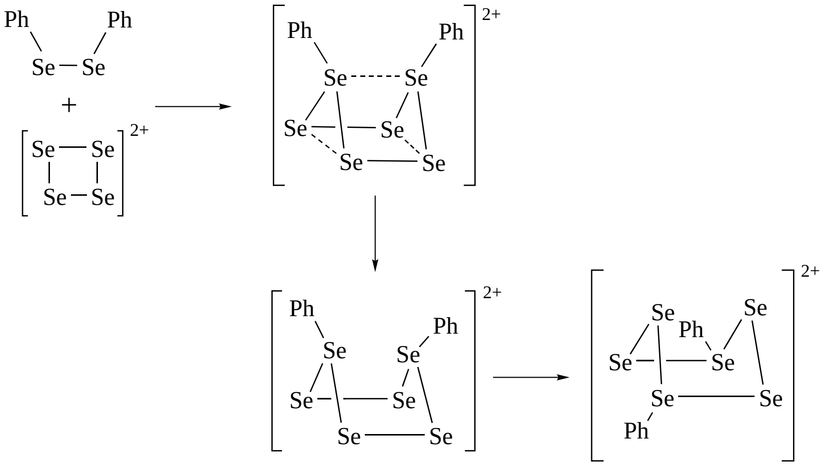

Scheme 2

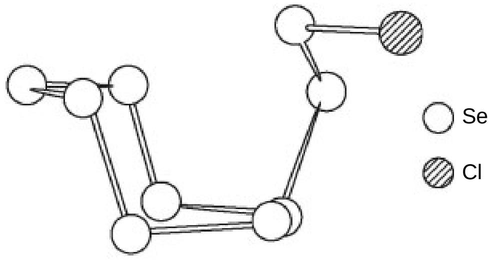

Figure 7 Se_9Cl^+ cation in $Se_9Cl(SbCl_6)$

2.2.4 Se_9Cl^+ Cation

The compound $Se_9Cl(SbCl_6)$ is prepared by the reaction of selenium with $NOSbCl_6$ in SO_2.[51] It is the first example of a seven-membered selenium ring (Figure 7). A Se_2Cl chain is joined to the ring which is in the chair conformation and in which the alternating Se–Se bond lengths around the ring vary from 2.270 to 2.430 Å.[52]

2.3 Acyclic Cationic Systems

$Se_2Br_5{}^+$, as the first reported example of a novel dinuclear cationic halogen–chalcogen species, was prepared as the deep-purple crystalline hexafluoroarsenate.[52] The cation consists of two trigonal pyramidal $SeBr_3$ units connected via a linear Se–Br–Se bridge. The formally positive Br^+ links two $SeBr_2$ molecules with formal oxidation number +2 for Se.

Reaction of selenium, bromine, and arsenic pentafluoride in liquid SO_2 leads to crystalline $(Se_3Br_3)(AsF_6)$. The crystal structure consists of discrete $Br_2Se^+SeSeBr$ and $AsF_6{}^-$ ions. The Se–Se bond lengths are 2.554 Å and 2.211 Å. The selenium–selenium bond alternation of 0.34 Å implies the presence of substantial partial $4p_\pi$–$4p_\pi$ bonding between the Se atoms in the Se–Se–Br unit.[53]

$Se_2I_4{}^{2+}$ has been reported recently as the first example of a novel type of diselenium tetraiodine(2+) cation.[54] It was synthesized by reaction of selenium with $[I_2][Sb_2F_{11}]$ in liquid SO_2. The cation consists of two $SeI_2{}^+$ units connected by a very weak Se–Se bond (2.841 Å) and has an eclipsed structure. The Se–Se bond length is comparable to the transannular bond in $Se_8{}^{2+}$.

2.4 Heterocyclic Selenium Cations

2.4.1 S_3Se^{2+} Cation

The heterochalcogen cations $S_xSe_{4-x}{}^{2+}$ ($x = 0$–3) have been characterized in SO_2 solution by ^{77}Se NMR studies. X-ray structural analysis of $(S_{3.0}Se_{1.0})_2(Sb_4F_{17})(SbF_6)_3$[55] have shown that the compound consists of two crystallographically independent $S_{3.0}Se_{1.0}{}^{2+}$ cations (for mixed Se/Te heterocyclic cations *see* ***Tellurium: Inorganic Chemistry***).

3 HALIDES AND RELATED COMPOUNDS

3.1 Monohalides

3.1.1 SeF, SeCl, and SeBr Radicals

Until recently, no selenium monohalide could be isolated; only the short-lived radicals SeF, SeCl, and SeBr were identified in the gas phase. SeF, can be produced by reaction of fluorine atoms (by passing CF_4 through a microwave discharge) with carbonyl selenide in a flow system. It has been detected by ESR spectroscopy[56,57] and the Se–F bond length (1.742 Å) is close to the value reported for SeF_2 (1.69 Å), deduced from infrared spectra.[9,58]

SeCl is formed by flash photolysis of $SeCl_2$ in the presence of N_2 or Ar. Addition of oxygen results in the formation of SeO.[59] Formation of SeCl is assumed when liquid selenium is in equilibrium with gaseous $SeCl_2$ at 280 °C (equation 20).[60] Gaseous SeBr was observed by its UV spectrum during the flash photolysis of Se_2Br_2 vapor at 50–55 °C in a mixture with nitrogen (75 mbar).[61] Both $SeCl_2$ and $SeBr_2$ are available as solutions in thf.[62]

$$Se(1) + SeCl_2(g) \longrightarrow 2SeCl \qquad (20)$$

3.1.2 Se_2F_2, Se_2Cl_2, Se_2Br_2, and Se_2I_2

A mixture of lower selenium fluorides is obtained by the reaction between heated selenium (210 °C) and fluorine, highly diluted with argon. FSeSeF and the other species are detected by IR spectroscopy. UV irradiation of matrix-isolated FSeSeF yields thermodynamically less stable $Se{=}SeF_2$.[63]

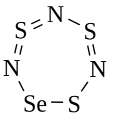
Selenium reacts with a stoichiometric amount of $SeCl_4$ to form reddish-brown liquid Se_2Cl_2. Se_2Br_2 can easily be prepared from the elements. Both have been characterized by X-ray structure analyses.[64] There are two different structure types (Se_2Cl_2, β-Se_2Br_2, and α-Se_2Br_2) containing X–Se–Se–X molecules with approximate C_2 symmetry and with dihedral angles of 87.4° (Se_2Cl_2) and 86.4° (Se_2Br_2). The average Se–X bond lengths are 2.202 Å (Se–Cl) and 2.364 Å (Se–Br). Different degrees of association of the molecules through Se···Se and Se···X contacts connect the molecules to layers and three-dimensional nets.

Orthorhombic α-Se_2Br_2 is thermodynamically stable compared to the monoclinic β-Se_2Br_2 modification. Monotropic exothermic transformation of the metastable into the stable form occurs in the range −40 to −5 °C.

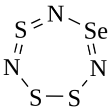
In the gas phase, Se_2Cl_2 and Se_2Br_2 are not detectable because of dissociation into selenium and gaseous SeX_2. Se_2Cl_2 is able to form ionic complexes with strong Lewis acids.[65] Reaction of Se_2Cl_2 with BCl_3 and $SbCl_5$ in liquid sulfur dioxide at −40 °C forms $Se_2Cl_2{\cdot}BCl_3$ and $Se_2Cl_2{\cdot}SbCl_5$. Their IR spectra suggest ionic structures $[Se_2Cl]^+[BCl_4]^-$

and $[Se_2Cl]^+[SbCl_6]^-$. At room temperature, both compounds disproportionate to yield selenium and $SeCl_4{\cdot}BCl_3$ or $SeCl_4{\cdot}SbCl_5$.

An interesting reaction occurs between Se_2Cl_2 and S_4N_4 in the presence of thionyl chloride:[66] Thiatrithiazyl chloride, S_4N_3Cl, is formed, together with a compound of empirical formula $SeS_2N_2Cl_2$. From IR spectroscopy a structure corresponding to that of selenotrithiazyl haxachloroselenate(IV), $(SeS_3N_3)_2SeCl_6$, has been suggested. The cation in this salt may have the configurations (**8**) or (**9**).



(**8**)



(**9**)

Simple binary selenium iodides are generally regarded as being nonexistent,[61] although several stable species with Se–I bonds have been reported: SeO_2I^-,[67] SeOClI,[68] areneselenium iodides,[69] SeI_6^{2-},[70] SeI_3^+,[71] $(C_2F_5)SeI_2^+$,[71] $Se_2I_4^{2+}$,[54] $Se_4I_4^{2+}$,[41] $Se_6I_2^{2+}$,[48,49] and $(Se_6I)_n^{n+}$.[50,51] ^{77}Se NMR studies of solutions of selenium with iodine in carbon disulfide have been recently reviewed. These spectra indicate the presence of the selenium iodides Se_3I_2, Se_2I_2, and SeI_2 in such solutions, with Se_2I_2 as the main product.

3.2 Dihalides

Among the selenium dihalides, SeF_2, $SeCl_2$, and $SeBr_2$ are known to exist in the gas phase, while $SeCl_2$[62] and $SeBr_2$ are also known in solution. SeF_2 is obtained together with FSeSeF and SeF_4 by the reaction of heated selenium vapor with elemental fluorine diluted with argon (see above).[63] SeF_2 was also synthesized in good yield by UV photolysis of CF_3SeF_3 and isolated in an argon matrix:[72]

$$CF_3SeF_3 \xrightarrow{\lambda = 208\,\text{nm}} CF_4 + SeF_2 \quad (21)$$

IR spectra suggest the structure of the SeF_2 molecule to be nonlinear.[63] Photolysis of $SeCl_2$ as well as of $SeBr_2$ in an electrical discharge yields SeX· radicals.[59] In the case of the diselenium dihalides, only Se_2Br_2 gives detectable amounts of SeBr· species.[73]

Vapor pressure experiments and vibrational spectroscopic studies[74–77] show that $SeCl_2$ and $SeBr_2$ exist as dissociation products of the corresponding tetrahalides in the vapor phase or in organic solvents,[78] or as mixtures of SeO_2 and Se in aqueous HCl.[79] Their nonlinear structures were determined by photoelectron spectra and by electron diffraction.[80–82]

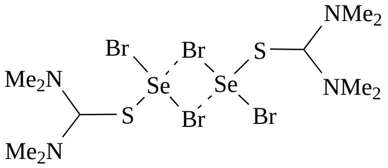
A remarkable stabilization of selenium dihalides is achieved if the central Se^{II} atom is coordinated with anionic (see Section 4.2) or neutral Lewis bases as ligands. $SeBr_2$ as well as $SeCl_2$ can be stabilized as crystalline tetramethylthiourea (tmtu) adducts, SeX_2(tmtu) (X = Cl, Br) (equations 22–23).[62,83]

$$RSeX_3 + \text{tmtu} \longrightarrow RX + SeX_2(\text{tmtu}) \quad (22)$$

$$R = Me, Et$$

$$SeX_4 + 3\text{tmtu} \longrightarrow (\text{tmtu})_2X_2 + SeX_2(\text{tmtu}) \quad (23)$$

$SeBr_2$(tmtu)[83] has a T-shaped heavy-atom $SSeBr_2$ framework (**10**), as previously suggested by IR spectroscopic studies.[84] The $SeBr_2$(tmtu) molecule can be described as a dimer with Se···Br contacts (3.34 Å) trans to sulfur that are shorter than the sum of the van der Waals radii (3.95 Å).[83] The arrangement around Se is distorted square planar.



(**10**)

When triarylphosphane ligands are introduced as two-electron donors by the reaction of triarylphosphane selenide with Br_2, the product is T-shaped Ar_3PSeBr_2 with the Br ligands in the trans position.[85]

3.3 Tetrahalides

3.3.1 *Selenium Tetrafluoride*

Selenium tetrafluoride can be prepared in various reactions involving a fluorinating agent (AgF, ClF, ClF_3, CoF_3, SF_4, F_2, BrF_3) acting upon elemental selenium, SeO_2, $SeCl_2$, or $SeCl_4$. Another convenient method of preparation[86] uses SeF_4 itself as the reaction medium during the fluorination (equation 24).

$$3Se + 4ClF_3 \longrightarrow 3SeF_4 + 2Cl_2 \quad (24)$$

SeF_4 is a useful fluorinating agent, especially in organic chemistry, as it has some advantages over SF_4. It permits milder conditions and, because of its convenient liquid temperature range, it can be employed at atmospheric pressure.[86] Dissolved SeF_4 molecules have a ψ-trigonal bipyramidal structure like SF_4. If the enhanced concentration is increased, gradual intermolecular association of the molecules is observed.[87]

An X-ray structure determination of SeF_4[88] essentially confirmed the results of detailed vibrational spectroscopic investigations.[89–91] There is significant intermolecular association of the ψ-trigonal bipyramidal SeF_4 molecules in the solid state; however, it is much weaker than in TeF_4 where

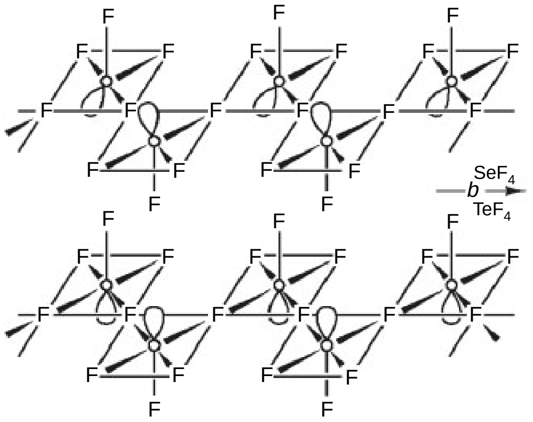


Figure 8 Polymeric structure of TeF_4 and the arrangement of monomeric SeF_4 subunits

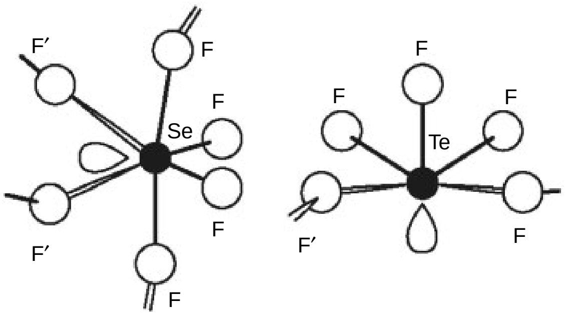

Figure 9 Coordination of selenium in crystalline SeF_4 as compared to the Te coordination in crystals of polymeric TeF_4

polymeric chains with square-pyramidal coordination of Te are formed (Figures 8 and 9).[92]

^{19}F NMR investigations have detected rapid intermolecular fluorine exchange in liquid SeF_4.[93] From conductometric measurements, SeF_4 in liquid hydrogen fluoride solution has been shown to be a weak base (equation 25).[94]

$$SeF_4 + HF \longrightarrow SeF_3^+ + HF_2^- \quad (25)$$

The estimated value of the ionization constant ($K_b = 4 \times 10^{-4}$) indicates that SeF_4 is a weaker base in HF than SF_4 ($K_b = 4 \times 10^{-2}$).[95] The adducts of selenium tetrafluoride with Lewis acids are considered to be ionic compounds containing the SeF_3^+ cation. The systems of SeF_4 with BF_3, SbF_5, AsF_5, NbF_5, and TaF_5 have been studied.[94,96,97] Crystal structure determinations of $SeF_4{\cdot}NbF_5$ and $SeF_4{\cdot}2NbF_5$ show that they are composed of the SeF_3^+ and NbF_6^- or $Nb_2F_{11}^-$ ions, respectively, although there is considerable interaction between the ions through fluorine bridging.[98,99] In the case of $SeF_3{\cdot}NbF_6$, four formula units are linked to give Se and Nb atoms at alternate corners of a distorted cube, while for $SeF_3{\cdot}Nb_2F_{11}$ the ions interact to form endless chains.

Conductometry and ^{19}F NMR spectroscopy have been used to study the systems of SeF_4 with BF_3 in HF.[94] Fluorine-bridged structures such as in $SeF_4{\cdot}NbF_5$ and $SeF_4{\cdot}2NbF_5$ with polymeric molecules and ions are present. The simplest equilibrium of this type involves the dimer $(SeF_4{\cdot}BF_3)_2$, which may be either linear or cyclic.[94]

$$(SeF_4{\cdot}BF_3)_2 \rightleftharpoons (SeF_3)_2BF_4^+ + BF_4^- \quad (26)$$

IR, Raman, and NMR studies of an adduct of SeF_4 with SO_2 in the solid and molten states are best interpreted as indicating a polymeric fluorosulfate-bridged structure.[100]

Adducts formed between SeF_4 and alkali metal fluorides[101] have been characterized by vibrational spectroscopy.[102] The observed Raman and IR spectra of $CsSeF_5$ indicate an ionic structure involving a square-pyramidal anion of C_{4v} symmetry.

3.3.2 Selenium Tetrachloride and Selenium Tetrabromide

Two characteristic structural and bonding features of the chlorine and bromine compounds of selenium(IV), in which the role of the inert pair determines much of stereochemistry and reactive properties of the entire class of compounds, are already evident in the simple binary halides.

1. Selenium(IV) as well as sulfur(IV) and tellurium(IV) tend to form a more or less distorted quasioctahedral (hypervalent) $XY_{3+3}E$ or $XY_{4+2}E$ coordination of six nearest neighbors in which there is a tendency to form stable trigonal pyramidal XY_3^+ subunits (X = Se, Y = Cl, Br, I; E is a more or less stereochemically active electron pair).
2. The harder (in Pearson's model[103]) or the more electronegative the ligand, the more pronounced the stereochemical activity of the inert electron pair localized at the chalcogen atom.

Selenium Tetrachloride. Selenium tetrachloride is usually prepared from the elements and decomposes thermally (equation 27).[104,105]

$$SeCl_4 \longrightarrow SeCl_2 + Cl_2 \quad (27)$$

As recent thermoanalytical and X-ray diffraction investigations show, $SeCl_4$ can be prepared in two polymorphic modifications, a metastable β-form[8,106,107] and a thermodynamically stable α-modification.[108,109] Crystallization from solvents such as $POCl_3$, sublimation of gaseous $SeCl_4$ into a zone with $T < 150\,°C$, or crystallization from the melt (360 °C) yields β-$SeCl_4$.

Increasing the sublimation and desublimation temperature ($T_d \sim 200\,°C$) causes the transformation of initial primary product, β-$SeCl_4$ into α-$SeCl_4$. Thus crystallization from the gas phase obeys Ostwald's rule.[106,110] α-$SeCl_4$ is also formed

in the solid state by monotropic transformation above 180 °C. Stable selenium tetrachloride (α-$SeCl_4$)[109] contains Se_4Cl_{16} molecules.

β-$SeCl_4$ is isostructural with $TeCl_4$ and also contains tetrameric cubane-like Se_4Cl_{16} molecules with approximate T_d symmetry. Within the distorted $SeCl_{3+3}$ octahedra, the bonds to the triply bridging chlorine ligands are much longer than to the terminal chlorines. The bonding can be described either as covalent Se_4Cl_{16} molecules, or, in an ionic approximation, as $[(SeCl_3^+Cl^-)_4]$ with a certain degree of stereochemical activity of the lone pairs toward the center of the voluminous cubane center (Figure 10).[111,112] In the presence of strong Lewis acids, the $SeCl_4$ molecule ionizes and $[SeCl_3]^+$ ions are formed by chloride ion transfer (equation 28).[113]

$$SeCl_4 + HSO_3F \longrightarrow SeCl_3^+ + SO_3F^- + HCl \qquad (28)$$

The $[SeCl_3]^+$ ion is also formed in chlorosulfuric acid containing Se_2Cl_2[114] or selenium and chlorine.[115]

Solid compounds containing $[SeCl_3]^+$ cations have been well characterized. Thus in the case of the $SeCl_4{\cdot}AlCl_3$ adduct, the presence of discrete $[SeCl_3]^+$ and $[AlCl_4]^-$ ions has been shown by an X-ray structure determination.[116] The structure contains distorted $SeCl_6$ octahedra with three long and three short Se–Cl bonds of 3.04 and 2.11 Å (mean values). The spectra have been interpreted by assuming pyramidal $[SeCl_3]^+$ ions with C_{3v} symmetry.[117–121]

Selenium tetrachloride behaves as an ansolvo acid in an $SbCl_3$ melt (equation 29).

$$SeCl_4 + 2SbCl_3 \rightleftharpoons (SbCl_2)_2SeCl_6 \rightleftharpoons 2SbCl_2^+ + SeCl_6^{2-} \qquad (29)$$

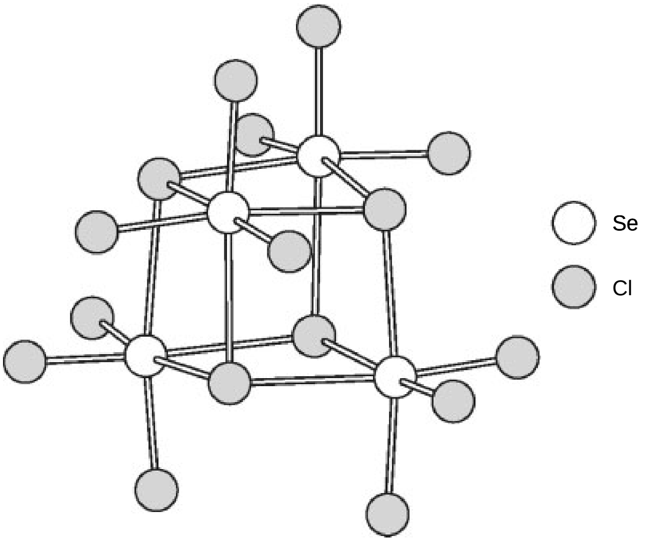

Figure 10 $Se_4Cl_{16}^-$ molecule in the structure of β-$SeCl_4$

Strong association of the ions was found by cryoscopy.[122] In the $SeCl_4$–$SbCl_5$ system, a compound of the composition $SeCl_4{\cdot}SbCl_5$ was concluded from the phase diagram.[123] $SeCl_4$ and excess $SbCl_5$ heated to 140–150 °C yield $SeCl_4{\cdot}SbCl_5$[97] $(SeCl_3^+SbCl_6^-)$,[117] which is also obtained by reaction in $SOCl_2$ solution.[124]

Unlike SeF_4, which forms 1:1 ionic complexes containing the SeF_5^- ion with alkali metal fluorides,[101,102] only octahedral ions of the type $[SeX_6]^{2-}$ are known for $SeCl_4$ and $SeBr_4$ (equation 30).

$$SeCl_4 + 2KCl \longrightarrow K_2SeCl_6 \qquad (30)$$

Some remarkable N-substituted derivatives of $SeCl_4$ with significant Se–N multiple bonding were reported from the reaction of Ph_3P–N–$SiMe_3$ with $SeCl_4$. The first product isolated was Ph_3P–N–$SeCl_3$, in which another chlorine can be replaced to give $(Ph_3P{=}N)_2SeCl_2$. On addition of $SbCl_5$ at −78 °C, one Cl is abstracted and $[(Ph_3P{=}N)_2SeCl^+]\,[SbCl_6^-]$ is formed.[125] $Cl_2Se{=}NTeF_5$, obtained as a reaction product from $SeCl_4$ and H_2NTeF_5,[126] is postulated to contain a Se=N double bond.

Selenium Tetrabromide. Selenium tetrabromide is mainly prepared by the reaction of the elements, either pure or dissolved in CS_2, using an excess of bromine. It occurs in two crystalline modifications, the thermodynamically stable α-$SeBr_4$ and the metastable β-$SeBr_4$. The latter forms first, in accordance with Ostwald's rule.

α-$SeBr_4$ crystallizes in the trigonal system and contains cubane-like $[SeBr_4]_4$ units.[106] Monoclinic β-$SeBr_4$ also consists of tetrameric cubane-like $[SeBr_4]_4$ molecules. β-$SeBr_4$ is isotypic with $TeCl_4$[127] and with β-$SeCl_4$; its chemical behavior and reactions are similar to $SeCl_4$.

3.3.3 Reactions of the Tetrahalides

Owing to their remarkable structural and bonding properties, their high general reactivity, and the significant influence of the lone pair on the reaction path and products, the reactions of the selenium(IV) halides are quite variable.

XY_4 + R^+Y^- ⟶ haloselenates(IV)
+ selenium (IV)oxide ⟶ selenium (IV)oxide halide
+ selenium (IV)oxide + R^+Y^- ⟶ oxohaloselenates(IV)
+ reducing agents + R^+Y^- ⟶ haloselenates(II)
+ alkyl(aryl)ating agents ⟶ organoselenium(IV)halides
+ halides BY_n as Lewis acids / bases ⟶ 'ionic' adducts
+ aqueous conc. HY ⟶ hydronium haloselenates(IV)
+ superacids ⟶ haloselenium polycations

Scheme 3

A wide variety of derivatives have been prepared according to the following reaction types (where Y = halogen, R^+ = metal ions or large cations such as tetraphenylphosphonium (arsonium)) (Scheme 3).

3.4 Hexahalides

3.4.1 Selenium Hexafluoride

SeF_6 can be prepared, stepwise directly from the elements (equation 31).[128] A patent claims the formation of selenium haxafluoride from selenium and chlorine monofluoride, ClF, at temperatures above 200 °C under substantially anhydrous conditions. Below 200 °C, SeF_4 is formed.[129] The rotational movements of the SeF_6 molecules in the plastic and liquid phases have been studied by ^{19}F NMR, IR, and Raman spectroscopy.[130]

$$Se(s) + 3F_2(g) \longrightarrow SeF_6(g) \quad (31)$$

X-ray measurements were made on polycrystalline material. It does not seem to be isotypic with the orthorhombic UF_6, as found by neutron diffraction.[131] SeF_6 is relatively inert to hydrolysis. It does not interact with water at room temperature over long periods, not even at elevated temperature.[132] The gas can be passed without change through aqueous 10% NaOH solution[133] and is resistant to aqueous 10% KOH solution as well.

3.4.2 Selenium Pentafluoride Chloride

Selenium pentafluoride chloride is the first compound isolated containing a stable Se–Cl bond. It was first obtained from SeF_4 and ClF,[134] but is best prepared from $CsSeF_5$ and $ClOSO_2F$:[135]

$$CsF + SeF_4 \rightleftharpoons CsSeF_5 \quad (32)$$

$$CsSeF_5 + ClOSO_2F \rightleftharpoons SeF_5Cl + CsOSO_2F \quad (33)$$

Normal-coordinate analyses were carried out for SeF_5Cl.[136–138] There is a decrease of the stretching force constant values from SeF_6 to SeF_5Cl, demonstrating that the substitution of one fluorine atom in SeF_6 by the less electronegative chlorine atom causes an increased polarity of the remaining Se–F bonds.

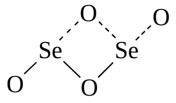
4 OXIDES

4.1 Properties of the Se–O Bond

The bond parameters of the oxygen compounds of selenium compared to those of sulfur have been investigated.[139] The basic similarity between the bonding in these compounds, related to the model of a p_π–d_π bond system, has been confirmed by means of a linear relationship between the SeO and SO valence force constants.[140] A similar linear relationship has also been found between the valence force constants and the length of the SeO bond.[141] The influence of electronegative substituents on the frequencies of XO bonds in IR spectra has been verified for compounds of the type A–SeO–B.[142]

4.2 Selenium Dioxide

In the solid state, SeO_2 has a polymeric structure of corner-linked flattened SeO_3 pyramids, each carrying a pendant terminal O atom.[143] Mass spectrometric studies of the vapor over solid SeO_2 at 400 K indicate small amounts (1%) of dimeric SeO_2 in the gaseous phase.[144] A normal-coordinate calculation for the four possible symmetries of $(SeO_2)_2$ prove the centrosymmetric C_{2h} chair configuration (**11**) for the dimeric molecule.[145]



(**11**)

Selenium dioxide dissolves in $H_2S_2O_7$[146] to yield a colorless solution. From conductometry and cryoscopy measurements, it has been shown that, at low concentrations, SeO_2 may be protonated in $H_2S_2O_7$[124] in a similar manner as for H_2SO_4 solutions (equation 34).[147]

$$SeO_2 + 2H_2S_2O_7 \rightleftharpoons SeO(OH)^+ + HS_3O_{10}^- + H_2SO_4 \quad (34)$$

The complex $H_2S_2O_7 \cdot Se_2O_4$ is proposed in concentrated solutions.[146] SeO_2 is also very soluble in water producing selenous acid (H_2SeO_3), from which it can be recovered by dehydration. It is readily reduced to the element by NH_3, N_2H_4, or aqueous SO_2. Thus it also finds use as an oxidizing agent in organic chemistry.

4.3 Selenium Trioxide

The structure of the trioxide consists of tetrameric cyclic molecules $(SeO_3)_4$ of S_4 symmetry.[148] The mean Se–O distances are 1.55 Å for nonbridging oxygen and 1.77 Å for bridging oxygen. Electron diffraction[149] and mass spectrometry[144] of the vapor indicates that there is appreciable dissociation to the monomer at 120 °C. The Se–O distances in the monomeric SeO_3 molecule are 1.69 Å. In the molten state, selenium trioxide is probably polymeric.[150,151]

Selenium trioxide shows the typical properties of a Lewis acid[152] and forms 1:1 complexes with organic bases[153] such as pyridine, γ-picoline, quinoline, morpholine, and triethylamine in liquid SO_2 or nitromethane. The complexes were found to be of donor–acceptor type, and IR spectroscopy suggests that selenium is coordinated via the nitrogen atom of the tertiary base. It has also been confirmed that the tetrameric ring of SeO_3 is retained in the adducts.

Lewis-base characteristics are also exhibited by SeO_3. Reaction with arsenic or antimony chlorides and selenium trioxide in liquid SO_2 produces $SeO_3{\cdot}AsCl_3$, $SeO_3{\cdot}SbCl_3$, $SeO_3{\cdot}SbCl_5$, and $2SeO_3{\cdot}AsCl_3$, and the existence of $2SeO_3{\cdot}SbCl_3$ has been assumed from conductometric measurements.[154] These crystalline adducts are stable below $-20\,°C$. According to the Raman spectra of $SeO_3{\cdot}AsCl_3$ and $2SeO_3{\cdot}AsCl_3$ the oxygen atom of selenium trioxide is the donor in these complexes and the As atom is the electron-pair acceptor.[155] A thermogravimetric and gas-volumetric study[156] has shown that the thermal decomposition of SeO_3 takes place in two stages, with the formation of an intermediate pentoxide and the evolution of oxygen. It was also observed that SeO_3 begins to decompose at a lower temperature in a nitrogen atmosphere than in oxygen.

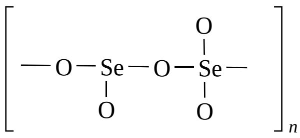
4.4 Diselenium Pentoxide

Se_2O_5 is formed as an intermediate during the thermal two-stage decomposition of SeO_3.[157] This has been confirmed by a thermoanalytical study and measurements of the evolved oxygen (equations 35 and 36).[156]

$$2SeO_3 \xrightarrow{185\,°C} Se_2O_5 + \tfrac{1}{2}\,O_2 \qquad (35)$$

$$Se_2O_5 \xrightarrow{225\,°C} 2SeO_2 + \tfrac{1}{2}\,O_2 \qquad (36)$$

Diselenium pentoxide can also be formed as a product in the reaction of selenium dioxide difluoride with SeO_2. Measurements of molten Se_2O_5 suggest that $[SeO]^+$ and $[SeO_4]^{2-}$ ions are present.[157] The structure of crystalline Se_2O_5 is that of a linear polymer with alternating Se^{IV} and Se^{VI} atoms (**12**), which has been confirmed by means of Raman spectroscopy.



(12)

4.5 Selenium Oxide Halides

4.5.1 *$SeOF_2$, $SeOCl_2$, and $SeOBr_2$*

$SeOF_2$ has a trigonal pyramidal structure (C_s symmetry), as shown by microwave studies[158,159] and supported by the spectroscopic investigations of gaseous, liquid, and dissolved and solid $SeOF_2$.[160–163] In the gaseous state it is monomeric, as in the liquid, although there is some degree of intermolecular interaction. Fluorine and oxygen bridges are formed in the condensed phases, as confirmed by an X-ray structure determination.[164] Figure 11 shows the projection of the crystal structure of $SeOF_2$. $SeOF_2$ reacts with Lewis acids such as NbF_5, forming adducts of the type $SeOF_2{\cdot}NbF_5$.[165] The structure is reproduced in Figure 12.

$KSeOF_3$ is formed exothermally by reaction of $SeOF_2$ and KF.[166] The spectra confirm the expected geometry with two fluorine atoms at the apices of a pseudotrigonal bipyramid, in agreement with the prediction of the Valence Shell Electron Pair Repulsion (VSEPR) model.[167]

Like $SeOF_2$, $SeOCl_2$ molecules have a tendency to associate.[168] The monomers are in equilibrium with $(SeOCl_2)_2$ dimers in CS_2 solution. $SeOCl_2$ displays Lewis properties similar to other $SeOX_2$ compounds (X = F, Cl, Br, OMe, OEt). In donor–acceptor complexes of the type $D \rightarrow SeOX_2$, the Se atom always acts as the acceptor.[166] On the other

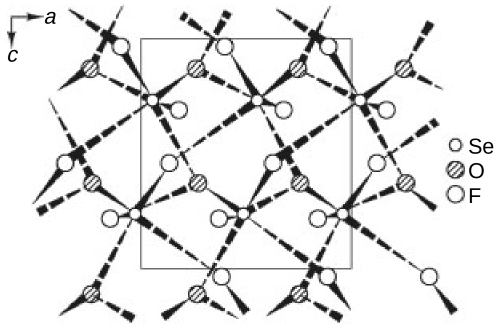


Figure 11 Projection of the crystal structure of $SeOF_2$

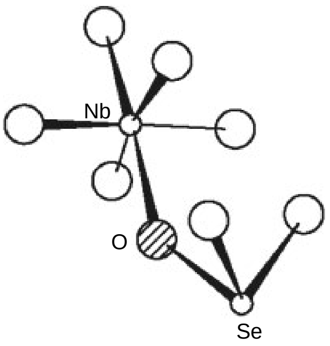

Figure 12 Atomic arrangement in $SeOF_2{\cdot}NbF_5$

hand, in complexes of the type $X_2SeO \rightarrow A$ the O atom is always the donor.[169–172] Reactions of $SeOCl_2$ with $S_2O_6F_2$ and $BrSO_3F$ yield, for example, a liquid of formula $SeO(SO_3F)_2$ as a product of both reactions.[173] This compound shows a partial temperature-dependent dissociation (equation 37). More recently, $SeOCl_2$ has been used as a selenium transfer agent.[174]

$$SeO(SO_3F)_2 \rightleftharpoons SeOSO_3F^+ + SO_3F^- \qquad (37)$$

Equimolar mixtures of $SeOCl_2$ and $SeOF_2$ react to form SeOClF, which is shown by ^{77}Se NMR[175] and Raman spectroscopy.[163] The reaction of $SeOCl_2$ with an equimolar amount of $SeOBr_2$ leads to red–orange liquid SeOBrCl.[163,175]

The $SeOBr_2$ molecule has a pyramidal structure (C_s symmetry), by analogy to $SeOF_2$ and $SeOCl_2$.[163] In the crystal structure, trigonal pyramidal $SeOBr_2$ molecules are associated with 3 + 3 coordinated selenium to polymeric double chains by oxygen and bromine bridges.[176]

4.5.2 SeO_2F_2

SeO_2F_2 is a very reactive gas, in contrast to SO_2F_2, due to the high oxidation power of selenium(VI) and the imperfect steric screening of the selenium atom by only four ligand atoms.[177] SeO_2F_2 has been used as a starting compound for the preparation of a large number of selenium–fluorine compounds. It reacts with dialkyl selenates to yield alkyl esters of fluoroselenic acid[178] and with N_2O_3 and N_2O_4 to yield nitrosonium and nitronium fluoroselenates.[179] When being fluorinated by HSO_3F, $HOSeF_5$ is formed.[180]

4.5.3 $SeOF_4$ and $Se_2O_2F_8$

$SeOF_4$ is prepared by vacuum decomposition of pure sodium pentafluoroorthoselenate (equation 38). The volatile rather unstable product is trapped at −196 °C.[181,182]

It can be assumed that $SeOF_4$ occurs as an intermediate in the decomposition of $As(OSeF_5)_3$,[183] $Ti(OSeF_5)_4$,[184] or $LiOSeF_5$[185] since the stable dimer of $SeOF_4$ is formed. In very small amounts, $SeOF_4$ is detected in the thermal decomposition of its dimer, $Se_2O_2F_8$, between 200 and 350 °C.[186,187]

$$NaOSeF_5 \xrightarrow{200\,^\circ C} NaF + SeOF_4 \qquad (38)$$

$$2SeOF_4 \longrightarrow F_4Se(\mu\text{-}O)_2SeF_4 \qquad (39)$$

The $SeOF_4$ molecule is distorted trigonal bipyramidal, as shown by the IR, Raman,[181] and ^{19}F NMR spectra.[181,182] It is one of the few known hexavalent selenium compounds with fivefold coordination.[182] At temperatures above −100 °C the compound dimerizes to $Se_2O_2F_8$ (equation 39).[181,182] The compound is also prepared by pyrolysis of $NaOSeF_5$ via the intermediate formation of $SeOF_4$. The structure consists of two octahedra connected by a common O–O edge with a planar four-membered ring (Figure 13).[188] The dimer has only a slight tendency to split into the monomer even at elevated temperature.

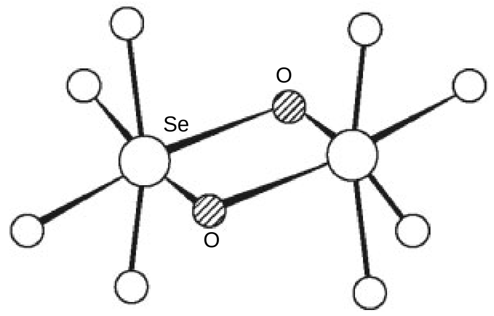

Figure 13 Molecular structure of $Se_2O_2F_8$

5 HALOSELENATES

5.1 Haloselenates(IV)

The nucleophilic stepwise degradation of the tetrameric Se_4X_{16} leads to tri-, di-, and mononuclear haloselenates(IV) (Figure 14).[8] In the case of the cubane-like Se_4Cl_{16}, the selenium atoms form three strong terminal bonds and three longer bridging bonds so that the bonding is close to an ionic formulation, $[(SeCl_3{}^+)_4(Cl^-)_4]$. As a general reaction scheme, it can be proposed that Cl^- ions attack the tetramer, eliminating one or two $SeCl_3{}^+$ groups in the form of neutral $SeCl_4$ species (equations 40 and 41). These products are obtained by reaction of stoichiometric amounts of the tetrahalides with R^+X^- (see

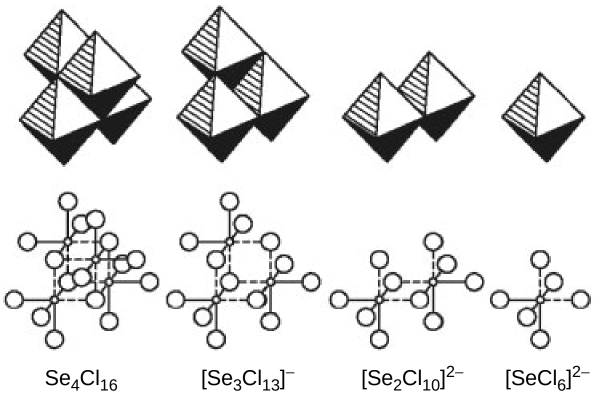

Figure 14 Degradation of the cubane-like tetrameric chalcogen(IV) halides exemplified by Se_4Cl_{16}

above) in organic solvents with low polarity.

$$Se_4Cl_{16} + R^+Cl^- \longrightarrow [R^+][Se_3Cl_{13}{}^-] + SeCl_4 \quad (40)$$

$$Se_4Cl_{16} + 2R^+Cl^- \longrightarrow [R^+]_2[Se_2Cl_{10}{}^{2-}] + 2SeCl_4 \quad (41)$$

5.1.1 Mononuclear Anions

The existence of $[SeF_6]^{2-}$ is doubtful because SeF_4 forms only $[SeF_5]^-$ anions with alkali fluorides.[101] The pentachloroselenate ion is present in a hydrochloric acid solution of selenium oxide at 0 °C[189] and in solid $[Et_4N][SeCl_5]$ or $[Ph_4As][SeCl_5]$.[190]

The hexahaloselenates(IV) $[SeX_6]^{2-}$ (X = Cl, Br) are the end-products of the nucleophilic degradation of the tetrahalides[8,61] (see Figure 14). The more or less ideal octahedral symmetry of these 14-electron SeX_6E systems cannot be described using simple models. They had been quoted as exceptions from the VSEPR theory.[167,191–193] From spectroscopic and theoretical studies, their bonding, structure, and their dynamic properties are well investigated.[61,194,195] Models to describe them extend from a simple $4p^34d^25s$ hybridization scheme,[196] with the inert pair shielding the bonding electrons, up to a molecular orbital-based model of three orthogonal three-center–four-electron bonds.[197]

5.1.2 Dinuclear and Trinuclear Anions

Decahaloselenates(IV) and tridecahaloselenates(IV) were isolated in salts such as $[Ph_4As]_2[Se_2Cl_{10}]$,[198] $[(C_{14}H_{13}ClN_3]_2[Se_2Cl_{10}]\cdot 2MeCN$,[199] $[Et_4N]_2[Se_2Br_{10}]$,[8] $[Ph_3C][Se_3Cl_{13}]$,[200] and $[Ph_3C][Se_3Br_{13}]$.[200] The dinuclear $[Se_2X_{10}]^{2-}$ structure consist of edge-sharing distorted octahedra. Also, as a fragment of Se_4X_{16} cubes, the anions $[Se_3X_{13}]^-$ consist of three edge-sharing octahedra with a central triply bridging chlorine or bromine atom (Figure 15).[200]

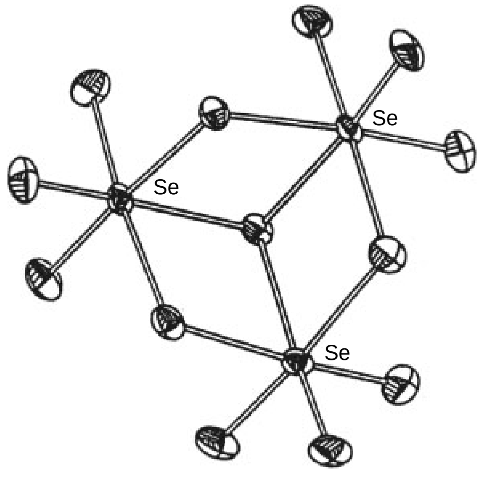

Figure 15 $[Se_3Cl_{13}]^-$ ion in $[Ph_3C][Se_3Cl_{13}]$

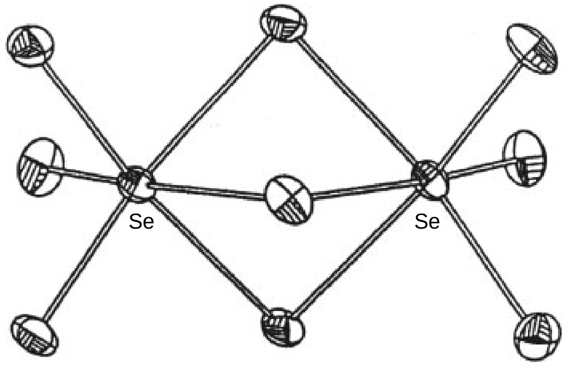

Figure 16 $[Se_2Br_9]^-$ ion in the crystal structure of $[EtPh_3P][Se_2Br_9]\cdot CH_2Cl_2$

The series of the decahaloselenates(IV) clearly demonstrates the stereochemical influence of the inert pair as a function of the halogen atom. The alkali metal pentafluoroselenates(IV) contain only the monomeric ψ-octahedral $[SeF_5]^-$ anions.[101,102]

If the degradation reaction of the tetramers is performed at slightly lower temperatures with very slow addition of halide as the nucleophilic agent, unexpected dinuclear nonahaloselenates(IV) are obtained. Their existence, together with evidence from their Raman spectra,[198] indicates the presence of an equilibrium between $[Se_2X_{10}]^{2-}$ and $[Se_2X_9]^-$ in aprotic solutions (equation 42).

$$[Se_2X_{10}]^{2-} \underset{+X^-}{\overset{-X^-}{\rightleftharpoons}} [Se_2X_9]^- \quad (42)$$

The $[Se_2X_9]^-$ ions were isolated in $[Ph_4As][Se_2Cl_9]$,[198] $[EtPh_3P][Se_2Br_9]\cdot CH_2Cl_2$,[201] and in the double salts $[Et_4N]_4[Se_2Br_{10}(Se_2Br_9)_2]$[188] and $[Et_4N]_4[Se_2Cl_{10}(Se_2Cl_9)_2]$.[8,198] In Figure 16, the $[Se_2Br_9]^-$ anion is shown.[201] These nonahaloselenates(IV) contain three μ-bridging halogens, resulting in face-sharing of the two octahedral halves of the molecule.

5.1.3 Polynuclear Anions

$[S_4N_3]_n[SeCl_5]_n$[202] was obtained by diffusion of Se_2Cl_2 and S_4N_4 in $SOCl_2$ for several days. It contains polymeric $[SeCl_5{}^-]_n$ chains built from *cis* corner-sharing octahedra, resulting in $SeCl_{4+2}$ coordination (Figure 17a).

A compound with the empirical composition $[Me_3NH]_2[SeBr_8]$[4,203] was formed from $SeBr_4$ and trimethylammonium bromide in boiling aqueous HBr. It contains distorted $[SeBr_6]^{2-}$ anions which are in bonding contact to two *cis*-coordinated Br_2 molecules to form endless chains of composition $[SeBr_6{}^{2-}\cdot Br_2]_n$ (Figure 17b). The bond length in the Br_2 unit is significantly elongated compared to the free molecule, and the distortion of the $SeBr_6$ octahedron reflects the effect of intermolecular bonding.

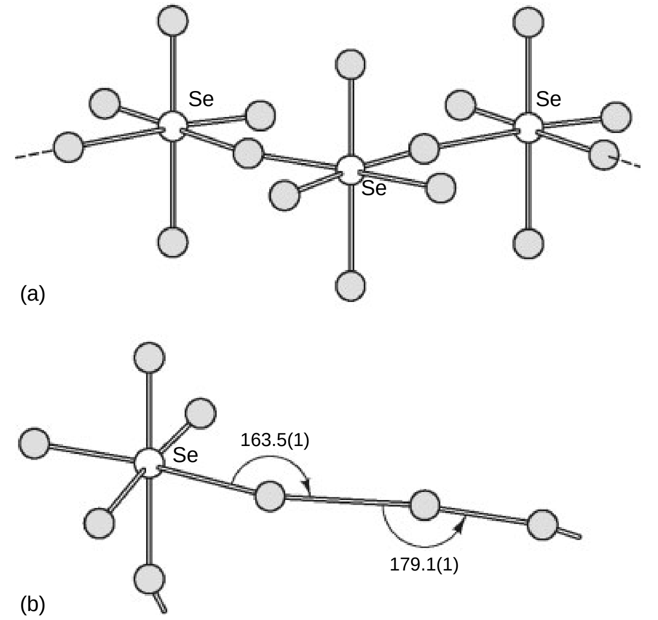

Figure 17 (a) Section of the polymeric $[SeCl_5^-]_n$ chain; (b) Section of the polymeric $[SeBr_6^{2-}\cdot Br_2]_n$ ion

5.2 Haloselenates(II)

5.2.1 Mononuclear and Dinuclear Anions

By symproportionation of elemental selenium and $SeCl_4$ in polar protic solvents, $[SeCl_4]^{2-}$ and $[Se_2Cl_6]^{2-}$ can be stabilized. They crystallize with voluminous organic cations (with $SeCl_2$:RCl ratios of 1:2 and 1:1) (equations 43–45).

$$SeCl_4 + Se \longrightarrow 2SeCl_2 \quad (43)$$

$$SeCl_2 + 2RCl \longrightarrow [R]_2[SeCl_4] \quad (44)$$

$$2SeCl_2 + 2RCl \longrightarrow [R]_2[Se_2Cl_6] \quad (45)$$

Using large organosubstituted countercations the anions could be isolated as $[Ph_3(C_2H_4OH)P]_2[SeCl_4]\cdot MeCN$ and $[Ph_4P]_2[Se_2Cl_6]$.[204] Also, the $S_4N_3^+$ cation is able to stabilize $[Se_2Cl_6]^{2-}$ in $[S_4N_3]_2[Se_2Cl_6]$.[202] Mononuclear planar haloselenates(II) are square-planar (ψ^2-octahedral) as predicted from VSEPR model considerations for these XY_4E_2 systems, which are isoelectronic with ICl_4^- or XeF_4. Their bonding can be described as a system of two four-electron–three-center bonds with a formal MO bond order of 0.5. The dinuclear planar $X_2Y_6^{2-}$ structure (isoelectronic with I_2Cl_6) consists of two edge-sharing distorted XY_4 squares. Tetrabromoselenate(II), $[SeBr_4]^{2-}$, and hexabromodiselenate(II), $[Se_2Br_6]^{2-}$, are formed in equilibrium mixtures of $SeOBr_2$ and/or $SeBr_4$ and their thermal reaction products in moderately polar organic solvents

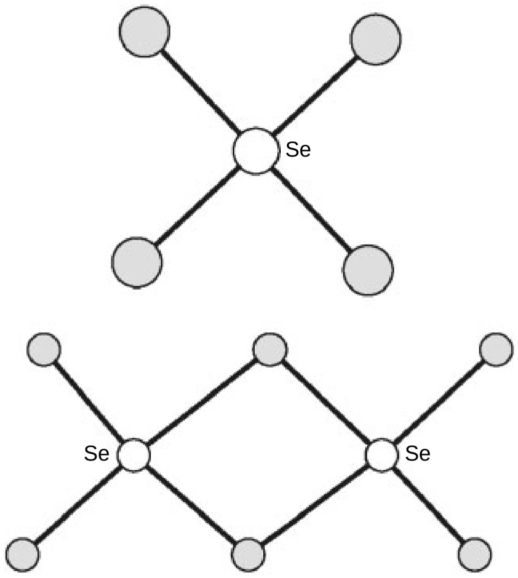

Figure 18 Structures of $[SeBr_4]^{2-}$ and $[Se_2Br_6]^{2-}$

(equations 46–49).[205,206]

$$2SeOBr_2 \xrightarrow[MeCN]{70\,^\circ C} SeBr_4 + SeO_2 \quad (46)$$

$$SeBr_4 \longrightarrow SeBr_2 + Br_2;\ 2SeBr_2 \longrightarrow Se_2Br_2 + Br_2 \quad (47)$$

$$SeBr_2 + Br_2 + SeO_2 + 4RBr \xrightarrow{MeCN} R_2[SeBr_4] + R[SeO_2Br] + RBr_3 \quad (48)$$

$$2SeBr_2 + 2Br_2 + 4RBr \xrightarrow[MeCN]{70\,^\circ C} R_2[Se_2Br_6] + 2RBr_3 \quad (49)$$

The structures of $[SeBr_4]^{2-}$ and $[Se_2Br_6]^{2-}$ are shown in Figure 18. From vibrational spectra it was concluded that the dimers dissociate in solution and form discrete T-shaped trihaloselenates(II).[207]

5.2.2 Tri-, Tetra-, and Pentanuclear Anions

Trinuclear $[Se_3Br_8]^{2-}$ was obtained in a 2-methyl propionitrile solution of $SeBr_4$, Se, and CuBr as the copper(I) salt $[(i\text{-PrCN})_4Cu]_2[Se_3Br_8]$.[203,208] The structure consists of a triangular arrangement of three planar $SeBr_4$ groups sharing a common edge (Figure 19a).

The tetranuclear $[Se_4Br_{14}]^{2-}$ anion was isolated as the ammonium salt $[Me_3PhN]_2[Se_4Br_{14}]$[209] and as the phosphonium salt $[EtPh_3P]_2[Se_4Br_{14}]$.[208] In these tetranuclear molecules, planar dinuclear Se_2Br_6 units are linked through two unusual nearly linear Se–Br–Se bridges. The bridging bromine atoms have the formal oxidation state +1. The Se–Br–Se bond angles are 175.9°[209] and 176.1°[208] (Figure 19b). If the ratio of $SeBr_2$ to R^+Br^- in the equilibrated

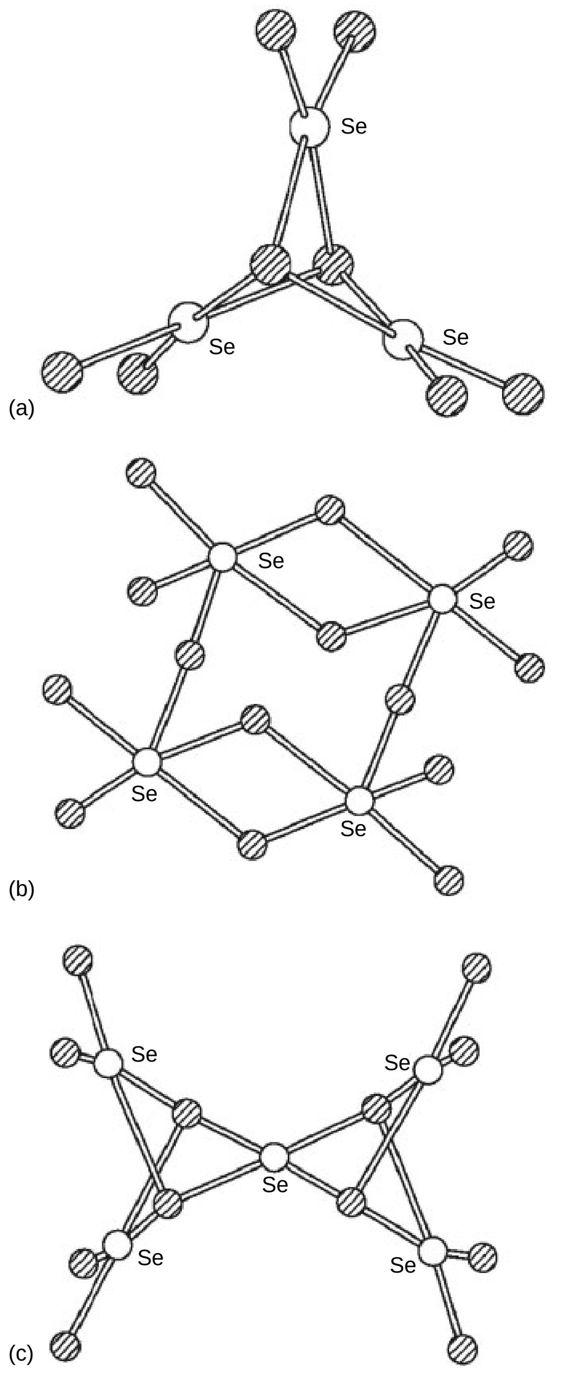

Figure 19 (a) $[Se_3Br_8]^{2-}$ anion, (b) $[Se_4Br_{14}]^{2-}$ anion, and (c) $[Se_5Br_{12}]^{2-}$ anion

reaction mixture is more than 2.5, the pentanuclear $[Se_5Br_{12}]^{2-}$ anion is formed.[208] It has D_{2h} symmetry and is composed of five planar $SeBr_4$ groups. Two pairs of two peripheral $SeBr_4$ units share one edge with one another and with the central unit (see Figure 19c). Because of the long Se–Br bonds from the terminal $SeBr_2$ groups to the μ_3-Br ligands, the bonding can also be approximated by the structural formula $[(SeBr_4^{2-})(SeBr_2)_4]$.

5.3 Mixed-Valence Haloselenates(II/IV)

From the complex reaction mixture of the redox system $SeBr_4/SeBr_2/Se/Br^-$ in aprotic solvents, di-, tri, and tetranuclear mixed-valence bromoselenates(II/IV) containing selenium in both oxidation states +2 and +4 were prepared: $[Se_2Br_8]^{2-}$, $[Se_3Br_{10}]^{2-}$, and $[Se_4Br_{12}]^{2-}$ (Figure 20).

In the $[Se^{II}Se^{IV}Br_8]^{2-}$ anion,[210,211] an octahedral $Se^{IV}Br_6$ group shares one edge with a square-planar $Se^{II}Br_4$ group. This coordination gives a clear assignment of the oxidation state of each selenium atom. The dihedral angles between the $Se^{II}Br_4$ plane and the basal plane of the $Se^{IV}Br_6$ octahedron are 34°[210] and 57°.[211]

By formal addition of a $SeBr_2$ group to this $[SeBr_8]^{2-}$ anion, the trinuclear decabromotriselenate(II/IV) $[Se_2{}^{II}Se^{IV}Br_{10}]^{2-}$ is formed, which was isolated as the *n*-propylammonium salt $[(n\text{-Pr})_4N]_2[Se_3Br_{10}]$.[210] In the centrosymmetric anion (see Figure 20b), a central $Se^{IV}Br_6$ octahedron is linked through two trans edges to two square-planar $Se^{II}Br_4$ groups with dihedral angles of 22° between the equatorial planes.

In the $[Se_3{}^{II}Se^{IV}Br_{12}]^{2-}$ ion,[210] two $SeBr_2$ moieties are coordinated via *cis* edges to the octahedral central $Se^{IV}Br_6$ unit. A third $SeBr_2$ group bridges one of the $Se^{IV}BrSe^{II}Br$ four-membered rings such that a short Se–Se distance of 3.335 Å results between Se(4) and Se(2) (see Figure 20c), indicating a

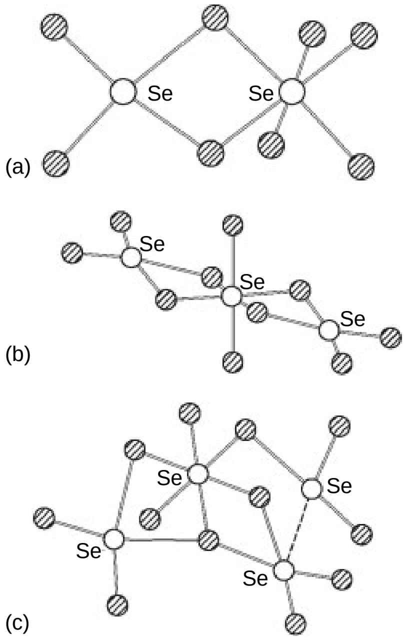

Figure 20 Mixed-valence bromoselenate(II/IV) anions: (a) $[Se_2Br_8]^{2-}$ in $[Et_4N]_2[Se_2Br_8]$; (b) $[Se_3Br_{10}]^{2-}$ in $[(n\text{-Pr})_4N]_2[Se_3Br_{10}]$; (c) $[Se_4Br_{12}]^{2-}$ in $[Ph_4P]_2[Se_4Br_{12}]\cdot CH_2Cl_2$

weak bonding interaction. Se(2) thereby completes the square-planar coordination geometry of Se(4).

The diamagnetic mixed-valence bromoselenates(II/IV) are to be assigned to class I in the Robin–Day scheme.[212] From the structural behavior, a significant valence exchange is not to be expected. The coordination geometries are always clear indications of different oxidation numbers.

6 OXOHALOSELENATES

6.1 Oxohaloselenates(IV)

Numerous oxohaloselenates(IV) with strong Se=O bonding are known. Three classes of these compounds can be prepared with stoichiometric compositions of $[SeO_2X]^-$, $[SeOX_3]^-$, and $[SeOX_4]^{2-}$ (X = F, Cl, Br).[8,213–216] The methods of preparation use nucleophilic addition reactions in different stoichiometric proportions of $SeOF_2$, $SeOCl_2$, or $SeOBr_2$ (or SeO_2 for oxygen-rich species, or SeX_4 + small amounts of H_2O) with the halide in aprotic solvents. $[SeO_2X]^-$ species had been predicted from spectroscopic considerations[190] and were confirmed by the preparation and structure of crystalline $[Me_4N][SeO_2Cl]$ and $[Ph_4P][SeO_2Br]$.[176] The structures of $[SeO_2Cl]^-$ and $[SeO_2Br]^-$ anions in these salts are shown in Figure 21. $[SeO_2Cl]^-$ is mononuclear, trigonal pyramidal, as expected for an $XY_2Y'E$ system. The closely related $[SeO_2Br]^-$, however, is associated through bridging bromine to polymeric chains. This shows once more the stereochemical flexibility and wide variability of the chalcogen inert-pair system as a function of the electronic environment.

This variability is also evident in the oxotrihaloselenates(IV). With different countercations, three isomers of the $[SeOX_3]^-$ anion could be prepared and structurally characterized (Figure 22).[8] A polymeric arrangement of $[SeOX_3{}^-]_n$ chains is found in $[C_9H_8NO][SeOCl_3]$.[216] The chains consist of distorted square $SeOCl_4$ pyramids with apical Se=O bonds (1.59 Å), two *cis* chlorines at 2.25 Å, and two bridging Cl at 2.96 and 2.99 Å from the selenium atom.

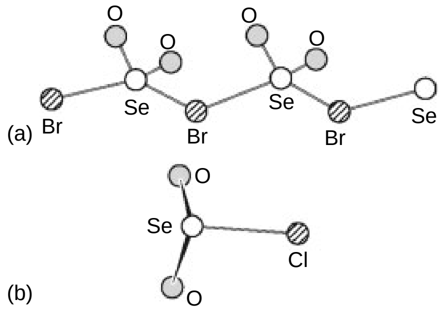

Figure 21 The two isomeric $[SeO_2Br^-]_n$ and $[SeO_2Cl]^-$ ions in (a) $[Ph_4P][SeO_2Br]$ and (b) $[Me_4N][SeO_2Cl]$

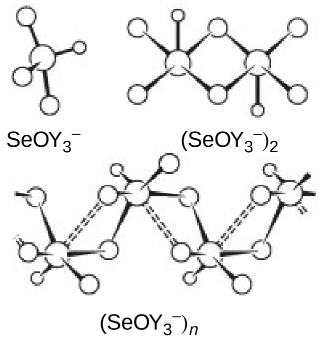

Figure 22 The three isomeric forms of oxotrichloroselenates(IV)

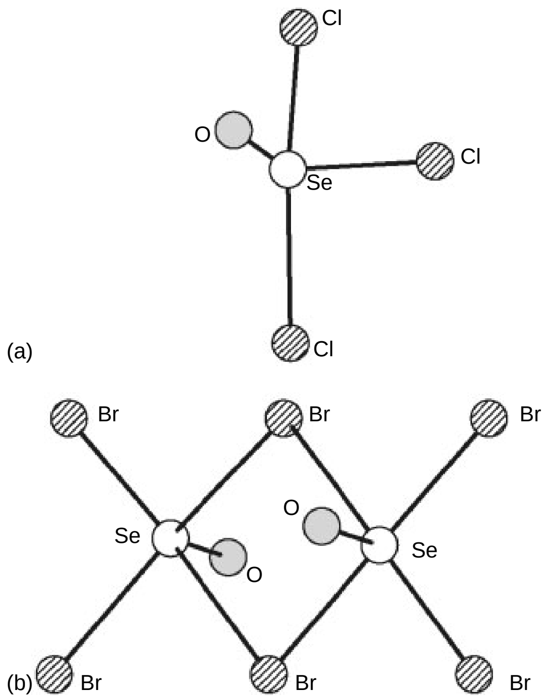

Figure 23 (a) Structure of the monomeric $[SeOCl_3]^-$ ion in $[Ph_4As][SeOCl_3]$ and (b) of the $[SeOCl_3{}^-]_2$ ion in $[Ph_4P][SeOCl_3]$

A monomeric $[SeOCl_3]^-$ anion with a trigonal bipyramidal structure is present in $[Ph_4As][SeOCl_3]$.[217] According to the VSEPR model, the oxygen (Se=O double bond) and the lone pair are located in the equatorial positions (Figure 23a). The third isomer is dinuclear; it can be isolated in the salts $[Et_4N][SeOCl_3]$,[217] $[Ph_4P][SeOCl_3]$, $[Ph_4P][SeOBr_3]$, and $[Ph_4As][SeOBr_3]$.[218] The centrosymmetric dianions consist of two edge-sharing tetragonal pyramidal $SeOX_4$ units with the inert pair at the selenium atom in trans positions to the strongly bonded axial oxygen atom (Figure 23b).

By formal exchange of one halogen for an oxygen atom, anions of the type $[SeO_2X_2]^{2-}$ are formed. The potassium salt $K_2SeO_2F_2$, which can be obtained by heating $KSeO_2F$

with an excess of KF to ≈300 °C or by decomposing $KSeO_2F$ in vacuum at 180 °C, contains the $[SeO_2F_2]^{2-}$ dianion. It is ψ-trigonal bipyramidal (C_{2v} symmetry) with the lone pair and the oxygen atoms in equatorial positions.[219]

The $[SeOCl_4]^{2-}$ anion is formed by nucleophilic attack of $SeOCl_2$ by two Cl^-:

$$SeOCl_2 \xrightarrow{+Cl^-} SeOCl_3^- \xrightarrow{+Cl^-} SeOCl_4^{2-} \quad (50)$$

A regular pyramidal anion $[SeOCl_4]^{2-}$ is observed in the pyridinium double salt $[(C_5H_5NH)_4(H_3O)][(SeOCl_4)_2Cl]\cdot 11H_2O$[8,220] (Se=O 1.602 Å; Se–Cl 2.482 Å). In the dipyridinium salt $[C_{10}H_8N_2H_2]_2[SeOCl_4]$[221] (Se=O 1.63 Å; Se–Cl 2.25, 2.48, 2.48, 2.99 Å), the anions are distorted by participation of one of the Cl ligand atoms in strong Se–Cl···H–N hydrogen bridges to the cation. The ion is also present in $[Et_4N]_2[SeOCl_4]$, and $[Ph_4As]_2[SeOCl_4]$.[222]

A polynuclear $[Cl_2(SeOCl_2)_{10}]^{2-}$ unit is formed in $[Me_4N]_2[Cl_2(SeOCl_2)_{10}]$.[223] The two chloride ions are solvated by 10 $SeOCl_2$ molecules so that each Cl^- is octahedrally surrounded by six $SeOCl_2$ units, two of them sharing an adjacent octahedron (Figure 24).

6.2 Oxohaloselenates(VI)

The anion $[SeO_3F]^-$ is present in the compounds $MSeO_3F$ (M = alkali metal, NH_4, Ag, Tl, Cu, Zn, Cd, Co, Ni). It also occurs in the salts $[NO][SeO_3F]$[179] and $[NO_2][SeO_3F]$.[224] The corresponding acid $HSeO_3F$ is a clear, colorless liquid which hydrolyzes immediately.[225] It decomposes even at room temperature (equation 51).

$$2HSeO_3F \rightleftharpoons H_2SeO_4 + SeO_2F_2 \quad (51)$$

$$SeO_2F_2 + 2HOSO_2F + KHF_2 \longrightarrow HOSeF_5 + KSO_3F + H_2SO_4 \quad (52)$$

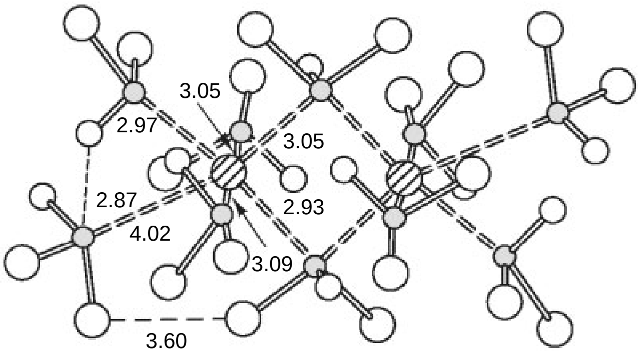

Figure 24 The arrangement of $SeOCl_2$ molecules around chloride ions in $[Me_4N]_2[Cl_2(SeOCl_2)_{10}]$ (distances in Å)

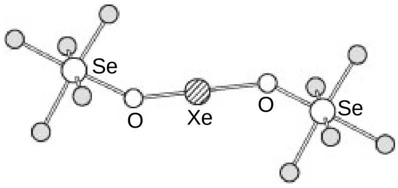

Figure 25 The structure of the $Xe[OSeF_5]_2$ molecule

The Raman and IR spectra of $[NO_2][SeO_3F]$ and $K[SeO_3F]$ can be assigned on the assumption of C_{3v} symmetry for the $[SeO_3F]^-$ anion.[224]

Pentafluoroselenic(VI) acid, $HOSeF_5$, was unexpectedly discovered during experiments to prepare the unknown $SeOF_4$.[202] It is best prepared from SeO_2F_2, $HOSO_2F$, and HF or KHF_2 (equation 52).

The anion $[OSeF_5]^-$ occurs in the pentafluoroorthoselenates $MOSeF_5$ (M = Li, K, Rb, Cs, NH_4,[226] Na,[181,226] NO_2[183,227]). The structure is octahedral, as derived from ^{19}F NMR, IR, and Raman spectra. The $OSeF_5$ group can best be characterized as a pseudohalogen or, more specifically, as a pseudofluorine. According to its reactions, this unit is more electronegative than fluorine. This is in line with the observation that the $OSeF_5$ groups in $F_nI[OSeF_5]_{5-n}$ occupy only equatorial positions.[228] The similarity to fluorine as a ligand is also shown in the ability of $[OSeF_5]^-$ to form the most stable xenon compound $Xe[OSeF_5]_2$[229] (Figure 25) besides the simple fluoride.

The extreme electronegativity of the $OSeF_5$ group is a result of the inductive effect of the five fluorines, thus additionally promoting p_π–d_π back-bonding from oxygen to the selenium atom.

7 SELENIUM AND NITROGEN

7.1 Selenium Nitrides

7.1.1 *The SeN Radical*

Selenium nitride, SeN, is formed by the reaction of selenium or selenium chlorides Se_2Cl_2 or $SeCl_4$[61] with active nitrogen produced by a high frequency discharge. To date, only the electron band spectra have been investigated.

7.1.2 *Tetraselenium Tetranitride, Se_4N_4*

Se_4N_4 is prepared by ammonolysis of selenium tetrahalides,[230–235] diselenium dichloride,[236] selenium dioxide,[232] or diethyl selenite.[226] It is rather unstable and decomposes explosively on heating or by sudden impact.

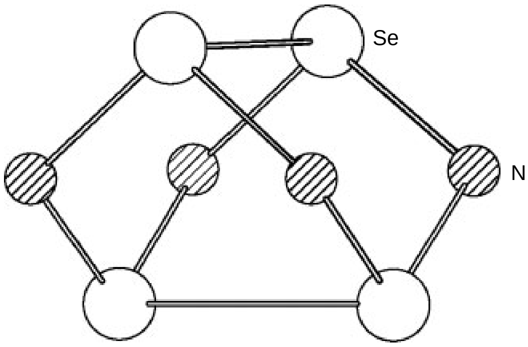

Figure 26 Structure of the Se_4N_4 molecule

In alkaline medium it is hydrolyzed to ammonia, elemental selenium, and selenium–oxygen compounds.

Se_4N_4 exists in at least two crystal modifications. The reaction of liquid NH_3 and $SeCl_4$, or $SeBr_4$, in an autoclave[232] yields crystals of the stable modification,[237] which is not isostructural with S_4N_4. It consists of discrete cage-like Se_4N_4 molecules. The eight-membered ring is puckered, the four selenium atoms being situated at the corners of a tetrahedron with the nitrogen atoms in a plane (Figure 26).

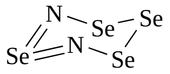
The metastable modification reverts to the first on heating.[238] Compounds of the type $(\overline{SeNSeNSe})_n(AsF_6)_2$, where n is 1 or 2, have been prepared by the reaction of stoichiometric quantities of $Se_4(AsF_6)_2$ ($n = 2$) or AsF_5 ($n = 1$ and 2) with Se_4N_4 in liquid sulfur dioxide.[239] ESR spectroscopy showed that $(\overline{SeNSeNSe})_2(AsF_6)_2$ contains the stable 7π radical $(\overline{SeNSeNSe})^{+}\cdot$ in solution while Raman and IR spectroscopy identified the 6π $(\overline{SeNSeNSe})^{2+}$ cation in $(\overline{SeNSeNSe})\ (AsF_6)_2$. The structures of the solid species were characterized by X-ray structure determination. The reaction of Se_4N_4 with $[PtCl_2(PMe_2Ph)]_2$ in $CHCl_3$ gives $Pt(Se_3N)Cl(PMe_2PH)$ as the first example of a metal selenium–nitrogen complex. It contains the square-planar bidentate Se_3N^- ligand coordinated through two selenium atoms.[240]

7.1.3 *Se_4N_2*

In comparison to Se_4N_4, the recently synthesized Se_4N_2 molecule[241] is thermally more stable. It is formed by the reaction of Se_2Cl_2 with trimethylsilyl azide in CH_2Cl_2 (equation 53).

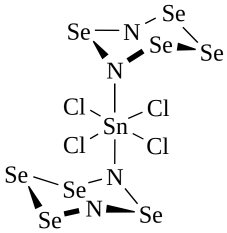
$$2Se_2Cl_2 + 4Me_3SiN_3 \longrightarrow Se_4N_2 + 5N_2 + 4Me_3SiCl \qquad (53)$$

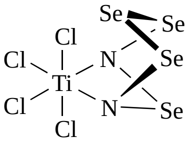
According to its IR spectra the molecule has C_s symmetry with a chair configuration (**13**).



(13)

Two donor–acceptor complexes, $[SnCl_4(Se_4N_2)_2]$ and $[TiCl_4(Se_4N_2)]$, have been prepared by the reaction of Se_4N_2 with $SnCl_4$ and $TiCl_4$, respectively, in CH_2Cl_2 suspensions.[242] According to IR and ^{119}Sn Mössbauer spectra, in the tin complex both Se_4N_2 molecules are bonded with one of the nitrogen atoms at the tin atom in trans positions (**14**), whereas in the titanium complex both nitrogen atoms are assumed to be bonded in a chelating fashion at the titanium atom (**15**).





(14) **(15)**

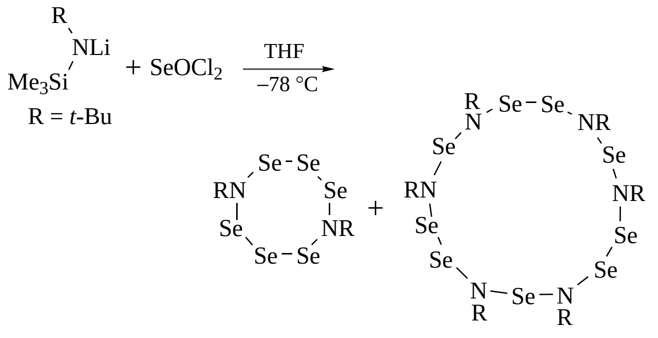
The reaction of tungsten hexachloride with Se_4N_2 leads to $[WCl_4(NSeCl)]_2$, which reacts with pyridine to form $[WCl_4(NSeCl)py]$, and with tetraphenylphosphonium chloride to form $PPh_4[WCl_5(NSeCl)]$.[243] The $[WCl_5(NSeCl)]^-$ ion contains an almost linear WNSe group.

7.1.4 *Selenium Chloride Nitrides*

Two stable chloride nitrides of selenium (with formal oxidation state +3 for Se), Se_2NCl_3 and $(Se_2NCl_2)(GaCl_4)$, have been synthesized.[244] The first structure consists of neutral Se_2NCl_3 units. The molecule is nearly planar with two linear Cl–Se–Cl moieties connected through a common bridging Cl atom. The nitrogen atom forms a second bridge between the two selenium atoms. The mean Se–N bond length of 1.738 Å and the Se–N–Se bond angle of 119.9° implies the presence of delocalized π-bonds between the Se atoms. The elimination of the bridging Cl atom with Lewis acids like $GaCl_3$ or $AlCl_3$ yields the cation $Se_2NCl_2{}^+$; it is nearly planar. The cation has approximately C_{2v} symmetry, with N–Se bond lengths of 1.695 Å, Se–Se distances of 2.147 Å, and bond angles of 146.6° (Se–N–Se) and 108.3° (Cl–Se–N).

7.1.5 *Related Selenium–nitrogen Rings*

Diselenium dichloride, Se_2Cl_2, and seleninyl chloride, $SeOCl_2$, react with a lithium salt of silylated t-butylamine with elimination of LiCl and Me_3SiCl or of LiCl, Me_3SiCl, and $(Me_3Si)_2O$, respectively, to form the cyclic compounds $(t\text{-Bu})_2N_2Se_6$ (**16**), a hexaselenadiazocin, and $(t\text{-Bu})_6N_6Se_9$



(**16**) (**17**)

(**17**), a nonaselenahexaazacyclopentadecane. The structures were established by X-ray diffraction.[245]

Another recently synthesized compound with a selenium atom coordinated by three nitrogen atoms is the tricyclic compound $SeSb_2Cl_2(NCMe_3)_4$, a product of the reaction between $[Se[NCMe_3(SiMe_3)]_2$ and $SbCl_3$.[246] According to an X-ray structure analysis, the six-membered $SeSb_2Cl_2(NCMe_3)_3$ ring is bonded to the triply bridging $NCMe_3$ moiety (Figure 27).

7.1.6 *Selenium Imides*

Newly available, pure, $SeCl_2$[62] was used, in combination with variable mole ratios of $^tBuNH_2$, to prepare the structurally characterized imide compounds, acyclic $ClSe[N(t{-}Bu)Se]_{1\,and\,2}Cl$, $Se_3(N^tBu)_2$; and by combining $SeCl_4$ and $^tBuNH_2$ with SO_2Cl_2 or $SeOCl_2$, c yclic $^tBuNSe(\mu\text{-}t\text{-}Bu)_2E$ (E = SO_2 and SeO).[247] The selenium-containing compounds were also studied by ^{77}Se NMR. The thermal decomposition of $Se(NAd)_2$ was studied by ^{77}Se NMR which indicated the presence of $Se_3(NAd)_3$, $Se(NAd)(\mu\text{-}NAd)_2SeO$ and $OSe(\mu\text{-}NAd)_2SeO$.[248] $Se_3(NAd)_2$ was isolated from the reaction and structurally characterized (Se–Se = 2.404(1) Å, Se–N = 1.873(4) Å).[249]

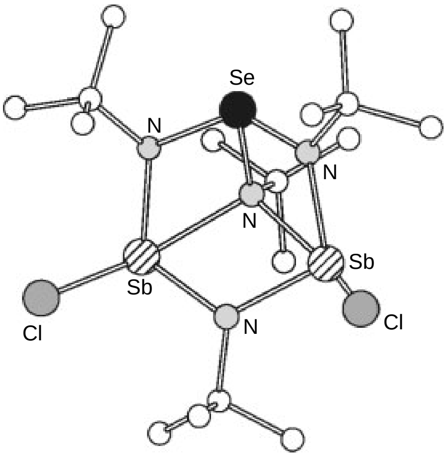


Figure 27 Structure of $SeSb_2Cl_2(NCMe)_4$

7.2 Amides of Selenious and Selenic Acid

7.2.1 *Selenious Diamide, $SeO(NH_2)_2$, and Related Compounds*

Selenious diamide is formed by reaction of ammonia with diethyl selenite or seleninyl bis(dimethylamide) (equation 54).[250]

$$(EtO)_2SeO + 2NH_3 \longrightarrow SeO(NH_2)_2 + 2EtOH \qquad (54)$$

$$(Me_2N)_2SeO + 2NH_3 \longrightarrow SeO(NH_2)_2 + 2Me_2NH \qquad (55)$$

The compound is sensitive to solvolysis and thermally unstable. $(NH)_2Se$ is formed by decomposition above −40 °C. Using methylamine or ethylenediamine instead of ammonia, seleninyl ethylenediamide, $(CH_2NH)_2SeO$, can be obtained by an analogous reaction. By the reaction of seleninyl bis(dimethylamide) with seleninyl chloride, a dimethylamide of chloroselenic(IV) acid results (equation 56).

$$(Me_2N)_2SeO + SeOCl_2 \longrightarrow 2Cl\text{–}SeO\text{–}NMe_2 \qquad (56)$$

7.2.2 *Amidoselenic Acid, $HSeO_3NH_2$, and the $SeO_3NH_2^-$ Ion*

The free acid $HSeO_3NH_2$ has not yet been prepared. The first salt of the acid was $NH_4SeO_3NH_2$, obtained by reaction of $C_5H_5N{\cdot}SeO_3$ with NH_3.[251] IR spectroscopy suggests C_s symmetry for the $SeO_3NH_2^-$ ion.[252,253]

In aqueous ammonia, $SeO_3NH_2^-$ anions react with excess Ag^+ ions to give two modifications of $AgSeO_3NAg_2$.[254] The crystal structure of α-Ag_3NSeO_3 consists of infinite chains of O_3SeNAg_3 molecules joined by O···Ag–N bridges,[255] in agreement with earlier IR results.[256] The molecules have almost regular tetrahedral configurations at each end and the Se–O and N–Ag bonds are almost eclipsed with a dihedral angle of 11.1°.[257]

7.2.3 *Selenic Diamide, $SeO_2(NH_2)_2$*

Selenic diamide, $SeO_2(NH_2)_2$, is formed by reaction of SeO_2F_2 and NH_3 in the gas phase or in inert solvents (e.g. CCl_4) among other selenium(VI)–nitrogen compounds.[177,257] In liquid ammonia, $SeO_2(NH_2)_2$ is thermally unstable (equation 57). It converts at −50 °C to the ammonium salts of cyclic triselenonylimide and at ambient temperature to the diamidopolyimidoselenic acids (equations 58–60).[258,259] Diamidoselenic acid hydrolyzes in water to form ammonium amidoselenate (equation 61).[258,259]

$$SeO_2F_2 + 4NH_3 \longrightarrow SeO_2(NH_2)_2 + 2NH_4F \qquad (57)$$

$$SeO_2(NH_2)_2 \longrightarrow SeO_2NH + NH_3 \qquad (58)$$

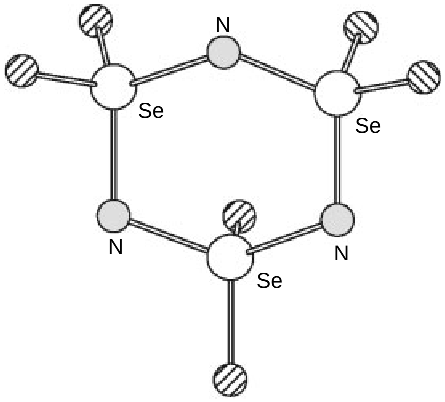

Figure 28 Molecular structure of $[SeO_2N]_3{}^{3-}$

$$3SeO_2NH + 3NH_3 \longrightarrow (NH_4)_3[SeO_2N]_3 \quad (59)$$

$$nSeO_2NH + nNH_3 \longrightarrow NH_2SeO_2[SeO_2NNH_4]_{n-1}NH_2 \quad (60)$$

$$SeO_2(NH_2)_2 + H_2O \longrightarrow NH_4SeO_3NH_2 \quad (61)$$

7.3 Polymeric Anions of Selenonylimide

Selenonylimide, SeO_2NH, has not yet been isolated. The trimeric anion, $[SeO_2N]_3{}^{3-}$, occurs in some salts and the tetrameric anion, $[SeO_2N]_4{}^{4-}$, was identified by paper chromatography.

7.3.1 The $[SeO_2N]_3{}^{3-}$ Ion

The cyclic triselenonylimide ion, $[SeO_2N]_3{}^{3-}$, is present in the salts $M_3[SeO_2N]_3$ with M = K,[259–261] NH_4,[258–260] Ag, Tl^I.[260] All are highly explosive. The $[SeO_2N]_3{}^{3-}$ anion in the potassium salt (Figure 28) is a six-membered ring of approximate C_{3v} symmetry in a chair configuration with a considerably flattened Se_3N_3 skeleton. The Se–N distances indicate p_π–d_π delocalization over the individual Se–N–Se units.[261]

7.3.2 The $[SeO_2N]_4{}^{4-}$ Ion

The tetraselenonylimide ion, $[SeO_2N]_4{}^{4-}$, could only be detected in a paper chromatogram of the reaction products of SeO_2F_2 and NH_3.[257]

Glossary

Ad_E2 mechanism: a bimolecular 1,2-addition of an electrophilic reagent to an alkene via a cationic intermediate
Baeyer–Villiger reaction: the oxidation of a ketone to an ester or lactone, usually by means of a peroxy acid
Enone: an unsaturated ketone, usually α,β relative to the carbonyl group
Markovnikov orientation: the 1,2-addition of an unsymmetrical electrophilic reagent to an alkene with attachment of the more positive moiety of the reagent (H in the original definition) to the less substituted carbon
Michael addition: conjugate addition; addition of a nucleophile to the β-position of a carbon–carbon double or triple bond that is conjugated to a carbonyl or other electron-withdrawing group
Pummerer reaction: the reaction of a sulfoxide or selenoxide with an acidic or electrophilic reagent, with cleavage of the S–O or Se–O bond and formation of an S- or Se-stabilized carbenium ion that rearranges or reacts further with nucleophiles
S_N2 mechanism: a concerted, bimolecular nucleophilic substitution that occurs with inversion of configuration
$S_{RN}1$ mechanism: a nucleophilic substitution that proceeds by a chain mechanism via radical anion intermediates

Abbreviations

LDA = lithium diisopropylamide; MCPBA = *m*-chloroperbenzoic acid; DMF = *N*,*N*-dimethylformamide; HMPA = hexamethylphosphoric triamide.

1 INTRODUCTION

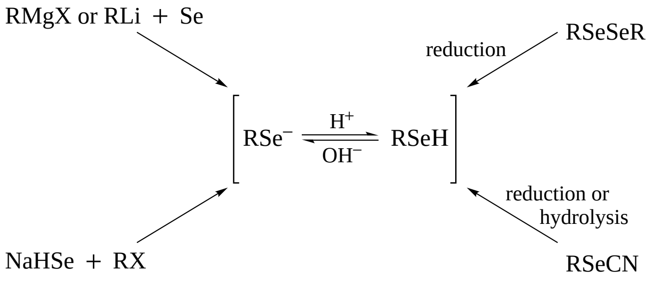
The element selenium was discovered by Berzelius in 1818, and reports of the first organoselenium compounds by Löwig, Wöhler, and others gradually appeared in the literature during the next 50 years. These compounds consisted mainly of simple aliphatic selenols (RSeH), selenides (RSeR), and diselenides (RSeSeR) that proved unpleasant to handle because of their highly malodorous nature. Difficulties in purification and the instability of certain derivatives also hampered early workers. Although the number and variety of known selenium compounds had grown dramatically by the 1950s, organoselenium chemistry remained a relatively arcane field of study until the 1970s. Around that time, the discovery of several useful new reactions and of a variety of novel structures with unusual properties began to attract more general interest in the discipline. This led to the appearance of several comprehensive texts on the chemical and biological properties of organoselenium compounds in the 1970s and 1980s.[1–6] Recent advances have also been driven by potential technological applications of, for example, selenium-containing organic conductors; by an increasing awareness of the biological importance of selenium compounds; and by the utility of organoselenium compounds in modern organic synthesis.[7,8] Today, a plethora of such species is known and key compounds are commercially available. Aryl-substituted derivatives and those containing selenium in higher oxidation states are generally less volatile and less offensive to handle than the original aliphatic compounds, and even the latter are now relatively easy to manipulate by modern techniques.

There are formal and behavioral resemblances between many types of organoselenium compounds and their sulfur and tellurium counterparts owing to their proximity in group 16 of the periodic table. For instance, selenols, selenides, diselenides, and selenoxides are in many ways analogous to thiols and tellurols, sulfides and tellurides, disulfides and ditellurides, and sulfoxides and telluroxides, respectively. However, despite formal similarities, there are also many differences between organoselenium, -sulfur, and -tellurium compounds with respect to their stabilities, properties, and reactions. The resemblance between organoselenium and oxygen compounds is considerably less pronounced because of the latter element's substantially higher electronegativity, lower polarizability, stronger bonds with carbon, and lack of available d orbitals for bonding.

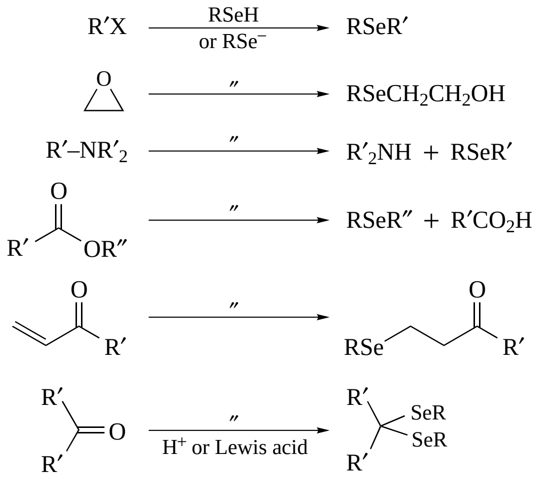
2 SELENOLS AND SELENOLATES

Selenols (RSeH) are relatively strong acids (e.g. p$K_a = 5.9$ for PhSeH[9]) and so their conjugate bases, the selenolates (RSe^-), are readily formed in alkaline solutions. They are most commonly prepared by the reaction of Grignard reagents or alkyl- or aryllithiums with elemental selenium, followed by acidification. Alternatively, selenols and selenolates can be obtained by the monoalkylation of hydrogen selenide or the HSe^- anion with alkyl halides or by the reduction of diselenides with reagents such as sodium borohydride, alkali metals, sodium or potassium hydride, sodium hydroxymethyl sulfoxylate (Rongalite), or hypophosphorous acid. The use of sodium borohydride results in the formation of a borane complex of the selenolate, which tends to suppress the reactivity of the selenolate. On the other hand, alkali metal selenolates in polar aprotic solvents such as DMF or HMPA display enhanced reactivity. The reduction or basic hydrolysis of selenocyanates (RSeCN) also affords selenols and selenolates. These processes are shown in Scheme 1. Both types of products react readily with oxygen to afford diselenides, and so they must be stored and handled under an inert atmosphere.

Although selenols and selenolates are weak bases, they are, nevertheless, powerful, soft nucleophiles[10–12] because of the high polarizability of the selenium atom. They therefore react readily with electrophilic compounds such as alkyl halides and tosylates to afford selenides, and with epoxides to give β-hydroxy selenides. These reactions occur via an S_N2 mechanism with an inversion of configuration at carbon. Aryl halides also undergo substitution with selenolates by means of an $S_{RN}1$ radical mechanism. Selenols are sufficiently acidic to protonate amines and form the corresponding ammonium selenolates. Attack by the highly nucleophilic selenolate anion upon an alkyl group of the ammonium cation of these species then affords the alkyl selenide and dealkylated amine.[9] Similar N-to-Se alkyl transfers have been carried out in the presence of ruthenium catalysts.[13] In contrast with most other nucleophiles, selenolates attack esters and lactones preferentially at the softer alkyl rather than the harder acyl carbon atom, with displacement of the corresponding carboxylate anion.[10–12] However, substitution at the acyl



Scheme 1

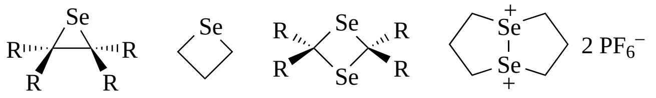


Scheme 2

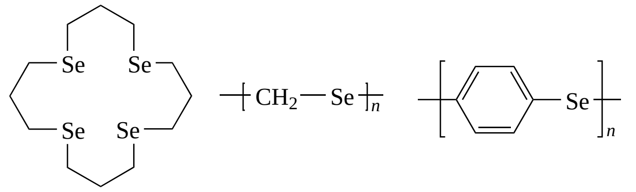
center of methyl esters can be achieved with the selenoalane $Me_2AlSeMe$,[14] to afford selenoesters. The cleavage of arylmethyl ethers and cyclopropanes with selenolates has also been reported. Selenols and selenolates perform Michael additions to enones and other activated alkenes and afford selenoacetals from aldehydes and ketones.[10–12] The selenoboranes $B(SePh)_3$ and $B(SeMe)_3$ are useful alternatives to selenols for this purpose.[15] These processes are illustrated in Scheme 2. Selenols and selenolates act as reducing agents toward a variety of organic functional groups, transforming vicinal dihalides into alkenes; α-halo carbonyl compounds into dehalogenated products; nitro, nitroso, azo, azoxy, and hydrazo compounds into primary amines; imino compounds into secondary amines; and sulfoxides into sulfides.[16,17] Selenolates have also been immobilized on solid supports, and several synthetic applications have been reported.[12]

3 SELENIDES

Acyclic alkyl and aryl selenides (RSeR) are generally stable and have a nonlinear structure. The C–Se–C bond angle of dimethyl selenide is 96.3° and the C–Se bond lengths are 1.945 Å, as determined by microwave spectroscopy.[18] A variety of cyclic selenides of varying stability are also known.[19] For example, episelenides (**1**) are highly labile and extrude selenium spontaneously to generate alkenes. Selenetane (**2**) is isolable but polymerizes easily, while its 3,3-dimethyl derivative is more stable. Several 1,3-diselenetanes (**3**), as well as a variety of relatively stable larger rings, have been prepared. Transannular interactions between the selenium atoms of oxidized cyclic bisselenides (e.g. **4**) have been studied[20] and several selenium analogs of crown ethers (e.g. **5**) have been reported.[21] Polymeric selenides such



(**1**) (**2**) (**3**) (**4**)



(**5**) (**6**) (**7**)

as (**6**) and (**7**) are available from the reactions of Na_2Se with methylene bromide and *p*-dibromobenzene, respectively.

Alkyl selenides are most conveniently prepared by the dialkylation of Na_2Se or by the monoalkylation of selenolates. Common routes to aryl derivatives include the reaction of a selenolate with a diazonium salt, the $S_{RN}1$ reactions described earlier, and the reaction of aryllithiums with aryl selenocyanates (ArSeCN). A different approach employs the reaction of alcohols with aryl selenocyanates or *N*-(phenylseleno)phthalimide (see Section 6) in the presence of tri-*n*-butylphosphine.[22] Similar conditions can also be used to convert carboxylic acids to selenoesters (**8**). These reactions are illustrated in Scheme 3.

Selenides are also nucleophilic and produce isolable selenonium salts (**9**) when treated with alkyl halides. They are easily oxidized to selenoxides (**10**) and further to selenones (**11**) under more forcing conditions (see Section 4). Reduction of selenides to the corresponding hydrocarbons is most conveniently achieved with nickel boride,[23] or with tri-*n*-butyl- or triphenyltin hydride under radical conditions.[24] Other reagents for reductive deselenization include Raney nickel, lithium triethylborohydride, and lithium in ethylamine (Scheme 4). Benzylic selenides undergo radical extrusion reactions under thermal or photolytic conditions to produce

$$Na_2Se + 2\,RX \longrightarrow RSeR$$

$$RSe^- + R'X \longrightarrow RSeR'$$

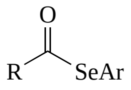
$$ArSe^- + Ar'\text{–}\overset{+}{N}{\equiv}N\ \ X^- \longrightarrow ArSeAr'$$

$$ArSe^- + Ar'I \xrightarrow{h\nu} ArSeAr'$$

$$ArSeCN + Ar'Li \longrightarrow ArSeAr'$$

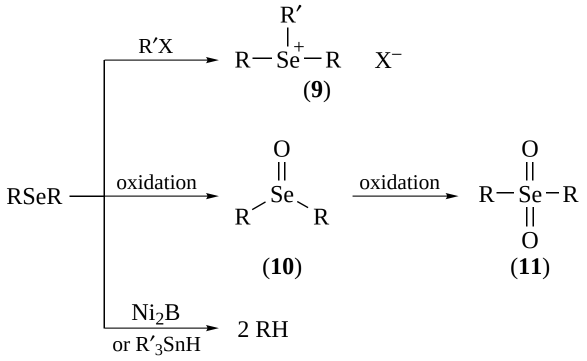
$$ArSeCN + n\text{-}Bu_3P + ROH \longrightarrow ArSeR$$

$$ArSeCN + n\text{-}Bu_3P + RCO_2H \longrightarrow$$

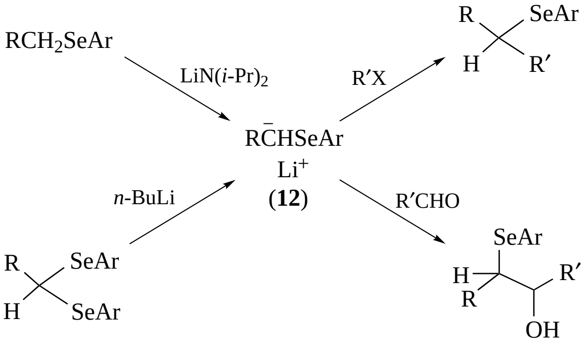


(**8**)

Scheme 3

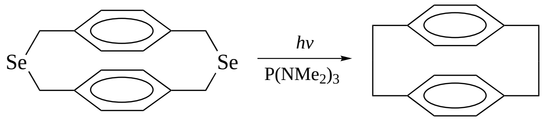


Scheme 4



Scheme 5

coupled hydrocarbon products, including highly strained products such as benzocyclobutane and paracyclophanes (e.g. equation 1).[25] Selenium-stabilized carbanions (**12**) are usually formed by treating selenoacetals with *n*-butyllithium, which cleaves the C–Se bond in preference to deprotonating the α-position. Alternatively, selenides containing α-hydrogens can be deprotonated by strong bases such as lithium diisopropylamide (LDA), although the presence of an additional anion-stabilizing group, apart from the selenium atom, is generally required.[26–29] The anions can then be alkylated, acylated, or added to the carbonyl groups of aldehydes and ketones. These reactions are summarized in Scheme 5.



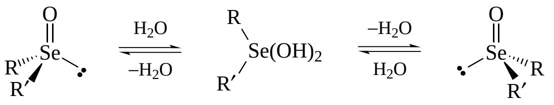
(1)

4 SELENOXIDES AND SELENONES

Selenoxides (**10**) are easily prepared by the oxidation of selenides with numerous types of oxidants, including hydrogen

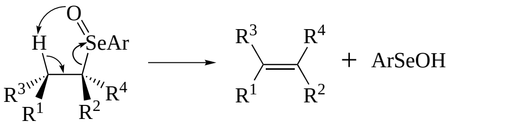
peroxide, peroxy acids, ozone, and sodium *m*-periodate. The reaction is easy to stop at this stage, and further oxidation to the selenone (**11**) requires strong oxidants such as peroxy acids and proceeds relatively slowly. This behavior contrasts with that of the analogous sulfur compounds, where the further oxidation of sulfoxides to sulfones is generally facile and often difficult to avoid.

Selenoxides derived from unsymmetrical selenides are chiral and stable toward pyramidal inversion at room or even higher temperatures.[30] They are produced enantioselectively by the use of chiral oxidants such as the Sharpless reagent[31] or camphor-derived oxaziridines[32] or diastereoselectively with achiral oxidants when one of the selenide substituents is itself chiral (see Section 9). Racemic selenoxides have been resolved by chromatography over chiral adsorbents.[33] Chiral selenoxides racemize readily in water,[30] particularly under acid-catalyzed conditions, presumably via the intermediacy of achiral selenoxide hydrates (equation 2).

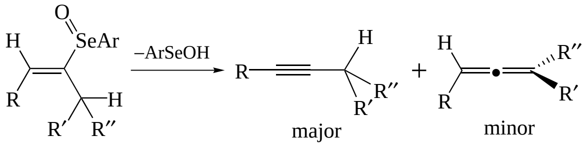


(2)

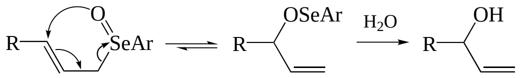
The syn elimination of selenoxides[34,35] containing β-hydrogens is an exceptionally mild alkene-forming reaction that generally takes place at or below room temperature (equation 3). The introduction of an arylseleno group into an organic substrate, followed by its oxidation and elimination, is therefore one of the most valuable synthetic transformations effected with selenium chemistry. The reaction is stereospecific, and the transition state requires all five participating centers to assume a coplanar geometry, with the O atom and the abstracted H atom on the same side of the C–C bond. When diastereotopic β-hydrogens are present, abstraction of the one leading to the trans alkene is favored. The reaction often displays good regioselectivity in those cases where several sites containing β-hydrogens are available. Thus, the double bond is formed preferentially at conjugated positions, away from oxygen substituents to give allylic rather than vinylic products, and toward the less substituted position in the absence of other factors. Vinylic selenoxides containing cis hydrogens produce acetylenes as the major products along with smaller amounts of allenes, while those lacking cis hydrogens afford only the latter products (equation 4). Allylic selenoxides undergo rapid [2,3] sigmatropic rearrangements to the corresponding selenenate esters (**13**).[35–37] The latter then decompose readily to allylic alcohols by hydrolysis (equation 5). It is interesting to note that the reverse process is favored in the analogous sulfur rearrangements, where the equilibrium shifts toward the corresponding sulfoxides instead of the sulfenate esters. Under acidic conditions, or in the presence of electrophiles such as acetic anhydride, selenoxides undergo Pummerer reactions (equation 6).



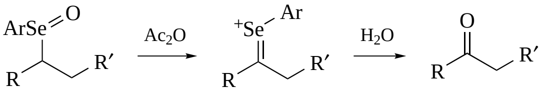
(3)



(4)

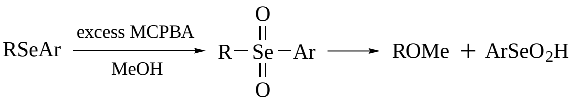


(**13**)
(5)

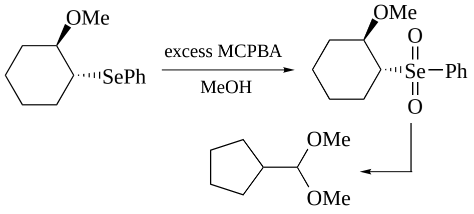


(6)

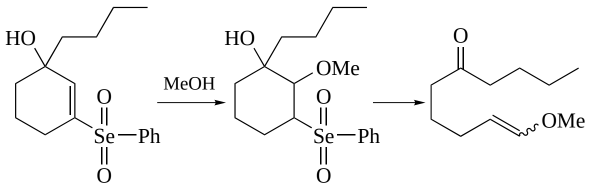
The chemistry of selenones[38] (**11**) has not been studied as extensively as that of selenoxides. However, it has been demonstrated that selenones function as good leaving groups, comparable to tosylates or halides.[39,40] For example, they are readily solvolyzed in methanol and produce rearranged products when β-substituents with high migratory aptitudes are present (equations 7 and 8). Vinylic selenones also act as Michael acceptors,[41] as in the first step of the process shown in equation (9).



(7)



(8)

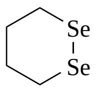


(9)

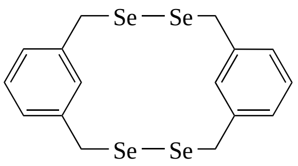
5 DISELENIDES

Acyclic diselenides (RSeSeR), like disulfides and peroxides, are nonplanar and exhibit large dihedral angles. An X-ray

structure of diphenyl diselenide (PhSeSePh) revealed a dihedral angle of 82° and C–Se–Se angles of 104.6° and 107.5°, as well as Se–C and Se–Se bond lengths of 1.93 and 2.29 Å, respectively.[42] Bulky substituents increase the dihedral angle (e.g. 112.1° for *t*-Bu_2CHSeSeCH-*t*-Bu_2), lengthen the C–Se and Se–Se bonds, and result in bathochromic shifts in the UV spectrum,[43] while electronegative substituents shorten the diselenide bond. The preferred conformations of typical diselenides (roughly gauche with a dihedral angle of ca. 80°) are chiral but interconvert rapidly by rotation about the diselenide bond. The barrier to rotation in benzyl phenyl diselenide ($PhCH_2SeSePh$) has been measured to be 6.3 kcal mol^{-1} by dynamic NMR methods at low temperatures and is therefore 1.4 kcal mol^{-1} lower than that in the corresponding disulfide.[44] Simple cyclic diselenides such as (**14**) are known but tend to polymerize readily. A number of more complex cyclic diselenides have also been studied.[45] For example, the conformational properties of the paracyclophane diselenide (**15**) and its selenide counterpart were also investigated by dynamic NMR methods. The diselenide shows nonequivalent methylene protons at low temperatures and interconverts between syn conformers.[46] Theoretical, NMR, electrochemical, and photoelectron spectroscopic studies of cyclic diselenides and related 1,2-dichalcogenins have also been reported.[47,48]



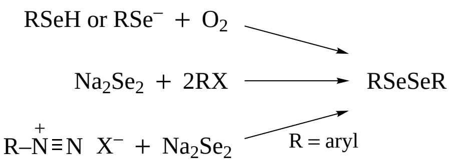
(**14**)



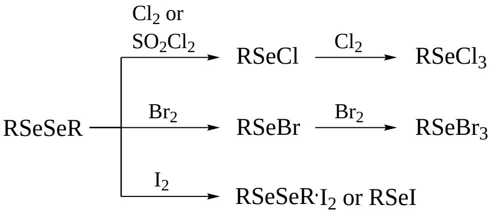
(**15**)

Diselenides are generally prepared by the aerial oxidation of selenols or selenolates (see Section 2) or by the reaction of Li_2Se_2, Na_2Se_2, or other Se_2^{2-} species with alkyl or aryl halides. In the latter case, elevated temperatures and DMF as the solvent are recommended. Aryl diselenides may also be obtained from the reaction of Se_2^{2-} with diazonium salts (Scheme 6). Relatively few unsymmetrical diselenides have been reported. Triselenides are also known but have not been as widely studied.

As shown in Scheme 1, the reduction of diselenides generates selenols and selenolates, while their oxidation results in the formation of selenenic and seleninic acids and related compounds (see Section 7). Halogenation of diselenides with



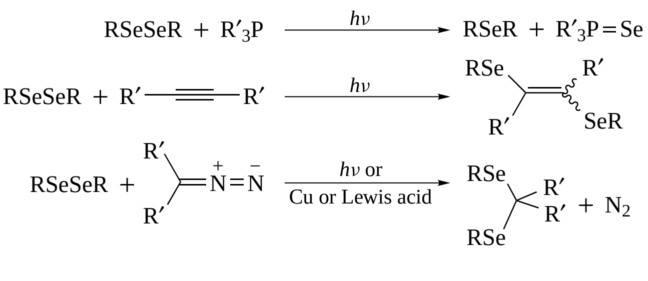
Scheme 6



(**16**)

Scheme 7

sulfuryl chloride, chlorine, or bromine affords selenenyl halides (RSeX) or, with a second mole of halogenating reagent, the corresponding selenium trihalides ($RSeX_3$). The reaction of diphenyl diselenide with iodine produces an adduct (**16**) that is probably a charge transfer complex instead of the selenenyl iodide.[49] This substance performs a number of typical reactions characteristic of a selenenyl halide, suggesting that free PhSeI may be present in solution. The more hindered bis(2,4,6-tri-*t*-butylphenyl) diselenide produced an authentic selenenyl iodide that was characterized by X-ray crystallography.[50] These processes are summarized in Scheme 7. The direct formation of selenenyl fluorides from the fluorination of diselenides has not yet been documented, but PhSeF, or an equivalent species, appears to be generated in situ from the sonication of PhSeBr or PhSeCl, in turn, obtained from halogenolysis of the corresponding diselenide, and AgF in a suitable solvent.[51] Similarly, the reaction of PhSeSePh with XeF_2 generates a species that behaves as the equivalent of PhSeF.[52] When photolyzed or pyrolyzed, diselenides undergo homolytic cleavage of the Se–Se bond, resulting in some interesting radical reactions,[53] such as radical 1,2-additions to acetylenes.[54,55] A palladium-catalyzed 1,2-addition of diselenides to acetylenes has also been reported, which can be performed in the presence of CO to afford (*Z*)-1,3-bis(arylseleno)-2-alken-1-ones.[56] Diazo compounds insert into the Se–Se bond and into a variety of selenium–heteroatom bonds.[57] Some examples of these processes are shown in Scheme 8. Benzylic diselenides extrude selenium under either photolytic or pyrolytic conditions to produce selenides (equation 10),[53] which in turn afford hydrocarbons from



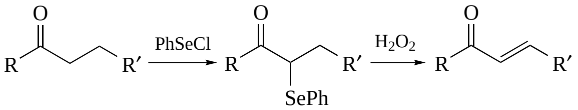
Scheme 8

further extrusion reactions, as indicated earlier.

$$\mathrm{ArCH_2SeSeCH_2Ar} \xrightarrow{h\nu \text{ or } \Delta} \mathrm{ArCH_2SeCH_2Ar} + \mathrm{ArCH_2CH_2Ar} + \mathrm{Se} \quad (10)$$

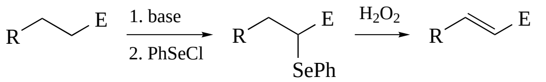
6 SELENENYL HALIDES AND PSEUDOHALIDES

Selenenyl halides are relatively stable, though moisture sensitive, compounds that are generally prepared by the reactions shown in Scheme 7 and behave as electrophilic selenium species.[57–59] They react with ketones and aldehydes via their enols or enolates to afford α-seleno derivatives (e.g. (**17**) in equation 11). Similar α-selenenylations of β-dicarbonyl compounds, esters, and lactones can be performed, although the latter two types of compounds require prior formation of their enolates. Moreover, the α-selenenylation of anions stabilized by nitrile, nitro, sulfone, or various types of phosphorus substituents has also been reported (equation 12). In many such cases, the selenenylation step is followed by oxidation to the selenoxide and spontaneous syn elimination to provide a convenient method for the preparation of the corresponding α,β-unsaturated compound (e.g. **18** in equation 11). Enones react with benzeneselenenyl chloride (PhSeCl) and pyridine to afford α-phenylselenoenones (equation 13).



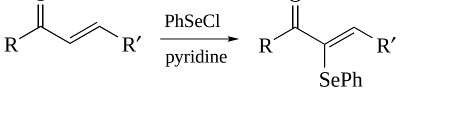
(**17**) (**18**)

(11)



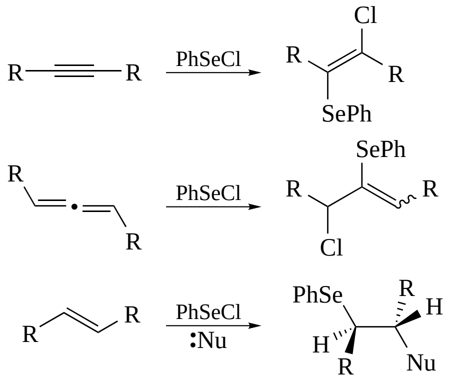
(12)

E = electron-withdrawing group (e.g. CO_2R, CN, NO_2, SO_2Ar, $Ph_2P(O)$, etc.)



(13)

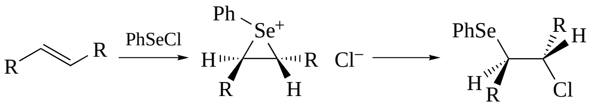
Selenenyl chlorides add to alkenes, often via an Ad_E2 mechanism involving a bridged seleniranium ion intermediate[60] (**19**) (equation 14). These reactions are therefore highly stereospecific, resulting in anti addition. The regiochemistry of the process can be under either kinetic or thermodynamic control. In some cases, initial anti-Markovnikov products were observed at low temperature and Markovnikov adducts dominated after further equilibration. Analogous electrophilic additions to acetylenes and allenes (Scheme 9) have also been reported. When selenenyl halides react with alkenes in the presence of other nucleophiles such



:Nu = OH, OR′, RCN, N_3, NO_2, etc.

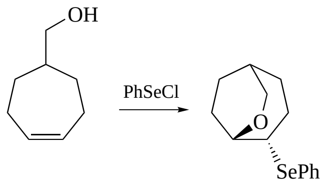
Scheme 9

as water, alcohols, nitriles, or azide or nitrite anions, a 1,2-addition of the selenium residue and the nucleophile to the C=C double bond is often observed (Scheme 9). When a nucleophilic group is present elsewhere in the alkenic substrate, the reaction is intramolecular, resulting in cyclization (e.g. equation 15).[58,59,61,62]



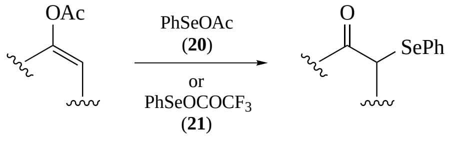
(**19**)

(14)

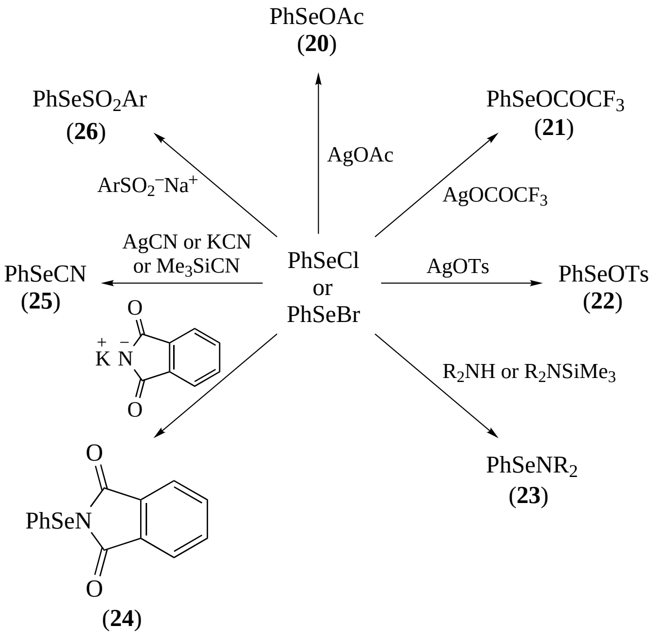


(15)

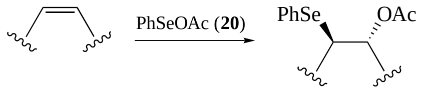
Other species of general structure RSeX, where X = a nonhalide leaving group, are also known and often show similar behavior to that of the selenenyl halides.[57–59] For example, benzeneselenenyl acetate (**20**), trifluoroacetate (**21**), and tosylate (**22**) can be generated in situ from the reactions of the selenenyl halides with silver acetate, trifluoroacetate, or tosylate, respectively (Scheme 10). The former two electrophiles react with enol acetates to produce α-seleno ketones and with alkenes and acetylenes to give 1,2-addition products, while the latter adds similarly to acetylenes. Examples are shown in equations (16) to (18).



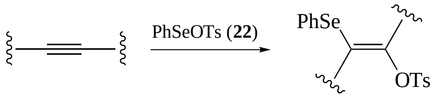
(16)



Scheme 10

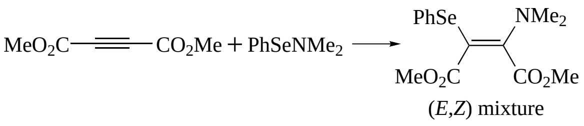


(17)



(18)

Selenenamides (**23**) are obtained by the substitution of selenenyl halides with amines[63] or by the metathesis of the former compounds with *N*-silylamines.[64] *N*-(Phenylseleno)phthalimide (**24**) is similarly obtained using potassium phthalimide (Scheme 10).[65] These compounds can be isolated but are prone to hydrolyze when exposed to moisture. Selenenamides react with aldehydes or β-dicarbonyl compounds to afford α-seleno derivatives (as in the process shown in equation 11), and add to activated double and triple bonds, as in the example in equation (19). The imide (**24**) is a useful alternative to PhSeCl in various selenenylation reactions, and to ArSeCN in the conversion of alcohols and carboxylic acids to selenides and selenoesters (**8**), as shown in Scheme 3.



(19)

The preparation of selenocyanates[66] such as (**25**) can be achieved by the methods shown in Scheme 10, although a useful alternative employs the reaction of potassium selenocyanate (KSeCN) with alkyl halides or arenediazonium salts (equation 20).

$$\text{R–X or Ar–}\overset{+}{\text{N}}{\equiv}\text{N X}^- + \text{KSeCN} \longrightarrow \text{RSeCN or ArSeCN} \quad (20)$$
$$\text{X = halide}$$

Selenocyanates produce selenols or diselenides upon either reduction (e.g. with sodium borohydride) or hydrolysis (see Scheme 1). They undergo displacement of the cyanide ion by various nucleophiles and add to alkenes in a manner similar to selenenyl halides (see equation 14), except that catalysis with Lewis acids is required in the case of unactivated alkenes. The selenocyanates are also popular reagents for the preparation of selenides from alcohols, and (**8**) from carboxylic acids, as indicated in Scheme 3.

The selenosulfonates (**26**) comprise another class of selenenyl pseudohalides.[67] They are stable, crystalline compounds available from the reaction of selenenyl halides with sulfinate salts (Scheme 10) or more conveniently from the oxidation of either sulfonohydrazides ($ArSO_2NHNH_2$) or sulfinic acids ($ArSO_2H$) with benzeneseleninic acid (**27**) (equations 21 and 22). Selenosulfonates add to alkenes via an electrophilic mechanism catalyzed by boron trifluoride etherate, or via a radical mechanism initiated thermally or photolytically. The two reaction modes produce complementary regioselectivity, but only the electrophilic processes are stereospecific (anti). Similar radical additions to acetylenes and allenes have been reported, with the regio- and stereochemistry as shown in Scheme 11. When these selenosulfonation reactions are used in conjunction with subsequent selenoxide eliminations or [2,3] sigmatropic rearrangements, they provide access to a variety of unsaturated sulfone products.

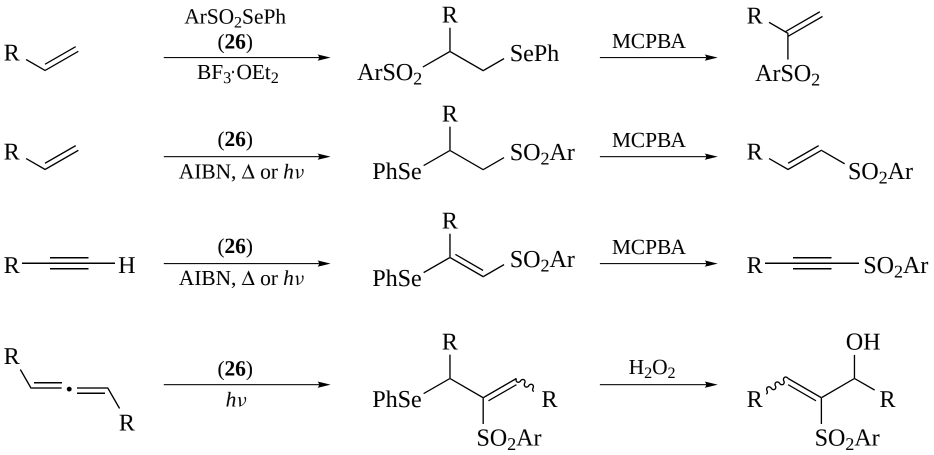
$$ArSO_2NHNH_2 + \underset{(\mathbf{27})}{PhSeO_2H} \longrightarrow \underset{(\mathbf{26})}{ArSO_2SePh} + N_2 + 2H_2O \quad (21)$$

$$2ArSO_2H + \underset{(\mathbf{27})}{PhSeO_2H} \longrightarrow \underset{(\mathbf{26})}{ArSO_2SePh} + ArSO_3H + H_2O \quad (22)$$

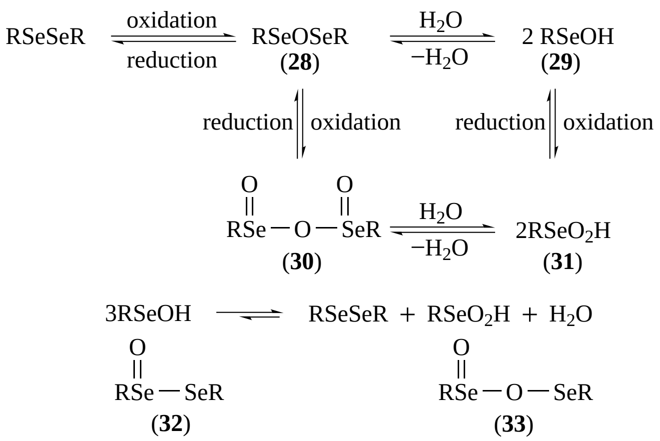
Several types of electrophilic selenium species have been immobilized on solid supports, for more convenient application to organic synthesis. These include selenenyl halides,[68–71] selenocyanates,[72] and selenosulfonates.[73]

7 SELENENIC AND SELENINIC ACIDS AND DERIVATIVES

The partial oxidation of diselenides with appropriate oxidants such as hydrogen peroxide initially generates the corresponding selenenic acids (**29**) or anhydrides (**28**). Further oxidation leads to the corresponding seleninic acids (**31**) or

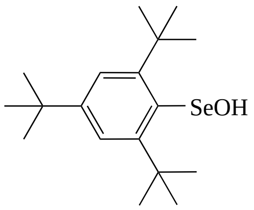


Scheme 11

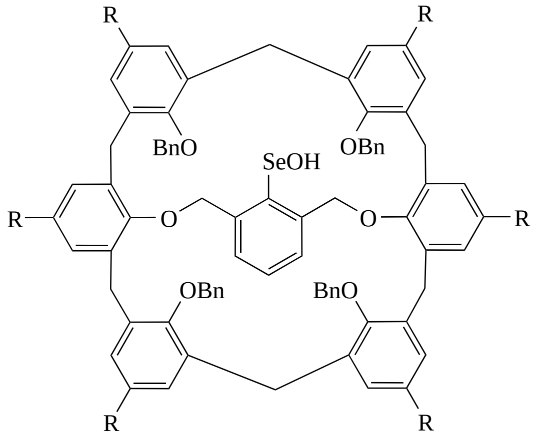


Scheme 12

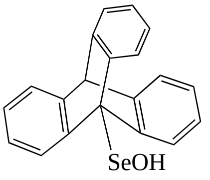
anhydrides (**30**), as shown in Scheme 12. Though the seleninic compounds (**30**) and (**31**) are usually stable and isolable, their selenenic counterparts (**28**) and (**29**) are generally not and disproportionate to mixtures of the initial diselenide and the seleninic acid or anhydride. The disproportionation probably involves intermediates (**32**) and (**33**) (Scheme 12). Several early reports of isolable selenenic acids proved erroneous, although (**34**) has been characterized in solution.[74] More recently, selenenic acids (**35**)[75] and (**36**)[76] were isolated and characterized by X-ray crystallography. A few selenenic anhydrides have been prepared (e.g. **37** and **38**, which are stabilized by the ortho substituent).[77,78] The unstable selenolseleninate (**39**) was observed[79] when the corresponding cyclic diselenide was oxidized with 1 equiv of MCPBA (*m*-chloroperbenzoic acid) at low temperatures, and the similar oxidation of the 1,8-*peri*-diselenide of naphthalene produced a mixture of selenolseleninate (**40**) and selenenic anhydride (**41**).[80] The X-ray structure of an isolable selenolseleninate, structurally related to (**36**), has been reported.[76] Selenenic acids can also be generated in situ by the hydrolysis of selenenyl halides or other derivatives of the general structure RSeX, where X is a leaving group, and by the reduction of seleninic acids or anhydrides. The comproportionation of the latter with diselenides (i.e. the reverse of the disproportionation process in Scheme 12) also produces low equilibrium concentrations of (**28**) or (**29**). The continuous removal of (**28**) or (**29**) by their reaction with an appropriate substrate can, however, drive the reaction to completion.



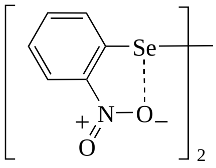
(**34**)



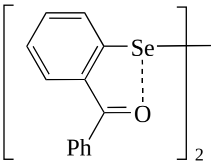
(**35**) R= *t*-Bu



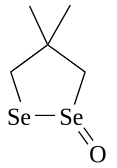
(**36**)



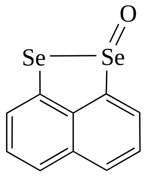
(**37**)



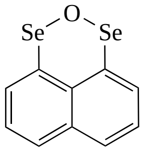
(**38**)



(**39**)

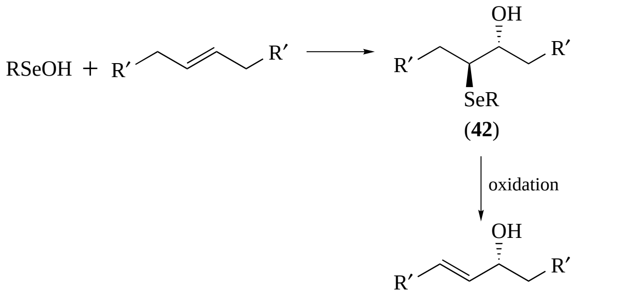


(**40**)



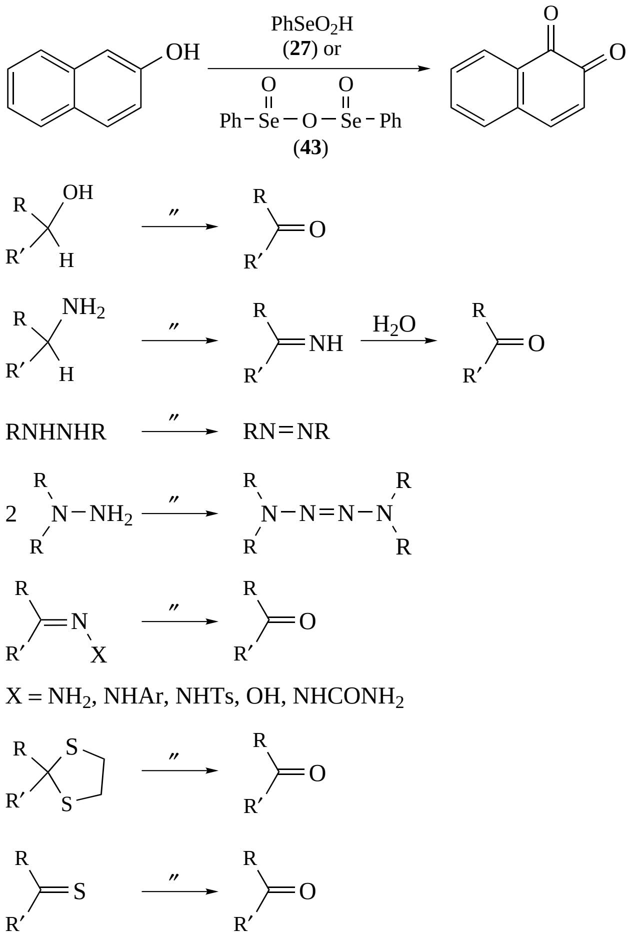
(**41**)

When selenenic acids are generated in the presence of alkenes, addition reactions similar to those of selenenyl halides occur. Oxidation and syn elimination of the adducts (**42**) provide a convenient synthesis of allylic alcohols (equation 23).[57–59]



(23)

Benzeneseleninic acid (**27**) and the corresponding anhydride (**43**) are widely employed as oxidants in organic synthesis.[81,82] The acid is conveniently prepared by the oxidation of diphenyl diselenide (PhSeSePh) with nitric acid, followed by neutralization of the resulting hydronitrate complex ($PhSeO_2H{\cdot}HNO_3$) with a base. The anhydride is obtained by heating the acid in vacuo at ca. 120 to 130 °C. These reagents oxidize phenols to quinones, and primary and secondary alcohols to aldehydes and ketones, respectively. Amines afford imines and the corresponding ketones by subsequent hydrolysis, while hydrazine and its 1,2- and 1,1-disubstituted derivatives produce diimide,

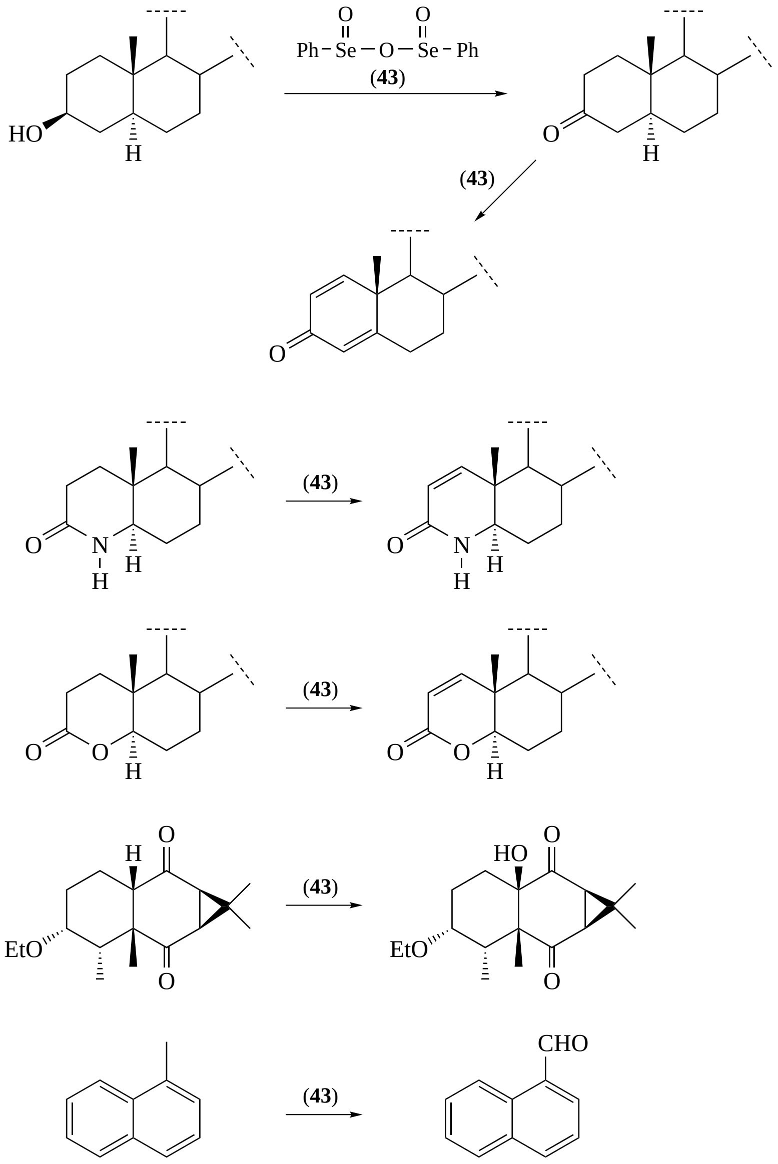


Scheme 13

azo compounds, and tetrazenes, respectively. *N*-Acyl- and *N*-sulfonylhydrazines give selenoesters (**8**) and selenosulfonates (**26**) (see equation 21). These reagents are also useful in regenerating ketones from their hydrazones, oximes, semicarbazones, and dithioacetals. Thiones and other thiocarbonyl compounds are converted into the analogous ketones and other corresponding carbonyl compounds, and sulfinic acids afford (**26**) via equation (22). These processes are illustrated in Scheme 13. They augment the uses of inorganic selenium oxidants such as selenium dioxide (*see* ***Selenium: Inorganic Chemistry***).

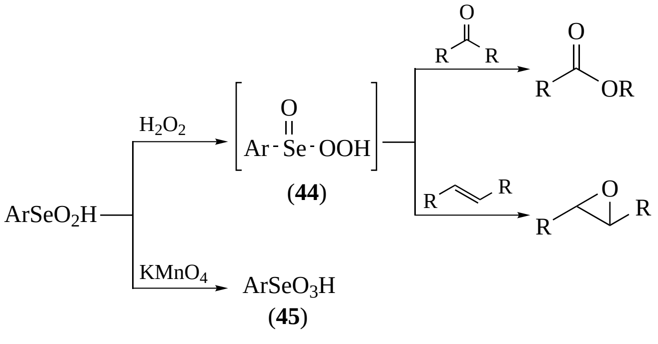
The dehydrogenation of steroidal and other ketones can be accomplished with (**43**) at elevated temperatures.[81,82] Similar reactions with lactones and lactams have also been reported. Other interesting oxidations include the angular hydroxylation of ketones and the oxidation of benzylic hydrocarbons, as shown in Scheme 14. In some cases, the selenium reagent may be employed catalytically in the presence of a less expensive cooxidant that reoxidizes Se^{II} by-products back to the required Se^{IV} oxidation state.

Seleninic acids can also be employed in epoxidation and Baeyer–Villiger reactions[81,82] when used in conjunction with



Scheme 14

hydrogen peroxide (Scheme 15). Intermediate peroxyseleninic acids (**44**) are likely intermediates in these processes.

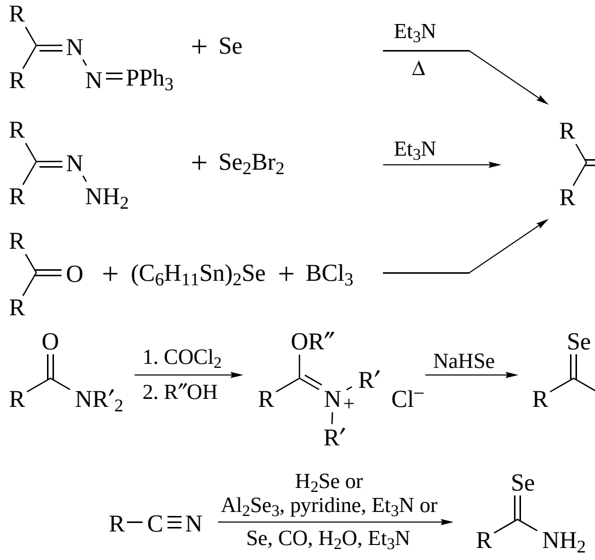


Scheme 15

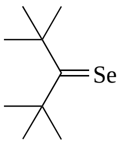
Selenonic acids (**45**) have been little studied but can be produced by the further oxidation of seleninic acids with potassium permanganate.

8 SELENOCARBONYL COMPOUNDS

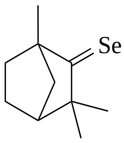
The relatively poor 2p–4p π-overlap of carbon–selenium double bonds makes selenocarbonyl groups less stable than the corresponding thiocarbonyl and carbonyl analogs. Until the mid-1970s, only those selenocarbonyl compounds where the bond order of the C=Se bond was lowered by coordination or resonance were known. However, the isolation of two deep blue, thermally stable selones (**46**) and (**47**) proved that such



Scheme 16

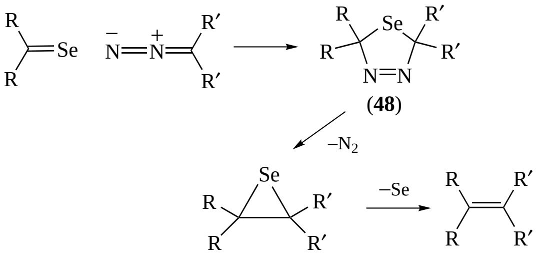


(**46**)



(**47**)

species could exist without electronic stabilization, provided that they were sterically protected.[83] Scheme 16 shows several methods for preparing selones and related selenocarbonyl compounds.[83–86] Perhaps their most notable chemical property involves their cycloaddition with diazo compounds to afford cycloadducts (**48**), which undergo twofold extrusion of N_2 and Se to afford alkenes (equation 24).[83] This method has been employed to produce some of the most hindered alkenes known to date.[83–86] Unlike ketones, selones are attacked by nucleophiles such as phenyllithium at the Se and not the C atom, producing selenium-stabilized carbanion intermediates. They act as spin-traps for radicals, which also attack at the selenium atom. Selones are easily reduced to diselenides by hydrogen selenide, by typical reducing agents such as sodium borohydride, or by photolysis. Less stable selones and selenoaldehydes have been trapped by cycloaddition with cyclopentadiene or other 1,3-dienes,[87] or isolated as the dimeric 1,3-diselenetanes (e.g. (**3**; R = Ph) from $Ph_2C{=}Se$)[88] or as higher oligomers or polymers. Selenoesters and selenoamides tend to be inherently more stable than selones because of resonance and can be prepared as shown in Scheme 16. A variety of other selenocarbonyl compounds, including carbon diselenide, carbon oxyselenide, selenoureas, selenocarbonates, selenoketenes, and others have also been reported.[84–86]



(24)

9 CHIRAL ORGANOSELENIUM COMPOUNDS

As indicated in Section 4, selenoxides bearing two different substituents are intrinsically chiral (i.e. the selenium atom itself is a stereocenter), although their resolution can be challenging. Certain other types of organoselenium compounds, such as selenonium salts (**9**) containing three different substituents, are also chiral and can sometimes be resolved into their respective enantiomers. Moreover, there is growing interest in organoselenium compounds that contain chiral auxiliary groups attached to the selenium atom. In this case, the selenium atom is not the stereocenter, which is instead present in the auxiliary.

A number of useful enantioselective syntheses can be performed by attaching a chiral auxiliary group to the selenium atom of an appropriate reagent.[89,90] Examples of such chiral auxiliaries include (**49–53**). Most of the asymmetric selenium reactions reported to date have involved inter- or intramolecular electrophilic additions to alkenes (i.e. enantioselective variations of processes such as shown in equations (23) and (15), respectively) but others include the desymmetrization of epoxides by ring-opening with chiral selenolates, asymmetric selenoxide eliminations to afford chiral allenes or cyclohexenes, and the enantioselective formation of allylic alcohols by [2,3]sigmatropic rearrangement of allylic selenoxides or related species.

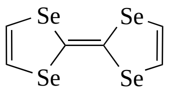
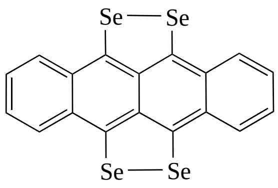
(**53**)

10 ORGANIC CONDUCTORS

A plethora of selenium-containing heterocycles are known to act as the donor component for donor–acceptor complexes that have properties as electrical conductors.[91–93] Two examples that have provoked widespread interest are tetraselenafulvalene (**54**) and tetraselenotetracene (**55**). A variety of selenium-containing polymers such as (**7**) are also of interest in this regard.



(**54**)



(**55**)

11 BIOLOGICALLY IMPORTANT ORGANOSELENIUM COMPOUNDS

Organoselenium compounds play several important biological roles.[2,94–98] They are generally toxic and so must be handled with appropriate care. Selenium intoxication symptoms in animals include ‘alkali disease’ and ‘blind staggers’, symptoms of which have been known for many years. On the other hand, selenium is also an essential trace element and its deficiency in the diet is severely detrimental to both animal and human health and has been implicated in white muscle disease and cardiac myopathy. Moreover, selenium compounds have been claimed to act as carcinogens, while other reports suggest that in appropriate doses they are anticarcinogens. Selenium compounds, in some cases acting synergistically with vitamin E, have apparent roles as anti-inflammatory agents, in maintaining the normal functioning of the immune system, and possibly in retarding the aging process. Much of the biological activity of selenium is associated with its incorporation into selenocysteine residues in the enzyme glutathione peroxidase (*see* ***Selenium Proteins Containing Selenocysteine***), which functions as an antioxidant. This protein catalyzes the reduction of harmful peroxides by glutathione. The peroxides are produced during the course of normal oxidative metabolism and result in damage to biologically important molecules, as well as to cell membranes. A variety of inflammatory conditions and other disease states are related to the undesired physiological effects of peroxides and the free radicals that are produced by them. A number of other selenium-containing proteins are known, along with the semisynthetic enzyme selenosubtilisin.[99] Several small-molecule synthetic compounds designed to mimic the antioxidant effects of glutathione peroxidase have been reported. These include ebselen (**56**),[100] a compound which has undergone clinical trials, as well as more recent compounds[98,101] (e.g. **57**–**61**), some displaying improved catalytic activity. Organoselenium compounds with antibacterial, antiviral, antifungal, antiparasitic, and antiradiation properties have also been reported, as well as selenium analogs of a variety of carbohydrates and nucleosides.

1 INTRODUCTION

As a member of group 6 of the periodic table of elements, selenium shares many chemical properties with its neighboring homolog, sulfur (*see* ***Selenium: Inorganic Chemistry***; ***Selenium: Organoselenium Chemistry***). Both elements occur in the same oxidation states −2, 0, +2, +4, and +6 and they both enter biological macromolecules (protein; tRNA) in the −2 state. However, selenium also differs from sulfur in a number of important properties. The most significant one is that selenol is a more powerful nucleophile than thiol. Since the –SeH group of selenocysteine in proteins exhibits a pK of about 5.2, it is mostly dissociated at the physiological pH, whereas the –SH group with an average pK of 8.6 is predominantly protonated. Therefore, as has been shown for several enzymes, the incorporation of a chemically more reactive selenol group into the active center instead of a thiol confers a dramatic catalytic advantage. This review deals with enzymes from prokaryotes and eukaryotes, which contain a covalent selenocysteine residue, and also describes the present knowledge of its biosynthesis and mode of incorporation. The topic has been covered in several reviews concentrating on the biochemical, the nutritional and physiological, the molecular biological, and the biomedical aspects.[1–6] A comprehensive treatise has been compiled recently by Hatfield.[7]

2 PROKARYOTIC SELENOPROTEINS

2.1 Formate Dehydrogenases

Selenocysteine-containing formate dehydrogenases occur widely in nature. Operationally, they can be differentiated into two groups: enzymes that unidirectionally cleave formate into CO_2 and reducing equivalents, and enzymes that can act bidirectionally by interconverting formate and CO_2 plus reducing equivalents.

2.1.1 Unidirectionally Acting Formate Dehydrogenases

Unidirectionally operating formate dehydrogenases couple formate oxidation to the reduction of endogenously formed or exogenously added electron acceptors. Well-studied examples are the three formate dehydrogenase isoenzymes from *Escherichia coli* or the F_{420}-reducing formate dehydrogenases from archaea.

Under fermentative conditions, *E. coli* synthesizes the so-called formate hydrogenylase complex, which consists of formate dehydrogenase H, several electron carriers, and hydrogenase 3. The formate dehydrogenase H component consists of an 80-kDa selenopolypeptide encoded by the *fdhF* gene and catalyzes the reaction[1]

$$HCO_2H \longrightarrow CO_2 + 2e^- + 2H^+ \qquad (1)$$

The *fdhF* gene product has been purified and subjected to a detailed biochemical and structural analysis.[8,9] It contains an Fe_4S_4 cluster, two molybdopterin–guanine dinucleotide cofactors and a selenocysteine in the active site, and it displays ping-pong bi-bi kinetics for the substrate formate and the artificial one-electron acceptor benzylviologen. The pH profile of inactivation by alkylation follows exactly the dissociation state of the selenol and indicates that selenocysteine is participating in the binding of formate.[8,9]

During anaerobic growth in the presence of nitrate, *E. coli* synthesizes formate dehydrogenase N, which couples formate oxidation to nitrate reduction:

$$HCO_2H + NO_3^- \longrightarrow CO_2 + NO_2^- + H_2O \qquad (2)$$

The enzyme has been first purified by Enoch and Lester[10] and recently shown by X-ray analysis to be a 510-kDa membrane-bound complex of $(\alpha\beta\gamma)_3$ structure.[11] It channels the electrons withdrawn from formate by the α-subunit, which is a selenopolypeptide of 110-kDa molecular mass[12] via 11 redox centers consisting of molybdopterin–guanine dinucleotides and five Fe_4S_4 centers in a single unbranched chain to two heme b groups in the γ-subunit, which also contains a quinone binding site. The formate-binding site is located at the periplasmic side, the quinone reduction site at the opposite side of the cytoplasmic membrane.

Formate dehydrogenase O is present in *E. coli* cells grown aerobically or anaerobically in the presence of nitrate.[13] It is the least well-studied of the three isoenzymes, although it is this system for which a biological role of the element selenium was first demonstrated.[14] Formate dehydrogenase O appears to act as an oxidoreductase coupling formate oxidation with quinone reduction, but a detailed analysis of its structure and redox partners has not yet been carried out.

Depending on the selenium status of the growth medium, *Methanococcus vannielii* synthesizes either one of the two formate dehydrogenases.[15] In the absence of selenium, cells contain a formate dehydrogenase activity that is associated with a 105-kDa polypeptide, which carries a molybdenum cofactor and Fe/S center(s) (1 Mo and 10 FeS), but lacks selenium. When selenite is added to the medium, a 100-kDa selenocysteine-containing polypeptide is formed, which is associated with the 105-kDa polypeptide carrying the Mo–FeS centers. This enzyme complex exhibits a higher catalytic activity than the 105-kDa species alone.[15] Both catalytic species couple formate oxidation to the reduction of the 8-hydroxy-5-deazaflavin cofactor (F_{420}) present in methanogenic bacteria.

2.1.2 Bidirectionally Acting Formate Dehydrogenases

Acetogenic bacteria such as *Clostridium (Cl.) thermoaceticum* or *Cl. formicoaceticum* catalyze an $NADPH_2$-driven CO_2 reduction to formate, which is further reduced via the tetrahydrofolate pathway to the $–CH_3$ oxidation state, as the methyl is finally incorporated into acetic acid. This 'anabolic' formate dehydrogenase has long been known to depend on the presence of Se in the medium for its formation.[16] The enzyme is an $\alpha_2\beta_2$ heterooligomer of 340 kDa; the complex contains two selenocysteine residues, two moles of a tungsten cofactor, and Fe/S centers.[17]

2.2 Hydrogenases

Hydrogenases that catalyze the reversible oxidation of molecular hydrogen into protons and electrons can be classified based on their metal cofactor content into 'Fe-only' hydrogenases and [NiFe] hydrogenases, which also include [NiFeSe] hydrogenases.[18] The amino acid position occupied by the selenocysteine residue in [NiFeSe] hydrogenases is taken by a cysteine residue in [NiFe] hydrogenases. [NiFeSe] hydrogenases are formed by methanogenic bacteria, such as *Methanococcus* (*M*.) *vannielii*,[19] *M. voltae*,[20] *M. jannaschii*,[21] and *M. maripaludis*,[3] and by several sulfate-reducing bacteria such as *Desulfomicrobium* (*D*.) *baculatum*.[18] The [NiFeSe] hydrogenase of *D. baculatum* exhibits the classical $\alpha\beta$ heterodimeric structure of Ni-containing hydrogenases[18] with the large (α) subunit displaying a molecular mass of 62 kDa and the small (β) one a mass of 32 kDa. The large subunit is the selenocysteine-containing polypeptide and also carries the Ni in a 1:1 ratio to Se. Fe/S centers are present in both subunits.[18] EPR spectroscopy of the ^{77}Se-enriched enzyme and Ni and Se EXAFS studies revealed a direct coordination of the nickel atom to selenium,[22] which indicates that one of the four thiolate ligands of the metal center in [NiFe] enzymes is replaced by a selenocysteyl moiety in [NiFeSe] enzymes.

2.3 Glycine Reductase

A number of obligate anaerobic bacteria can ferment amino acids or purine bases by using glycine as the electron acceptor. The key enzyme for this fermentation pathway is glycine reductase; it is unique since it is the only reduction reaction known, which is coupled with energy generation via a substrate-level phosphorylation.[23] The overall balance of the fermentation of an alanine/glycine pair by Stickland organisms like *Cl. sticklandii* or *Eubacterium* (*E*.) *acidaminophilum* is given by equation (3), and that of the purine degradation intermediate formiminoglycine by *Cl. purinolyticum* or *Cl. cylindrosporum* by equation (4).

$$\text{Alanine} + 2\ \text{glycine} + 3\text{ADP} + 3\text{P}_i \longrightarrow 3\ \text{Acetate} + \text{CO}_2 + 3\text{NH}_4^+ + 3\text{ATP} \qquad (3)$$

$$\text{Formiminoglycine} + 2\text{ADP} + 2\text{P}_i \longrightarrow \text{Acetate} + \text{CO}_2 + 2\text{NH}_4^+ + 2\text{ATP} \qquad (4)$$

Three proteins, termed P_A, P_B, and P_C, contribute to the formation of the membrane-bound glycine reductase complex.[1,2] P_A is a 12.5-kDa acidic glycoprotein containing a single selenocysteine (U) residue in a sequence context (CxxU) also present in thioredoxins. P_A actually was the first protein for which the organoselenium compound selenocysteine was identified.[24] Protein P_B also contains a single selenocysteine residue[25] and appears to function in the activation of the specific substrate. Finally, P_C is an $\alpha_4\beta_4$ oligomer where β (48 kDa) carries an acetyl-accepting SH group and α (57 kDa) serves as a membrane anchor for the total glycine reductase complex.

The reaction cycle (Figure 1) initiates by the formation of a Schiff base between glycine and a pyruvoyl group carried by protein P_B. The Schiff base is then attacked by the selenol of protein P_A, resulting in formation of a Se–carboxymethyl intermediate. The next step has not yet been clearly resolved, but on completion, results in the transfer of an acetyl group to the thiol of the β-subunit of protein P_C to yield an acetyl-thioester of P_C and leaving protein P_A in an intramolecular selenadisulfide form. The acetyl-thioester is then cleaved phosphoroclastically with acetylphosphate being released,[23] and the oxidized protein P_A can be reduced involving a redox chain from $NADH_2$, thioredoxin reductase, and thioredoxin.[26]

2.4 Selenoenzymes Involved in Methanogenesis

The analysis of the genome of methanogenic bacteria, in particular, of *M. jannaschii*, disclosed the existence of a number of selenoenzymes involved in the reduction of CO_2 into CH_4.[3,21] Apart from the two classes of hydrogenases (F_{420}-reducing and F_{420}-nonreducing hydrogenases) and the formate dehydrogenase mentioned above, these are formylmethanofuran dehydrogenase and heterodisulfide reductase. Since these enzymes are essential for energy generation, the

organism displays an obligate growth requirement for selenium. Intriguingly, growth of the closely related methanogen *M. maripaludis* on H_2 and CO_2 is independent of the availability of selenium since it possesses a 'backup' system of homologs, which contain a cysteine residue in the position of selenocysteine.[27] An exception is formate dehydrogenase for which no such sulfur homolog exists and consequently growth at the expense of formate requires a supply of selenium. When *M. maripaludis* is cultivated under selenium-adequate conditions, the sulfur enzymes are not synthesized; therefore, selenium or a follow-up product in its metabolism must exert a repressive effect on their formation.[27]

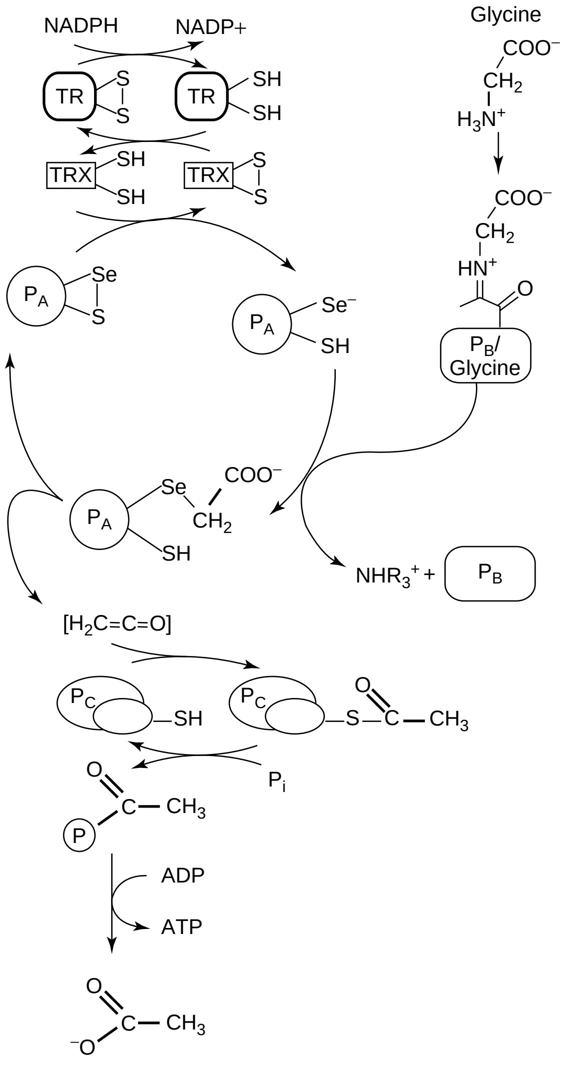

Figure 1 Reactions involved in the glycine reduction pathway by *Clostridia*. P_A, P_B, and P_C denote the components of the glycine reduction complex where P_B is specific for the substrate (e.g. glycine, betaine, sarcosine). The reduction of oxidized protein P_A occurs via a redox chain involving thioredoxin reductase (TR) and thioredoxin (TRX). The involvement of ketene as an intermediate has not yet been proven

3 EUKARYAL SELENOPROTEINS

A recent computational screen of the human genome resulted in the identification of 25 open reading frames as coding for putative selenoproteins.[28] Because of space limitation, this review concentrates only on the discussion of those proteins for which a biochemical function or an important physiological role had been attributed.

3.1 Glutathione Peroxidases

Four different classes of selenium-dependent glutathione peroxidases are known at present: cytoplasmic glutathione peroxidases, plasma glutathione peroxidases, gastrointestinal glutathione peroxidase, and phospholipid hydroperoxide glutathione peroxidases. They all catalyze the reduction of hydroperoxide and organic hydroperoxides by reduced glutathione:

$$\text{ROOH} + 2\text{GSH} \longrightarrow \text{ROH} + \text{H}_2\text{O} + \text{GSSG} \qquad (5)$$

Cytoplasmic glutathione peroxidase is by far the most thoroughly studied species and has been extensively reviewed.[29] It was also the first selenoenzyme to be purified and demonstrated to contain covalently bound selenium.[30] The enzyme is present in the tissues of all mammalia and birds studied. Depending on the species, the molecular mass of the enzyme ranges between 76 and 94 kDa. It is composed of four identical constituent subunits that contain a single selenocysteine residue each.

A detailed kinetic analysis and the modeling of enzyme–substrate complexes with the aid of the 3D structure[31] have led to the suggestion of the reaction mechanism detailed in Figure 2.

According to this model, the dissociated selenol of the selenocysteine in the active center reacts with the

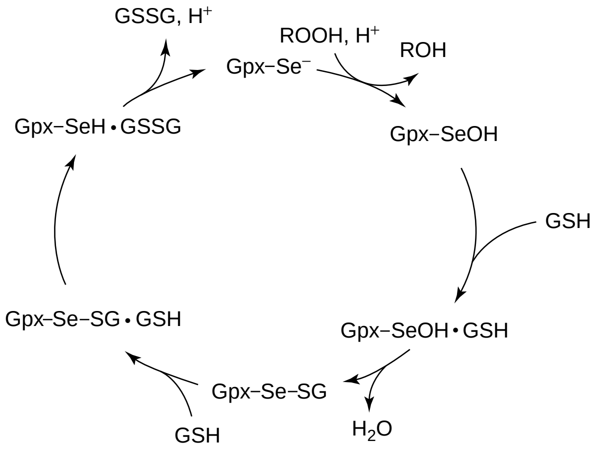

Figure 2 Reaction cycle catalyzed by glutathione peroxidase. GSH and GSSG denote reduced and oxidized glutathione, respectively

hydroperoxide (ROOH), which is reduced to the alcohol state. The selenolate, however, is oxidized to selenic acid, which can now react with reduced glutathione to form a mixed protein–glutathione–selenadisulfide. Experimentally, such an intermediate has been demonstrated to exist. In a consecutive and final step, the mixed selenadisulfide is reduced by a second glutathione molecule, regenerating the protein with a free selenol and producing oxidized glutathione. The efficiency of this regeneration depends on the glutathione concentration, a high concentration in the mM range being crucial, since the rate of this reaction is about two orders of magnitude lower than that of the hydroperoxide with the selenolate. According to the suggested model, selenium changes its oxidation state during the reaction cycle.

A glutathione peroxidase, distinct from the cellular enzyme species, has been purified from human plasma.[32] Its molecular mass was determined to be approximately 100 kDa and it was shown to be a tetrameric protein of identical subunits. Like the cytoplasmic form, it contains four atoms of selenium per mole of protein. In contrast to its cellular counterpart, however, the plasma protein is glycosylated. It catalyzes the reduction of both H_2O_2 and organic hydroperoxides, its affinity for glutathione being an order of magnitude lower than that of the cytoplasmic enzyme. Since the concentration of glutathione in plasma is far below the affinity of the enzyme, it is questionable whether glutathione is the natural substrate. Whereas the cellular enzymes from different species or tissues generally share sequence similarities between 80–95%, the plasma enzyme is evolutionarily more distant.

Ursini and collaborators purified a glutathione peroxidase from pig heart and pig liver that reduced phospholipid hydroperoxides with glutathione as a reductant, especially in the presence of a detergent.[33] Cellular and plasma glutathione peroxidases do not attack lipid hydroperoxides in vitro even in the presence of detergents. The enzyme is a 21-kDa monomer and contains a single selenocysteine residue.[34] The enzyme, termed 'phospholipid hydroperoxide glutathione peroxidase' (PHGPx), is believed to be the major determinant that protects membrane phospholipids from oxidative damage. Apart from this protective effect, PHGPx is involved in the modulation of inflammatory processes by regulating the biosynthesis of leukotrienes and prostaglandins, and may downregulate cytokine-induced transcription activation.[35]

PHGPx also fulfills a fascinating structural role during spermatogenesis It is an active peroxidase in the spermatids and develops into a major structural protein of the mitochondrial capsule of the spermatozoa. The formation of the capsule involves the H_2O_2-stimulated formation of keratin-like protein polymers linked via intramolecular and also intermolecular selenadisulfides with thiols of other proteins. It appears that PHGPx, which is present in extraordinarily high levels and also in different forms in the testes, is responsible for the long-known selenium dependence of male fertility.[36]

3.2 Tetraiodothyronine Deiodinases

3,3′,5,5′-Tetraiodothyronine (T_4; thyroxine) is synthesized in the thyroid gland and converted into 3,3′,5-triiodothyronine (T_3) and 3,3′,5′-triiodothyronine (reverse T_3, rT_3) by tetraiodothyronine deiodinases in nonendocrine organs.[37] The type I deiodinase is formed in the liver and the kidney, and catalyzes the formation of T_3 and rT_3; this class of deiodinase is responsible for producing the major part of T_3 present in the plasma. The type II enzyme is present in other tissues such as the central nervous system and is thought to contribute most of the rT_3 of the plasma. A third deiodinase (type III) is responsible for converting T_4 into hormonally inactive T_3 metabolites. All three deiodinases are selenoenzymes[37–39] with a single selenocysteine residue each. They are encoded by different genes and they control the tissue-specific availability of the endocrine hormone T3.[40]

The reaction cycle depicted in Figure 3 proposes that the enzyme with a free selenolate reacts with T_4 to produce T_3 and an enzyme–iodide intermediate. The selenolate is regenerated and the iodide released by reaction with reduced glutathione. The model also explains the inhibitory actions of gold thioglucose, which reacts with the selenolate, and of propylthiouracil, which releases the iodide from the enzyme–iodide intermediate and forms an enzyme–propylthiouracil–selenadisulfide.

3.3 Thioredoxin Reductase

In 1996, Tamura and Stadtman showed that thioredoxin reductase from mammalia – in contrast to the bacterial homologs – is a selenoprotein, and that selenocysteine is the penultimate C-terminal amino acid residue.[41] Selenium-containing isoenzymes, which are tissue specific, have later on been characterized biochemically, or the existence of such isoforms was suggested by in-silico methods.[4,28,42] The substrate of thioredoxin reductase is thioredoxin, which is the key regulator of the redox status within cells. Thioredoxin catalyzes thiol-disulfide exchange reactions in proteins and peptides; it is involved as redox mediator in the

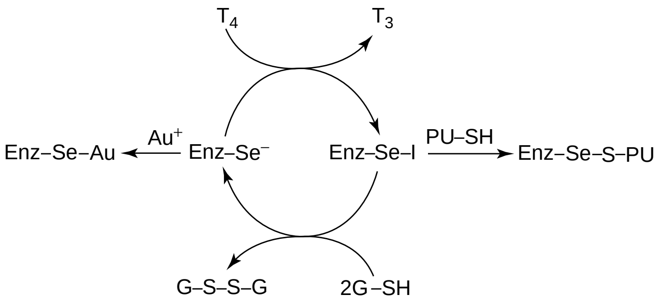

Figure 3 Reaction cycle catalyzed by the type I tetraiodothyronine deiodinase. T_4 = 3,3′,5,5′-tetraiodothyronine; T_3 = 3,3′,5-triiodothyronine; Au^+ = gold thioglucose; PU-SH = propylthiouracil

reaction of ribonucleotide reductase and in the activation of transcription factors and nuclear receptors. Thus, thioredoxin reductase regulates a multitude of metabolic processes and is involved in regulatory cascades within the eukaryal cell.[43] The enzyme is a homodimer with a head-to-tail orientation of the two subunits that form an intersubunit catalytic center.[44] The required reducing equivalents are derived from NADPH and transferred via FAD to a central CysXXXXCys motif of the protein, which in its oxidized form interacts with the selenocysteine of the opposite subunit via a selenadisulfide bond with the concomitant transfer of the reducing equivalents to the oxidized thioredoxin[45] (Figure 4). Both thioredoxin and thioredoxin reductase are essential proteins; the knock out of their genes causes embryonic lethality.

3.4 Methionine Sulfoxide Reductase

Mammalia contain two methionine sulfoxide reductases, forms A and B. Methionine sulfoxide reductase B is a selenoprotein, which reduces the R form of free or protein-bound methionine sulfoxides to methionine with thioredoxin as the reductant.[46] Together with isoform A (which does not contain selenium), the enzyme can repair oxidatively damaged protein and thus contributes to the antioxidant system of the cell.[47]

3.5 Plasma Selenoprotein P

Plasma from mammalia contains a selenoprotein that carries more than 50% of the selenium present. In rat, about 8% of the total selenium content is associated with this protein, selenoprotein P.[48] A change in the selenium status of the rat leads to a rapid change of the selenium level attached to selenoprotein P, preferential to changes of other selenoproteins such as plasma glutathione peroxidase.[48]

Selenoprotein P is a glycoprotein; the sequence of the protein moiety within it, having a molecular mass of about 41 kDa, was deduced from the nucleotide sequence of the rat gene.[49] It is unique since, dependent on the organism, it contains more than a dozen selenocysteine residues per monomer. The sequence also contains histidine- and cysteine-rich stretches, which could be involved in metal binding. Other putative functions discussed for selenoprotein P are selenium transport and tissue-specific delivery or a reducing role.[50]

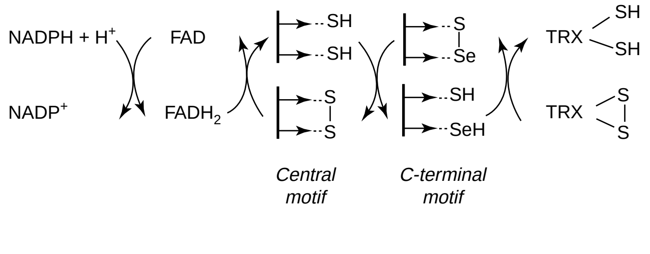

Figure 4 Cascade of redox reactions catalyzed by mammalian thioredoxin reductase

3.6 Selenophosphate Synthetase

Selenophosphate synthetase (SPS) catalyzes the synthesis of the activated selenium species required for the biosynthesis of selenocysteine (see below). The enzyme from *E. coli*, which was isolated first does not contain selenium.[51] It turned out, however, that in most other organisms, SPS is a selenocysteine-containing protein of about 37 kDa in which the selenocysteine occupies the position of a cysteine (Cys-17) in the *E. coli* homolog. Most mammalia possess two types of SPS homologs, one designated SPS II, which is a selenoprotein and possesses SPS activity; the other one, SPS I, has a threonine or arginine residue in the position of Cys-17 (*E. coli* nomenclature) and at least the arginine homolog lacks this activity. The actual function of SPS I is unknown. The reaction catalyzed by SPS is postulated to follow the sequence presented in equations (6) and (7).

$$\text{ATP} + \text{SPS} \longrightarrow \text{SPS-P} \sim [\text{ADP}] \qquad (6)$$

$$\text{SPS-P} \sim [\text{ADP}] + \text{HSe}^- \longrightarrow \text{HSe-PO}_3\text{H}_2 + \text{AMP} + \text{P}_\text{i} \qquad (7)$$

Thus, the γ-phosphate group of ATP is transferred to some group of the protein and the enzyme phosphoryl intermediate is attacked by the selenide generating the only known direct phosphorus–selenium bond in biology. The ADP, which stays complexed to the enzyme is concomitantly hydrolyzed to AMP, and thus thermodynamically drives the overall reaction.[51] Sulfide does not serve as a substrate even at high concentrations, so SPS is one of the few enzymes that can discriminate between its Se substrate and the sulfur homolog. Recent evidence also indicates that the actual substrate is not free selenide but rather some selenium species generated from selenocysteine via the activity of one of the selenocysteine lyases present in the cell.[52]

4 CATALYTIC ROLE OF SELENOCYSTEINE

A question of particular interest concerns the catalytic advantage that a selenol in the active site of an enzyme has in comparison to a thiol group. It has been approached by replacing the selenocysteine in the formate dehydrogenase H by a cysteine residue and by determining the catalytic parameters of the Se-wild-type species with the mutant S-species. Table 1 presents the data obtained. They show that k_{cat} of the Se enzyme is more than 300-fold higher than that of the S variant and that the affinity to the substrate is only marginally affected.[53] Similar replacements of selenocysteine by cysteine in other enzymes like the deiodinase type I or methionine sulfoxide reductase B corroborated these results.

Table 1 Comparison of catalytic parameters of formate dehydrogenases

Enzyme	K_m (mM formate)	k_{cat} (min^{-1})	k_{cat}/K_m ($mM^{-1}\ min^{-1}$)
E. coli, N[10]	0.12	33 800	2.8×10^5
E. coli, H			
Se form[9]	26	170 000	6.5×10^3
S form[9]	9	540	6.0×10^1
M. formicicum[54]	not known	3100	–

In *Methanobacterim formicicum*, the formate dehydrogenase can be considered as a natural S variant of the *E. coli* formate dehydrogenase H since it has 46% sequence similarity and a cysteine residue in the position where the *E. coli* enzyme contains a selenocysteine residue.[1,54] Its k_{cat}, although being sixfold higher than the *E. coli* S species, is almost 50-fold lower compared to the Se form. This protein makes about 3% of the total cellular protein of the methanogen, so it appears that the organism compensates for the low turnover number by synthesizing an increased amount of the enzyme.[54]

In several enzymes, the selenolate group of the selenocysteine residue participates in the coordination of a metal. The catalytic advantage of the liganding of the Ni in the active center of NiFe-hydrogenases via a selenolate to the protein backbone is still not clear since no isogenic mutant forms are available. A comparison of the catalytic performance of [NiFeSe] hydrogenases with [NiFe] hydrogenases led only to some suggestions: (1) [NiFeSe] enzymes may be more efficient in H_2 evolution; (2) they may be activated more easily; (3) the stability of a nickel-bound hydride intermediate may be decreased by the less electronegative selenium, which would increase the probability of a double H^+ exchange.[22] In formate dehydrogenases, the molybdenum, which bridges two pterin guanine dinucleotides, is coordinated to the selenolate of the selenocysteine of the α subunit. In this case, the selenolate appears to directly participate in the reaction by facilitating the abstraction of a proton from the substrate.[9,11]

5 INCORPORATION OF SELENOCYSTEINE

5.1 A UGA Codon Directs Selenocysteine Insertion

A result emerging from the genetic analysis of selenoproteins was the discovery that selenocysteine is the 21st amino acid encoded in DNA.[55] Its insertion is directed by an in-frame UGA codon in the selenoprotein mRNA. UGA is used for this purpose in all three lines of descent (bacteria, archaea, and eukarya): The consistent use of UGA as a signal points to a common evolutionary origin of the selenocysteine coding system.

In the universal genetic code, UGA is one of the three stop codons that signal termination of polypeptide formation. Questions of basic biological relevance emerged from the use of this codon as the selenocysteine insertion signal: (1) What are the mechanisms which warrant that selenocysteine be inserted only at the position of this particular UGA codon, and not at the site of ordinary UGA termination codons? (2) Why does this particular codon not function as a termination signal? The investigation of the sequence context around this UGA did not reveal any peculiar features, which might contribute to its specificity. Rather, a secondary structure downstream of the UGA was found to be crucial (see below).

The existence of a special codon for selenocysteine implied that the amino acid is inserted cotranslationally. This was proved by means of gene fusions in which the 5′ terminal portion of the fusion was derived from the formate dehydrogenase gene (including the TGA) and the 3′ terminal portion was the *lacZ* reporter gene. The *lacZ* portion was translated into β-galactosidase only when the medium was supplemented with selenium although a full-length transcript was present in each case. Ribosomes, therefore, require selenocysteine to move into the *lacZ* mRNA portion.

5.2 tRNA^{Sec} is Responsible for Decoding the UGA

A cotranslational mode of selenocysteine insertion necessitates the existence of a tRNA that carries this amino acid. This tRNA was identified during a screening for *E. coli* mutants blocked in selenoprotein formation.[55] The genes and the function of the gene products found to be involved in selenoprotein synthesis are listed in Table 2.

The product of the *selC* gene, tRNA^{Sec}, was identified as a novel tRNA species. Its structure differs from the features of all elongator tRNAs.[56] With 95 nucleotides, it is the longest tRNA known to date. It has a variable loop of 22 nucleotides, an eight-base-pair aminoacyl acceptor stem, and a number of deviations from tRNA consensus structure. tRNA^{Sec} is charged with L-serine by the cellular seryl–tRNA synthetase, which is responsible for aminoacylation of the serine isoacceptor species. Thus, selenocysteine is formed from a serine residue charged to tRNA^{Sec}.

By chemical and enzymatic probing, the solution structure of this tRNA was analyzed. tRNA^{Sec} is identical to other tRNAs concerning the T-arm and anticodon arm conformations, and the joining of the D- and T-loops by

Table 2 *E. coli* genes and their products with a function in selenoprotein synthesis

Gene	Product function	Size
SelA	Selenocysteine synthase	10×50 kDa
SelB	Translation factor	69 kDa (monomer)
SelC	tRNA^{Sec}	95 nucleotides
SelD	Selenium activation	37 kDa (monomer)

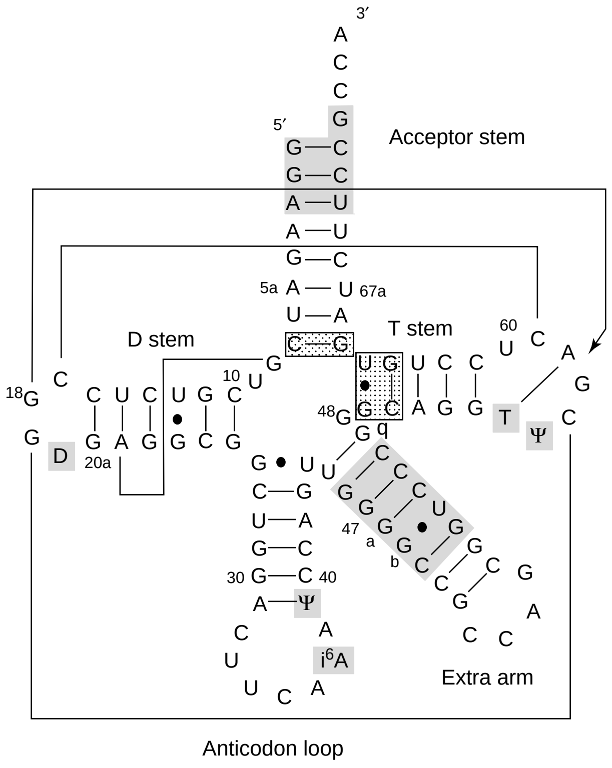

Figure 5 Structural features of the $tRNA^{Sec}$ from *E. coli*. Elements involved in recognition by seryl-tRNA synthetase are shaded, antideterminants against recognition by EF-Tu are hatched. The modified bases are: D: dihydrouridine; Ψ: pseudouridine; i^6A: isopentenyl-adenosine; T: ribothymidine. Tertiary interactions involving base pairing are indicated by lines, those with intercalations by arrows

a tertiary Watson–Crick G19–C56 interaction. Its extra-long arm is double-stranded and closed by a four-nucleotide loop. It possesses novel interactions, namely, a G8–A21–U14 triple pair and an interaction between C16 of the D-loop and C59 of the T-loop. The D-arm has six base pairs instead of three, with the D-loop containing only four nucleotides. The interactions within the $tRNA^{Sec}$ and for comparison, the $tRNA^{Ser}{}_1$ structures are presented in Figure 5. Altogether, the results show that although $tRNA^{Sec}$ displays the canonical L-shape in the three-dimensional structure, nature has used different sets of tertiary interactions to reach this structure.

5.3 Selenocysteine Biosynthesis

Displacement of the OH group of seryl–$tRNA^{Sec}$ by an –SeH group to yield selenocysteyl–tRNA requires the activation of the hydroxyl. When the *selA* gene product was purified, it was found that the protein contains pyridoxal phosphate as a prosthetic group. Accordingly, the reaction mechanism involves the formation of a Schiff base between the carbonyl of the pyridoxal moiety and the α-amino group of serine followed by 2,3-elimination of a water molecule, resulting in the formation of dehydroalanyl–$tRNA^{Sec}$. Nucleophilic addition of selenide from selenophosphate as the selenium donor molecule then delivers selenocysteyl-tRNA.[1,55] Selenocysteine synthase is a decamer of 50 kDa subunits. Two of these subunits bind one seryl–$tRNA^{Sec}$ molecule. Electron microscopy at 20 nm resolution showed that the subunits are arranged with pentameric symmetry and that one tRNA molecule binds peripherally to two subunits.

In summary, selenocysteine is synthesized by the sequence of the reactions

$$\text{L-Serine} + \text{ATP} + \text{tRNA}^{\text{Sec}} \xrightarrow{\text{SerS}} \text{Seryl-tRNA}^{\text{Sec}} + \text{AMP} + \text{PP}_i \quad (8)$$

$$\text{L-Seryl-tRNA}^{\text{Sec}} + \text{SS} \longrightarrow \text{SS-Dehydroalanyl-tRNA}^{\text{Sec}} + \text{H}_2\text{O} \quad (9)$$

$$\text{HSe}^- + \text{ATP} \xrightarrow{\text{SelD}} \text{AMP} + \text{P}_i(\beta) + \text{H}_3\text{PO}_3\,\text{Se} \quad (10)$$

$$\text{SS-Dehydroalanyl-tRNA}^{\text{Sec}} + \text{H}_3\text{PO}_3\,\text{Se} \longrightarrow \text{SS} + \text{Selenocysteyl-tRNA}^{\text{Sec}} + \text{H}_3\text{PO}_4 \quad (11)$$

where SS = selenocysteine synthase and SerS = seryl–tRNA synthetase. Selenophosphate synthesized by SSP (the *selD* gene product) also serves as an activated selenium species for another type of reaction, the conversion of 5-methylaminomethyl-2-thiouridine into 5-methylaminomethyl-2-selenouridine. This modified nucleoside is present in position 34 of the anticodon of $tRNA^{Glu}$ and $tRNA^{Lys}$ acceptor species, both from prokaryotes and eukaryotes.[2]

With regard to selenocysteine biosynthesis in archaea and eukarya, a tRNA has been known for some time, which accepts L-serine and possesses an anticodon complementary to UGA.[5] It shares a number of structural features with $tRNA^{Sec}$ from *E. coli*, such as extended aminoacyl acceptor and D-arms. In eukarya, the serine residue attached to this tRNA can be phosphorylated by a specific kinase and it was first assumed that this tRNA inserts phosphoserine into proteins. However, closer examination revealed that this tRNA carries selenocysteine in vivo and certainly is the pendant to $tRNA^{Sec}$ from *E. coli*. It is still elusive whether *O*-phosphoseryl–tRNA is the biosynthetic intermediate for selenocysteyl-tRNA formation in eukaryotes; also, there is no evidence yet of an eukaryal and archaeal enzyme, equivalent in its function to selenocysteine synthase from bacteria.

5.4 SelB, a New Translation Factor

Mutants of *E. coli* with a lesion in the *selB* gene were unable to synthesize selenoproteins although they accumulated selenocysteyl–$tRNA^{Sec}$ in vivo. This indicated a function of SelB in the decoding process itself. The following experimental results revealed that SelB is a translation factor, specialized for selenocysteyl–$tRNA^{Sec}$: (1) SelB, over its N-terminal two-thirds, displays sequence homology with translation factors such as EF-Tu and IF2α; (2) SelB, like other

translation factors, is a guanine nucleotide-binding protein; (3) SelB binds selenocysteyl–tRNA^{Sec}. The precursor species, seryl–tRNA^{Sec} is not recognized, a fact which contributes to the specificity of insertion. EF-Tu binds selenocysteyl–tRNA with less than 1% of the affinity with which it binds aminoacyl–tRNAs of one of the 20 classical amino acids. This indicates that SelB has a function which is distinct from that of EF-Tu. Thus, EF-Tu forms a ternary complex with one of the 20 standard amino acids and GTP, whereas SelB forms an equivalent complex with selenocysteyl–tRNA and GTP.[57]

Regarding the structural features that enable EF-Tu and SelB to distinguish 'their' tRNAs, an extensive mutational analysis was performed and synthetic RNA 'minihelices' were analyzed for binding to EF-Tu and SelB. It was found that both the length of the aminoacyl–tRNA acceptor stem and the basal helical part of the acceptor arm were crucial.[58]

5.5 mRNA Determinants Required for Decoding UGA with Selenocysteine

In those genes that code for selenoproteins, TGA (UGA) directs the insertion of selenocysteine in all biological systems studied. The question of the recognition of the UGA as a signal for selenocysteine insertion was approached by a mutational analysis. Deletions introduced upstream and downstream of the UGA within the formate dehydrogenase H and N genes revealed the requirement of a segment of 40 nucleotides downstream of the codon.[59] A stable RNA hairpin structure (the SECIS element) can be formed within this RNA segment. The functional role of this hairpin in the selenocysteine decoding process has been proved by genetic and biochemical strategies. It was found that an intact secondary structure with a sequence determinant residing within a single-stranded (loop) region serves as a recognition element for differentiating the selenocysteine-specific UGA codons, thus providing evidence that it is the mRNA context that directs tRNA^{Sec} to decode this position. The nature of the codon/anticodon sequence is irrelevant, the only requirement is that they are complementary.

On the basis of a dual function of UGA as a codon for selenocysteine insertion and for translation termination within a single cell, it has to be assured (1) that this UGA codon is not used as a termination signal and (2) that selenocysteyl–tRNA is directed only to this position. The results of a biochemical analysis indeed revealed that this is achieved by the formation of a complex between SelB, selenocysteyl–tRNA, and the stem–loop structure downstream of the UGA. The binding to the SECIS element was shown to involve an ultimate 17-kDa C-terminal domain of SelB.

The interaction of SelB with its ligands was analyzed by stopped flow methods. The main finding was that binding of the two RNA ligands (selenocysteyl-tRNA and the SECIS element) confers to the SelB protein, a conformation that

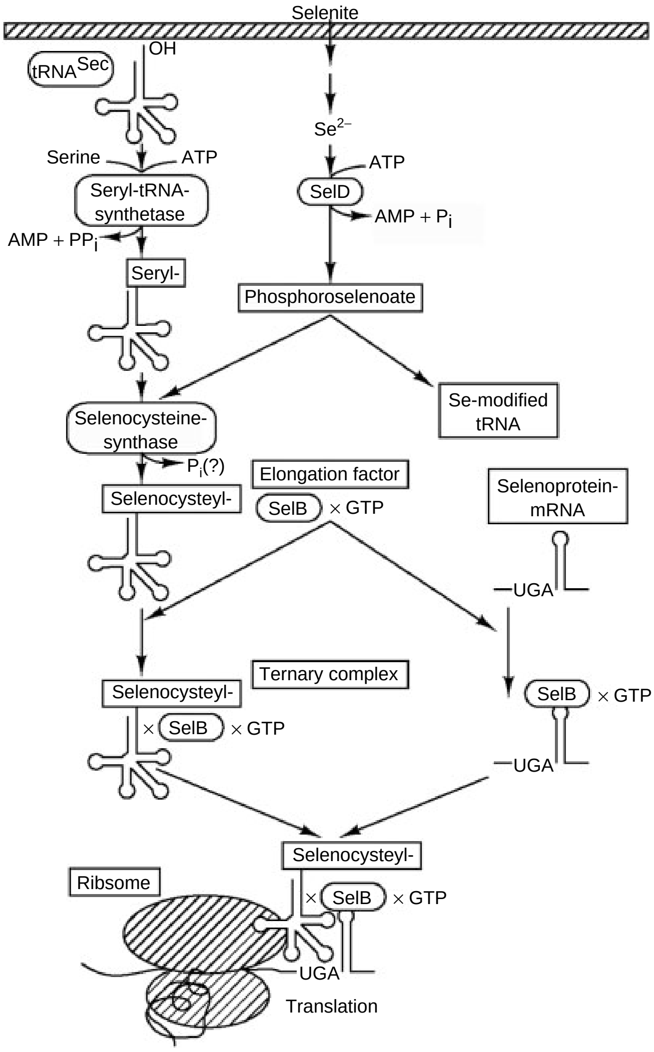

Figure 6 Pathway of selenocysteine biosynthesis and incorporation into protein as resolved for *E. coli*; for details, see text

renders it compatible for interaction with the ribosome. Upon this interaction, GTP is hydrolyzed and the charged tRNA is released in the vicinity of the ribosomal A site. This scenario explains why ordinary UGA stop codons are not translated: since they lack a SECIS element in their vicinity, SelB (which is not complexed to the mRNA) does not possess the productive conformation for the decoding process.[57]

Figure 6 summarizes the steps of selenocysteine synthesis and incorporation, as elucidated for the *E. coli* system.

In mammalia, a recognition element of selenoprotein mRNAs (SECIS) exists within the 3′ untranslated region, and the UGA within the selenoprotein mRNAs is decoded with selenocysteine only when the 3′ untranslated region is present.[5] Substitution of the homologous 3′ region by that of another selenoprotein mRNA allows selenocysteine insertion again. The eukaryal SECIS element is the binding target for a protein designated SBP2 (SECIS element binding

protein 2). SBP2 undergoes protein–protein interaction with a eukaryal homolog of the bacterial translation factor SelB.[6] This interaction is stabilized in the presence of selenocysteyl-tRNA.[60] Therefore, in analogy to the bacterial system, the function of SelB is taken over by two proteins and their stable interaction requires the binding of the charged tRNA thus resembling the formation of the stabilized quaternary complex of SelB.

6 DESIGN OF NEW SELENOPROTEINS

The construction of synthetic selenocysteine-containing proteins or selenium-containing proteins attracts considerable interest at present, mainly for the reason that it can be used to solve the phase problem in X-ray crystallography. Selenomethionine incorporation has been used mostly until now for this purpose. There are also two reports on new synthetic selenocysteine-containing proteins. In one case, the active site serine of subtilisin has been converted into a selenocysteine residue by chemical means, with the result that the enzyme gains a predominant esterase instead of protease activity. In the second case, automated peptide synthesis was carried out to produce a peptide in which all seven-cysteine residues of the *Neurospora crassa* metallothionein (Cu) were replaced by selenocysteine. The replacement resulted in an alteration of both the stoichiometry and the affinity of copper binding.[2]

Future investigations will concentrate on the replacement of cysteine residues by selenocysteine using biological methods. Thus, a system has been established to substitute all cysteine residues of a protein in an overexpression system and it has been used successfully in structural analysis of cysteine-rich proteins and also to replace an active site cysteine by selenocysteine.[61,62] A strategy for the replacement of both methionine and cysteine by their selenium homologs has also been developed recently.[63] It may also be possible, however, to use the information on selenoprotein synthesis in bacteria to achieve targeted replacement of a selected, single cysteine residue. In rare cases, a change of the mRNA sequence by the introduction of silent mutations may be possible to create the determinants necessary for interaction with the translation factor SelB. To this end, a cysteine codon has to be changed to a UGA codon and the 3′ flanking region has to be altered such that the stem-loop structure determining selenocysteine incorporation is generated. This approach, of course, suffers from the strict sequence constraints that may preclude the formation of this mRNA recognition element and may be open for application only in special cases. Thus, the methionine sulfoxide reductase gene from mammalia has been engineered such that the UGA is followed by the *E. coli* consensus SECIS element in the mRNA and in this way recombinant production of the eukaryal enzyme in *E. coli* could be achieved.[64] Also, recombinant mammalian thioredoxin reductase (in which the selenocysteine is the penultimate C-terminal amino acid residue) could be produced in *E. coli* by fusing the *E. coli* SECIS element downstream of the termination codon of the thioredoxin reductase gene.[65]

Glossary

Accumulation region: the region near a semiconductor interface where negative charges (for an n-type semiconductor) accumulate
Band bending diagram: electric potential energy versus distance diagram of a semiconductor contact
Barrier height energy: the energy difference between the bottom of the conduction band of the semiconductor at the interface and the Fermi level of the contacting phase. It is the activation energy required to transfer charge from the contacting phase to the semiconductor
Built-in voltage: the absolute value of the difference between the electric potential of an electron at the semiconductor surface and an electron in the bulk of the semiconductor
Current–voltage properties: dependence of the observed current on the applied potential
Depletion approximation: an approximation that assumes that the net concentration of charges in the depletion region is equal to the dopant concentration. This concentration is constant throughout the depletion region. Furthermore, there are no uncompensated charges in the quasineutral region
Depletion region: a charged region of width W at the semiconductor interface consisting of fixed positive charges (for an n-type semiconductor)
Depletion width: the depth of the depletion region in a semiconductor
Diode equation: the equation that describes the relationship between the applied bias and the resulting current of a semiconductor contact. It is generally of the form $I = -I_0(\exp(-qV/kT)-1)$ where I_0 is the equilibrium exchange current and V is the applied bias
Electrochemical potential: quantity that describes the thermodynamic tendency of a phase to gain or lose electrons to another phase
Exchange current: the microscopic current crossing a semiconductor interface in either direction at equilibrium
Fermi level: the energy level where the probability of finding an electron is 1/2
Fermi level pinning: the ability of surface states to 'buffer' the Fermi level of the semiconductor from changes in the electrochemical potential of the contacting phase
Forward bias: the sign of the applied potential that results in an exponential increase in the current passing through a semiconductor junction
Homojunction: a junction formed between two identical semiconductors of different doping densities or dopant atoms
Quasineutral region: the region in a semiconductor where the net charge density is zero
Rectification: the asymmetric current–voltage characteristics of a semiconductor junction, in which charge-carrier flow is impeded in one direction, but not in the other direction
Reverse bias: the sign of the applied potential opposite to forward bias. In reverse bias, the current through a diode is essentially independent of the applied potential
Schottky barrier: a rectifying semiconductor/metal junction
Surface states: energy levels arising from atoms at the semiconductor surface
Work function: the minimum energy required to remove an electron from a phase to vacuum

Abbreviations

A_s = surface area of a semiconductor contact; $[A^-]$ = concentration of the reduced form of a redox couple in solution; $[A]$ = concentration of the oxidized form of a redox couple in solution; A^{**} = effective Richardson constant; $E(A/A^-)$ = electrochemical potential of a solution; E_{cb} = energy of the conduction band edge; E_F = Fermi level; $E_{F,m}$ = Fermi level of a metal; $E_{F,sc}$ = Fermi level of a semiconductor; $E(A/A^-)$ = redox potential of a solution; $E^{\circ'}(A/A^-)$ = formal redox potential of a solution; $\mathcal{E}$ = electric field; $\mathcal{E}_{max}$ = maximum electric field at a semiconductor interface; e = number of electrons transferred per molecule oxidized or reduced; F = Faraday constant; I = current; I_0 = exchange current; k = Boltzmann constant; k_{et} = intrinsic rate constant for electron transfer at a semiconductor/liquid interface; k_n = forward electron transfer rate constant; k_n^{-1} = reverse electron transfer rate constant; N_d = concentration of donor atoms in an n-type semiconductor; NHE = normal hydrogen electrode; n = electron concentration; n_b = electron concentration in the bulk of a semiconductor; n_s = electron concentration at a semiconductor surface; n_{so} = electron concentration at the surface of a semiconductor under equilibrium conditions; Q = charge per unit area; q = elementary charge; R = gas constant; SCE = saturated calomel electrode; sc = semiconductor; T = temperature; V = electric potential; V_{bi} = built-in voltage; V_n = the potential difference between the Fermi level and the conduction band energy in the semiconductor bulk; W = depletion width in a semiconductor; x = distance; ε_s = static dielectric

constant; φ = work function; ϕ_b = barrier height; λ = nuclear reorganization energy for an interfacial electron transfer process.

1 INTRODUCTION

Semiconductors are technologically important, in large part due to their unique electrical and optical characteristics (*see* ***Semiconductors***). However, the construction of practical devices from semiconductors generally requires the formation of electrical contacts. The nature of these biphasic electrical contacts can modify, and can sometimes completely determine, the electrical and optical characteristics of the resulting device.[1] For example, contacting n-type Si with indium yields an ohmic, resistive electrical contact that freely passes current in both directions, whereas contacting n-type Si with gold yields a rectifying contact that passes current freely in one direction but effectively prevents its flow in the other direction.[2] Similarly, Si/HF(aq) junctions are useful for lithographically patterning and etching Si, while Si/methanol junctions provide the basis for efficient, stable, photoelectrochemical solar energy conversion devices.[3,4] Clearly, an understanding of the chemistry of semiconductor surfaces, and of contacts to these surfaces with other phases, is an important component in the design of any semiconductor-based device.[5–8] This article is therefore devoted to a description of the basic chemical and physical properties of semiconductor contacts.

The distinguishing feature of a semiconductor contact is the electric field that is present in the vicinity of the junction. Whenever two phases are brought into contact, charge must flow across the interface until the electrochemical potential of both phases is identical at all points in space. For example, when two metals are brought into contact, charge flows in response to the contact potential difference between the two phases. After this equilibration process has occurred, the physical characteristics of the metallic phases are essentially unchanged, because any excess charge at the metal/metal interface is screened in the first atomic layers of the metals (Figure 1). For contacts to semiconductors, however, the charge is not completely screened at the semiconductor surface, and an electric field is present in the semiconductor. A large interfacial electric field will generally induce a change in the charge-carrier concentration near the semiconductor surface. A large electric field will also direct and accelerate the motion of charge carriers, and can produce a nonzero flux of charge carriers toward the junction. Such effects can dramatically change the properties of the resulting semiconductor devices. For these reasons, chemical control over the electric fields at semiconductor contacts is desirable in essentially all semiconductor devices.

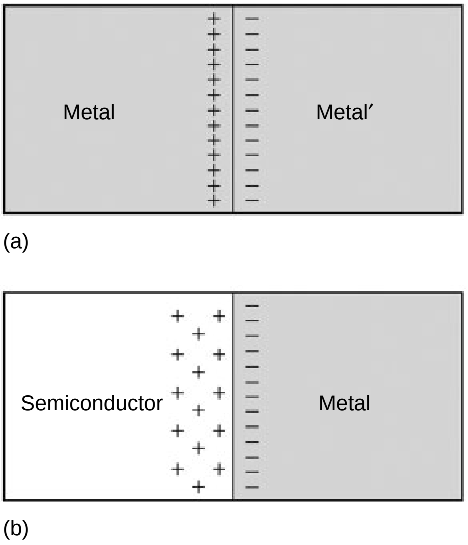

Figure 1 Charge transfer equilibration processes. (a) At a metal/metal′ junction; all the required charge is held within the first few layers of the junction. (b) At a metal/semiconductor junction; the charge arises from the ionization of dopant atoms, and produces an electric field in the bulk of the semiconductor

The focus of this article will be to describe, first qualitatively and then quantitatively, the electrical properties of semiconductor contacts. The goal is to understand the origin of the electric field at semiconductor contacts, to describe the field strength as a function of distance into the semiconductor bulk, and to understand the effects of the interfacial field on the current–voltage characteristics of the device. This discussion will be presented from a general perspective, and will be applicable to semiconductor/metal, semiconductor/liquid, semiconductor/semiconductor, and semiconductor/conducting polymer contacts. The discussion will provide an understanding of the principles behind the operation of diodes, transistors, photovoltaic cells, photoelectrochemical cells, light-emitting devices, and other technologically important semiconductor devices.

2 EQUILIBRIUM STATE AT A SEMICONDUCTOR JUNCTION

In its simplest terms, the charge transfer between a semiconductor and a contacting phase is no different from the charge transfer between atoms to form an ionic bond. For example, chemists realize that a neutral sodium atom will transfer charge when it encounters a neutral chlorine atom, because Na has a low electronegativity and Cl has a high electronegativity. The bond formation between these atoms results in an equilibrium state in which the compound NaCl is best represented with an ionic bond, that is, Na^+Cl^-. It is also obvious to chemists that the difference in electronegativities of the atoms will

determine the degree of charge transfer in the molecule, with HCl having a much more covalent bond than NaCl.

The charge transfer reaction between two phases is governed by similar principles. However, the controlling factor in this situation is the electrochemical potential. Whenever two phases of differing electrochemical potentials are brought into contact, the phase that has a more negative electrochemical potential will tend to lose electrons to the phase with a more positive electrochemical potential (*see* ***Semiconductors*** for the sign convention on the electrochemical energy scale). Net charge transfer between the two phases will then occur until equilibrium is established.

At equilibrium, one phase will have an excess of positive charge, and the other phase will have an excess of negative charge. The initial difference in electrochemical potentials between the two phases will determine the degree of charge transfer across the phase boundary, much as the difference in electronegativity indicates the degree of bond ionicity in molecules formed from neutral atoms. The only conceptual difference between the molecular case and the semiconductor contact is that a physical junction between the semiconductor and the contacting phase provides an obvious dividing line to separate the phase that loses electrons from the phase that gains them.

In most of our examples, the semiconducting solid will be one of the phases that is undergoing charge transfer. A metal, with its high density of electronic states available to accept or donate charges, will be the other phase. An analogous treatment can be used to describe the charge transfer at semiconductor/liquid, semiconductor/polymer, and semiconductor/semiconductor contacts, but the semiconductor/metal contact is the simplest to describe conceptually. These different contacts have quantitative differences in the actual degree of charge transferred upon equilibration, but the qualitative principles are the same in all cases. Whenever possible, the discussion will be generalized to cover all of the junction types, with specific features of the different junctions discussed where appropriate.

2.1 Depletion

2.1.1 *Qualitative Description of Interfacial Charge Equilibration*

The simplest case to consider is the situation that describes the contact between an n-type semiconductor and a metal. As discussed above, the factor that controls the charge transfer process is the electrochemical potential, or Fermi level, E_F, of each phase.[9] The initial difference in the electrochemical potentials of the two phases indicates that, after contact, charge must flow between the phases in order to reach equilibrium. We will consider the case where the electrochemical potential of an isolated n-type semiconductor ($E_{F,sc}$) is more negative than the electrochemical potential of an isolated metal phase

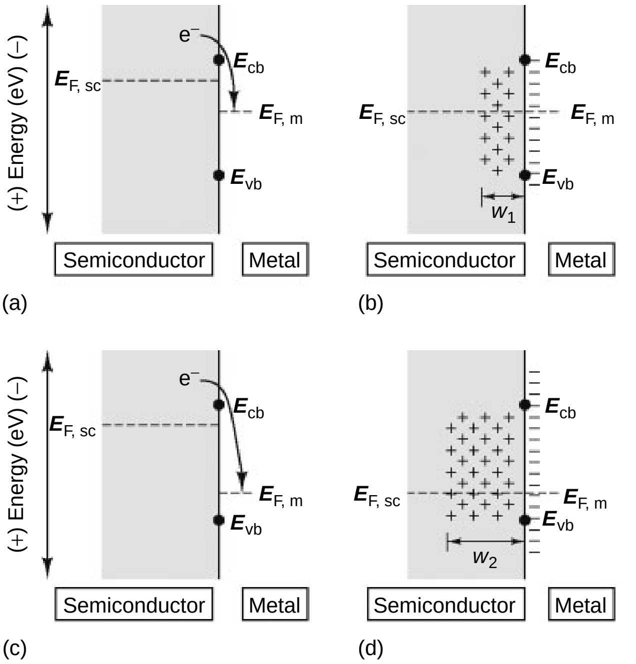

Figure 2 Charge transfer equilibration processes at semiconductor/metal junctions. (a) Before equilibrium is established, the entire semiconductor is neutral. (b) At equilibrium, a positively charged region of width W_1 is present in the semiconductor. (c) Similar to (a), except that the Fermi level in the metal ($E_{F,m}$) is farther from vacuum (more positive) than in (a). (d) Similar to (b), but the charged region extends deeper into the semiconductor ($W_2 > W_1$), because the number of charges that must cross the semiconductor/metal interface is greater. In both (b) and (d), the positions of the conduction and valence band edges are unchanged by the charge equilibration processes

($E_{F,m}$) (Figures 2a and c). In this situation, charge will leave the semiconductor, because it has a more negative initial electrochemical potential ($E_{F,sc} < E_{F,m}$). This charge will be accepted by the metal phase, which has a more positive electrochemical potential.

As a result of this initial difference in electrochemical potentials, the transfer of electrons across the semiconductor/metal junction disrupts the original charge neutrality of the semiconductor and the metal. This interfacial charge-transfer process produces an excess of positive charges in the semiconductor and an excess of negative charges in the metal (Figures 2b and d). In essence, a capacitor is charged during this process, and the components of the capacitor are the electrons in the metallic phase and the positive charges in the semiconducting phase. This charging process continues until the initial difference in electrochemical potentials is neutralized, that is, until the capacitor is sufficiently charged that no further net charge transfer is thermodynamically possible. At this point, equilibrium is attained between the two phases. At equilibrium, electric fields and electric potential gradients are present in both the semiconducting and metallic phases, since neither phase is electrically neutral.[10]

In general, the addition of excess negative charges to a phase will tend to decrease the value of its electrochemical potential (i.e. shift E_F more negative). This can be rationalized because it is easier to ionize a phase with excess negative charges than one without such an excess. For an arbitrary phase in contact with a semiconductor, it is not always possible to predict a priori whether the Fermi level of the semiconducting phase will move more or less than that of the contacting phase. However, for semiconductor/metal contacts, it is possible to predict what will occur. The number of available electronic states per unit energy in the metal far exceeds the number present in a semiconductor, because the semiconductor has essentially no available states in its band gap region.[9] Consequently, the capacitance of the metal phase is much larger than the capacitance of the semiconductor phase. Thus, during the equilibration process, a relatively small percentage of the available states in the metal are filled and there is little negative movement of the electrochemical potential of the metal. The Fermi level of the n-type semiconductor, however, shifts positively until it reaches the value of the metal Fermi level. In chemical terms, the metal acts as an excellent 'buffer' of energy with respect to the excess charge. This situation is analogous to aqueous buffers that resist changes in pH when mixed with nonbuffered solutions that contain small amounts of H^+.

The equilibrium positions of the Fermi level for both the semiconducting and the metallic phases are therefore essentially equal to the initial value of the electrochemical potential of the metal, $E_{F,m}$ (Figure 2). When sufficient charge has transferred across the interface to produce this change in $E_{F,sc}$, equilibrium is reached, and no further net flow of charge across the metallurgical boundary will occur.

Without any additional quantitative information, some important chemical trends in junction behavior can be clearly understood. In a molecule, a large difference in electronegativity between bonded atoms leads to a large degree of ionicity in the bond. A greater initial difference in the electrochemical potentials of the isolated semiconducting and metallic phases should therefore produce a greater propensity for interfacial charge transfer at the semiconductor/metal junction. Using our example of an n-type semiconductor, metals with more positive electrochemical potentials produce greater initial contact potentials to a given semiconductor surface. These metals would thus be expected to produce larger degrees of interfacial charge transfer than metals with less positive electrochemical potentials (Figure 2). Similarly, an n-type semiconductor with a more negative Fermi level, that is, either a more highly doped sample of a given material, or a semiconductor with a more negative conduction band edge at a similar doping level, would be expected to produce a greater degree of charge transfer when placed in contact with a given metal. This chemical control over the charge-transfer process is one of the key experimental features of semiconductor contacts.

2.1.2 *Depletion Width*

An important quantity, the depletion width (W), can also be understood using these qualitative concepts. For a doped semiconductor, charge-transfer equilibration removes carriers from the sites that are most easily ionized. Thus, charge is typically removed from the dopant atoms, as opposed to being removed from atoms of the semiconductor material. For example, in phosphorous-doped n-type Si, charge-transfer equilibration would be accomplished by transferring the easily ionizable fifth valence electron from the P dopant atoms, as opposed to transferring electrons arising from ionization of the Si lattice atoms (*see* ***Semiconductors***). In order to reach charge transfer equilibrium, a certain number of charges must be pulled out of the semiconducting solid. The number of charges is generally far larger than the number of dopant atoms present in one atomic layer of the semiconductor.[1] Thus, as depicted in Figures 2(b) and (d), greater degrees of charge transfer require that we 'reach further into' the bulk of the semiconductor to obtain the proper number of ionizable charges from the semiconductor.

The depth over which dopants are ionized can be readily calculated. For an n-type semiconductor of majority carrier density N_d, a good first approximation is that charge transfer produces a fixed concentration of charged dopant atoms for a depth W. Within this depth, essentially all of the electrons donated by the available dopants have been removed from the semiconductor, and the ionized dopant atoms are left in this region as fixed positive charges. Beyond this depth, however, essentially no electrons have been removed, and the ionized dopants are neutralized by the surrounding electrons. This approximation is called the depletion approximation.[10] In the semiconductor, the charged region of width W is called the depletion region.

With this approximation, W is readily calculated if the amount of charge transferred per unit area, Q, is known. The value of W is then simply Q/N_d. When a higher dopant density is available for donating electrons to the metal, one needs to 'reach in' less deeply into the semiconductor to achieve the same degree of charge transfer. Thus, for a given initial contact potential, the value of W becomes smaller as the dopant density increases. W will be an important quantity to understand when considering the effects of various chemical modifications on the behavior of semiconductor/metal interfaces. An accurate calculation of W, using the depletion approximation, depends only on a prediction of the amount of charge per unit area, Q, that must be transferred to equilibrate the desired semiconductor/metal interface.

2.1.3 *Quantitative Description of Interfacial Charge Equilibration*

It is also important to understand quantitatively the strength of the electric field, and the values of the electric potential that are produced as a result of this charge-transfer equilibration

process. Simple electrostatic considerations suggest that an electric field and an electric potential will be present in the semiconductor, because the interfacial charge transfer has removed negative charges from an initially neutral phase to produce a net positive charge density in the semiconductor portion of the junction.[11] Our goal now is to describe quantitatively the electric field and electric potential at a semiconductor junction.

The relationship between the charge density and the electric field strength is obtained from electrostatics. Consider a negative test charge that we will bring through the semiconductor and toward the semiconductor/metal interface. Within the bulk of the semiconductor, the negative charges on the metal side of the interface are offset (i.e. screened) by an approximately equal number of positive charges in the depletion region of the semiconductor. Thus, negligible electric fields are experienced by this test charge. This region is called the quasineutral region of the semiconductor, as a negative test charge in the bulk of the semiconductor is not influenced by the presence or absence of charge transfer at the semiconductor/metal interface.

As we move our negative test charge closer to the semiconductor/metal interface, it will penetrate the depletion region. This negative test charge will then be repelled from the interface, because it will experience the repulsion of those negative charges in the metal, which are not screened by the positive charges in the semiconductor. Another way of thinking about this situation is that there is now a net dipole acting on the test charge, and this dipole repels the charge from the interface. This net dipole arises from the excess of negative charges that are sensed by the test charge when it is located within the depletion region.

The presence of this electric dipole implies that work is required to push this negative test charge toward the interface. We can quantitatively express this work either in terms of the electric field strength at each position in the semiconductor, or in terms of the electric potential at each position of the system. According to electrostatics, the electric field is proportional to the integral of any excess charge density along the path of interest.[11] Thus, using the depletion approximation, which states that the charge density is simply the dopant density for all values of distance, x, up to the depletion width, we calculate that:

$$\mathcal{E}(x) = \left(\frac{qN_\mathrm{d}}{\varepsilon_\mathrm{s}}\right) x \tag{1}$$

where $\mathcal{E}(x)$ is the electric field at position x in the semiconductor, ε_s is the static dielectric constant of the semiconductor, q is the elementary charge, and N_d is the dopant density of the n-semiconductor. In equation (1), the origin of the x-axis has been defined as the position that separates the depletion region from the quasineutral region; therefore, the semiconductor/metal interface is at a distance W ($W > 0$) from the origin (Figure 3).

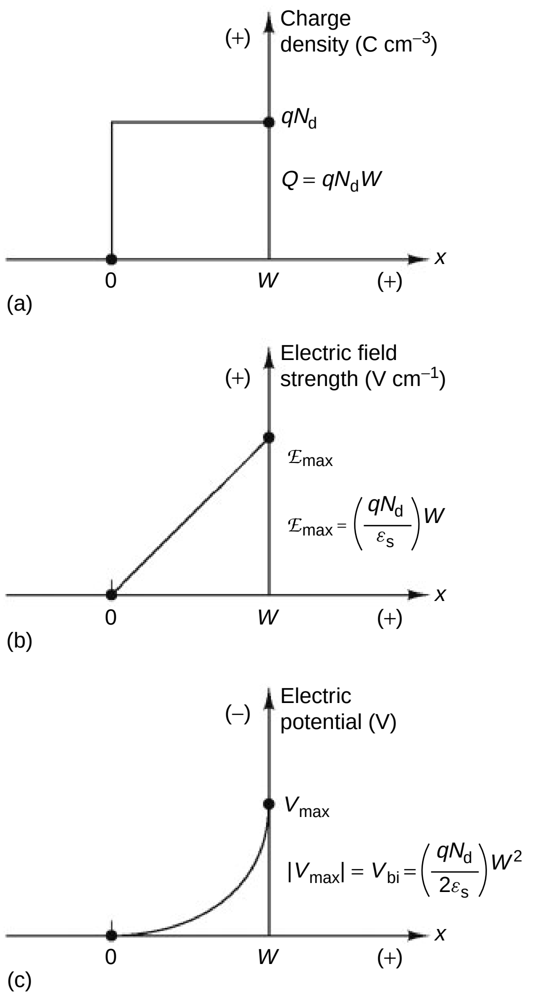

Figure 3 The spatial dependence of the charge density, the electric field, and the electric potential in the semiconductor at equilibrium for an n-type semiconductor/metal junction, where all of the voltage is dropped in the semiconductor space-charge region. The origin of the x-axis is chosen for convenience as the point closest to the interface where the net charge in the semiconductor equals zero. (a) The distance dependence of the charge density under the depletion approximation. (b) The electric field as a function of distance. Note that the maximum electric field occurs at the semiconductor interface. (c) The distance dependence of the electric potential. The electric potential in the bulk of the semiconductor has been defined as zero. Because the sign of the electric field strength is positive, the electric potential at the interface is more negative than in the bulk

As given in equation (1), since the depletion approximation ensures that the charge density in the depletion region is independent of distance, the electric field in this region increases linearly as it approaches the semiconductor/metal junction. The maximum electric field in the semiconductor ($\mathcal{E}_\mathrm{max}$) is obtained at the position $x = W$:

$$\mathcal{E}_\mathrm{max} = \left(\frac{qN_\mathrm{d}}{\varepsilon_\mathrm{s}}\right) W \tag{2}$$

Thus, the maximum electric field in a semiconductor/metal junction is located at the interface. This is an important feature for constructing numerous devices using semiconductor junctions, because the maximum ability for charge separation by the electric field occurs at the junction.

An alternate and convenient method of expressing the work required to push the negative test charge toward the interface is given by the electric potential at each point in the semiconductor. Electrostatics states that the electric potential is equal to the negative integral of the electric field over the path of interest.[11] Thus, integrating the linear electric field (equation 1) from the bulk of the semiconductor toward the semiconductor/metal interface yields a quadratic expression for the electric potential in the semiconductor phase:

$$V(x) = -\left(\frac{qN_{\mathrm{d}}}{2\varepsilon_{\mathrm{s}}}\right)x^2 \qquad (3)$$

The electric potential of an electron near the interface is thus higher than that of an electron in the bulk. The negative sign in equation (3) merely indicates that the electric potential at the interface is more negative than that in the bulk. This makes sense, because work is required to push the negative test charge toward the interface. The difference in electric potential between the quasineutral region and any other position is a quantitative measure of the work required to move this test charge in the semiconductor.

A similar treatment can be used to calculate the electric field and the electric potential in the metal. However, in a metal, both the electric field and the electric potential drop to zero at a very short distance from the semiconductor/metal interface.[2] This occurs because metals do not support electric fields, and all of the excess charge density resides on the surface of the metallic phase.[9] The surface dipole layer is therefore effectively screened from test charges at any finite distance into the metallic phase, and the width of the electric potential gradient is extremely small. Because charge carriers can pass freely through this extremely thin barrier, only the electric field in the semiconductor significantly affects the electrical properties of semiconductor/metal contacts.

Combining all of these concepts, we can concisely express the electrostatic situation for any semiconductor/metal contact at equilibrium. Figure 3 contains plots of the charge density, electric field, and electric potential versus distance for such a semiconductor/metal junction. Because these diagrams are all related to each other, only one type of diagram is often depicted when a particular semiconductor/metal interface is discussed. The most convenient diagram is that of the electric potential energy versus distance, because the electric potential energy can be directly related to the potential energy of an electron at any point in the system. The potential energy of an electron at each position in the semiconductor can be obtained by multiplying the electric potential by the charge on an electron.

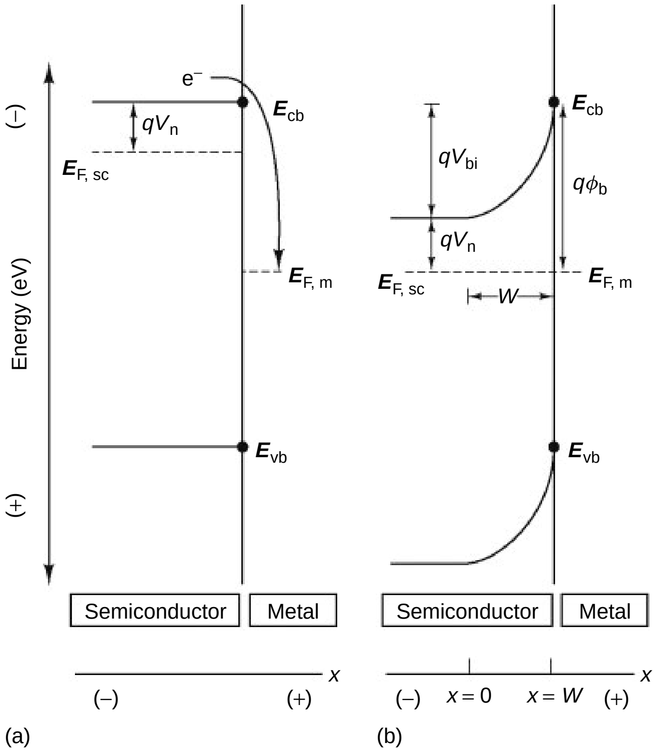

Figure 4 An energy diagram of an n-type semiconductor/metal junction. (a) Before charge equilibration occurs, the energy levels of the semiconductor conduction and valence bands are uniform at all points along the x-axis. (b) After charge equilibration has occurred, a depletion layer (W) is formed in the semiconductor. The electric potential energy levels of E_{cb} and E_{vb} are dependent on the distance into the depletion region. However, at equilibrium, the electrochemical potential is the same in the metal and at all points in the semiconductor (i.e. $E_{\mathrm{F,m}} = E_{\mathrm{F,sc}}$). qV_{n} is defined as the difference between $E_{\mathrm{F,sc}}$ and E_{cb} in the bulk of the semiconductor. V_{bi} is the built-in voltage of the junction and ϕ_{b}, the barrier height, is defined as $\phi_{\mathrm{b}} = V_{\mathrm{n}} + V_{\mathrm{bi}}$

A schematic of the energy versus distance relationship for a semiconductor/metal junction before and after equilibration is depicted in Figure 4. These potential energy versus distance diagrams are often called band bending diagrams. The electric potential gradient leads to a quadratic increase in the potential energy of an electron in the semiconductor as it approaches the semiconductor/metal junction. Both the conduction and valence bands are shown bent because the electric field acts equally well on test charges that are in either band. Note also that on these diagrams, the distance between the bottom of the conduction band and the top of the valence band always remains constant. This situation results because the presence of an electric field has a negligible effect on the value of the band gap for most semiconductors.[9]

Another chemical analogy is useful in elucidating the meaning of band bending diagrams. Chemists are quite comfortable with reaction coordinate diagrams, in which the free energy of the system is plotted versus some (typically

unknown) reaction coordinate for a chemical reaction. A similar interpretation is possible for band bending diagrams (Figure 4b). These diagrams can be interpreted as representing the activation energy required to move a negative charge along a reaction coordinate toward the interface. This movement will require energy, because of the repulsion due to the unscreened negative charges on the metallic side of the semiconductor/metal junction. The difference between the common chemical reaction coordinate diagram and a band bending diagram is that if the amount of charge is known, the electric potential (equation 3), and therefore the electric potential energy of the system, can be calculated precisely at each point along the reaction coordinate. In contrast, typical chemical reaction coordinates are schematic in both energy and in direction along the bond coordinates.

A few quantitative values are worth deriving in order to complete the diagrams of Figure 4. According to equation (3), the absolute value of the electric potential reaches its maximum at the interface ($x = W$). The absolute value of this potential difference between the interface and the semiconductor bulk is called the built-in voltage (V_{bi}). The built-in voltage is a direct result of the initial electrochemical potential difference between the semiconductor and the metal, with $V_{bi} = (|E_{F,sc} - E_{F,m}|)/q$ (Figure 4). This quantity is the total change in electric potential that would be experienced upon moving a test charge from the back of the semiconducting solid ($x = -\infty$) all the way to the interface between the semiconductor and the metal ($x = W$). The quantity V_{bi} is called the built-in voltage because this voltage is 'built-in' to the semiconductor as a result of equilibration of the semiconductor Fermi level with the electrochemical potential of the metal. V_{bi} can be related to the amount of charge transferred, and therefore, to the depletion width, W, using the equations developed above. From equation (3):

$$V_{bi} = \left(\frac{qN_d}{2\varepsilon_s}\right) W^2 \qquad (4)$$

$$W = \sqrt{\frac{2\varepsilon_s V_{bi}}{qN_d}} \qquad (5)$$

Another quantity of interest on the band bending diagrams refers to the bulk of the semiconductor. In the semiconductor quasineutral region where no electric fields are present, the difference between the Fermi level and the energy of the bottom of the conduction band remains the same as it was in the neutral semiconductor before equilibration with the metal. Thus, we can define $V_n \equiv (E_{F,sc} - E_{cb})/q$ as the potential difference between the Fermi level and the conduction band energy in the semiconductor bulk, as shown on the band bending diagram in Figure 4.

The difference between the equilibrium Fermi level energy and the energy of the bottom of the conduction band at the semiconductor/metal interface is also an important quantity often mentioned in literature.[10] This difference is called the barrier height energy of the junction and is generally abbreviated as $q\phi_b$, where ϕ_b is the barrier height in V, and $q\phi_b$ is the barrier height energy in eV, that is, $q\phi_b = E_{F,m} - E_{cb}$ (at the electrode surface). From Figure 4(b) and from the definitions of V_{bi} and V_n, it can also be seen that $\phi_b = V_n + V_{bi}$. It is generally convenient to use ϕ_b to characterize the barrier height of semiconductor/metal contacts, because unlike V_n and V_{bi}, ϕ_b is independent of the doping level of the semiconductor. In fact, the magnitude of ϕ_b depends only on the initial position of the semiconductor conduction band, E_{cb}, and on the initial electrochemical potential of the metal, $E_{F,m}$.

A final quantitative aspect of band bending diagrams concerns the equilibrium concentration of electrons at different positions in the semiconductor. Again we will refer to semiconductor/metal contacts in developing the equations, but analogous expressions are available for the other types of contacts as well. Before contact with another phase, the carrier concentration is equal at all points in the semiconductor. For a moderately doped semiconductor with completely ionized dopants, this carrier concentration is simply given by the quantity N_d. However, for a depleted n-type semiconductor/metal contact, the presence of unshielded negative charge on the metallic side of the interface will make it energetically difficult to support the negatively charged electrons in the semiconductor depletion region. Because the screening of interfacial charge is a function of distance away from the semiconductor/metal junction, the actual majority carrier concentration in a depleted semiconductor is expected to be a function of distance from the semiconductor/metal interface.

To obtain an expression for this carrier concentration versus distance relationship, we need to consider the potential energy difference between various points in the semiconducting solid. The relationship between the bulk carrier concentration, n_b, and the carrier concentration at any other position in the semiconductor can be obtained simply by using the Boltzmann equation:

$$n(x) = n_b \exp\left(\frac{qV(x)}{kT}\right) \qquad (6)$$

where $V(x)$ is the electric potential at any position of interest relative to the bulk semiconductor. The concentration of electrons in the bulk is the same as that in the neutral material, so $n_b = N_d$. The quantity $V(x)$ is negative with respect to the potential of the conduction band in the quasineutral region of the semiconductor (Figure 3c, equation 3). Therefore, as the semiconductor/metal interface is approached, $n(x)$ decreases exponentially from the bulk electron concentration. An identical expression can be applied to semiconductor/semiconductor and to semiconductor/liquid contacts, once $V(x)$ is known for the system of interest.

From equation (6), it can be seen that $n(x)$ reaches a minimum at the semiconductor surface. The concentration of

electrons at the surface, n_s, is given by

$$n_s = n_b \exp\left(-\frac{qV_{bi}}{kT}\right) \tag{7}$$

where V_{bi} is the absolute value of $V(x)$ at $x = W$. This expression clearly shows that V_{bi} represents the total electric potential barrier for electrons to move from the bulk of the semiconductor to the metal. As will be discussed in later sections, the surface concentration of electrons (n_s) is an important factor that controls the charge transfer events between the semiconductor and the contacting phase. Thus, V_{bi} directly affects the current–voltage properties of a semiconductor/metal junction.

2.1.4 Trends in Contact Properties

The values of V_{bi} and ϕ_b are key experimental quantities that are used to characterize the physical properties of semiconductor/metal interfaces. If V_{bi} or ϕ_b can be determined, then W, Q, $\mathcal{E}(x)$, and most of the other important thermodynamic quantities that are relevant to the electrical properties of the semiconductor contact can be readily calculated using the simple equations that have been presented above. Methods to determine these important parameters can be found in the literature.[2] However, it would be useful at this point in the discussion to consider what values of ϕ_b and V_{bi} are expected theoretically for a given semiconductor/metal interface. By definition, $\phi_b = (E_{F,m} - E_{cb})/q$ at the electrode surface (Figure 4b). Thus, in principle, the barrier height can be predicted if the energies of the semiconductor band edges and the electrochemical potential of the metal can be determined with respect to a common reference energy.

In the literature, the work function of a metal, φ (in eV), is often used to estimate the degree of charge transfer at semiconductor/metal junctions.[12] The work function of a metal is defined as the minimum potential experienced by an electron as it is removed from the metal into a vacuum. The work function φ is often used in lieu of the electrochemical potential of a metal, because the electrochemical potential of a metal is difficult to determine experimentally, whereas φ is readily accessible from vacuum photoemission data.[12] Additionally, the original model of semiconductor/metal contacts, advanced by Schottky, utilized differences in work functions, as opposed to differences in electrochemical potentials, to describe the electrical properties of semiconductor/metal interfaces.[13] A more positive work function for a metal (or more rigorously, a more positive Fermi level for a metal) would therefore be expected to produce a greater amount of charge transfer for an n-type semiconductor/metal contact.[2] Therefore, use of metals with a range of φ (or $E_{F,m}$) values should, in principle, allow control over the electrical properties of semiconductor/metal contacts.

To this point, we have restricted the specifics of our discussion to semiconductor/metal contacts. However, a similar description of the interfacial equilibration process also applies to contacts between two dissimilar types of semiconductors. The most common form of these types of junctions is obtained when an n-type semiconductor is contacted with a semiconducting layer that has been doped p-type. When the two materials differ only in the type of doping, such junctions are called p–n homojunctions. To control the electric field in the n-type semiconductor, the p-type semiconductor is usually highly doped. The conductivity, and capacitance, of the highly doped p-type phase is then much larger than that of the n-type phase. In this situation, the electrostatics of the p–n homojunction closely resemble those of n-type semiconductor/metal contacts.

The biggest advantage of semiconductor homojunctions is the lack of a metallurgical junction between two structurally dissimilar solid phases. A homojunction provides an interface that is more perfect structurally, as well as less chemically reactive, than the junction between a semiconductor and a metal. Another advantage of a homojunction is that control over the Fermi level of the contacting phase is readily accomplished through changes in its dopant density. In contrast, for semiconductor/metal junctions, changing the Fermi level of the contacting phase requires a change in the nature of the metal, and thereby produces entirely new chemical interactions at the semiconductor interface. Because of their high electrical quality and ease of fabrication, homojunctions are used in a variety of technological applications in the semiconductor industry. The equations describing their performance are well-documented, and will not be described in more detail here.[10,14] However, the electrostatics of charge-transfer equilibration are readily obtained using slight modifications of the description presented above in equations (1–7).

A third type of semiconductor junction uses a conducting liquid to contact the semiconductor. Generally, the solvent and electrolyte do not participate in the charge-transfer process. Therefore, to control the Fermi level of the liquid phase, a donor/acceptor pair (a 'redox couple') must be added to the solution. The electrochemical potential, or Fermi level, of the solution phase is then given by the Nernst equation (equation 8):

$$E\left(\frac{\mathrm{A}}{\mathrm{A}^-}\right) = E^{o'}\left(\frac{\mathrm{A}}{\mathrm{A}^-}\right) + \frac{RT}{eF}\ln\frac{\mathrm{A}}{\mathrm{A}^-} \tag{8}$$

where $E^{o'}(\mathrm{A/A^-})$ is the formal redox potential of the redox couple, [A] and [A^-] are the concentrations of the oxidized and reduced forms of the redox couple, R is the gas constant, F is Faraday's constant, and e is the number of electrons per molecule oxidized or reduced in the reduction/oxidation process. The redox potential of the solution ($E(\mathrm{A/A^-})$) is related to the electrochemical potential by $\mathcal{E}(\mathrm{A/A^-}) = E(\mathrm{A/A^-})/q$.

The electrostatics of charge transfer for semiconductor/liquid interfaces closely resemble those for semiconductor/metal contacts.[15] In the common experimental situation of

a liquid with a high concentration of a supporting electrolyte and with a significant concentration of electroactive reagents, the equilibrium electrochemical potential of the semiconductor/liquid contact is dictated by the initial electrochemical potential of the solution phase. This occurs because the liquid phase has a large capacity to accept charge with a minimal change in energy, in an analogous fashion to the metal portion of a semiconductor/metal contact. In addition, the significant capacitance of a liquid phase with a high concentration of supporting electrolyte dictates that essentially all of the voltage drop will occur in the semiconductor. This is also analogous to the situation for a semiconductor/metal contact. Under these conditions, equations (1–7) can therefore be directly applied to the electrostatic situation at a semiconductor/liquid contact, even though they were developed in our discussion during consideration of a semiconductor/metal contact.

As for semiconductor/metal contacts, a change in the Fermi level of the liquid phase should result in a different amount of charge transferred across the semiconductor/liquid junction. For semiconductor/liquid junctions, the important energetic trends for a series of different liquid contacts can thus be determined by measuring the solution redox potential relative to a standard reference electrode system. Within this model, solutions with more positive redox potentials should induce greater charge transfer in contact with n-type semiconductors.

Unfortunately, a problem arises when attempting to compare the electrochemical potential of the solution and the electrochemical potential of the semiconductor. Like most electronic energy levels for molecules, the Fermi level of the semiconductor is usually determined relative to the vacuum level. Experimental measurements to determine $E_{\mathrm{F,sc}}$ for semiconductors (generally through determination of the semiconductor work function and dopant density) yield values that can be related to the energy of an electron in vacuum.[16] However, electrochemical potentials of liquid phases can only be measured as potential differences between the test solution and a solution that is used as a reference.[15] Since it is not possible to measure directly the energy of an individual redox couple relative to the vacuum level, it is not possible to determine directly the desired relationship between the energy level on the solid side of the junction and that on the liquid side.

Typically, the reference level for the solution redox potential is chosen to be the normal hydrogen electrode (NHE). Some tabulations use the saturated calomel electrode (SCE) as the reference level with the difference between these two scales well-known to be NHE $= -0.2412$ V versus SCE.[15] The fundamental problem lies in the determination of the absolute energy of the NHE relative to vacuum. Although a method to determine directly the absolute electrochemical potential of an NHE has not yet been described, a recent indirect measurement has indicated that it is approximately 4.4 eV below the vacuum level.[17,18] This value is often used to relate the solution electrochemical potential scale to the solid electrochemical potential scale. It provides the best approximation that is presently available to calculate the values of ϕ_{b} and V_{bi} for semiconductor/liquid contacts, based only on the values of E_{cb} and $E(\mathrm{A/A^-})$.

2.2 Accumulation

We have described above the relevant physics and electrostatics for a depleted semiconductor/metal contact. It is also possible, however, that the initial electrochemical potential of the metal will be more negative than the Fermi level of the semiconductor. During the approach to equilibrium, electrons will then tend to flow into the semiconductor from the metallic phase. This flow of electrons into the semiconductor leads to a qualitatively different energetic situation at the semiconductor/metal junction relative to the situation in depletion. This situation is technologically desirable to form ohmic, electrically resistive contacts to semiconductors. We discuss the charge-transfer equilibration for these types of contacts in this section.

When electrons from the metallic phase are transferred into the n-type semiconductor, these electrons are not confined to dopant atom sites. Instead, the majority carriers exist as mobile charges in the conduction band. Because these excess majority carriers need not reside on dopant atoms, but can

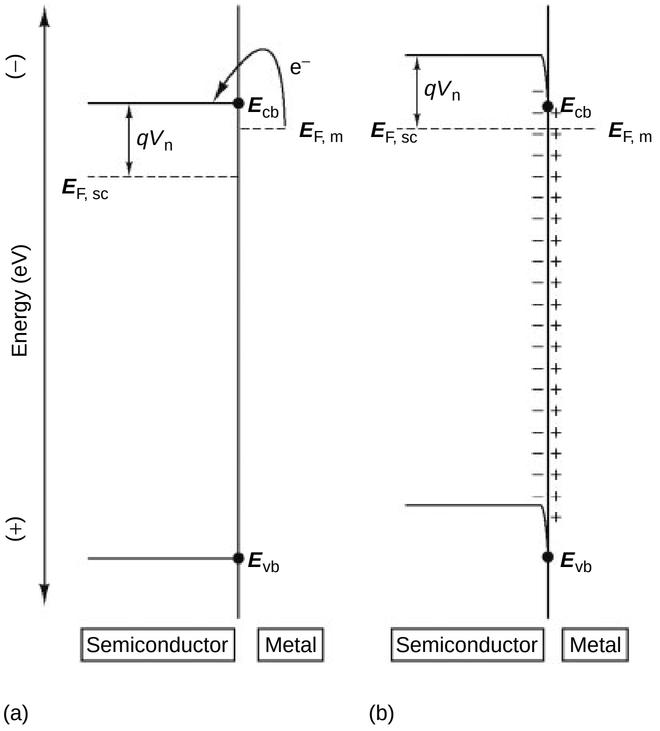

Figure 5 An energy diagram of a semiconductor/metal junction in accumulation. (a) Before charge equilibration occurs, the electrochemical potential of the semiconductor ($E_{\mathrm{F,sc}}$) is more positive than the Fermi level of metal ($E_{\mathrm{F,m}}$), and electrons will flow from the metal into the semiconductor. (b) After charge equilibration has occurred, an accumulation layer containing negative charges is formed in the semiconductor

also reside on lattice atoms of the semiconductor, the charge density that can be supported in accumulation is not limited by the dopant density. Instead, it is more closely approximated by the atom density in the crystal lattice. The spatial region in the semiconductor where the negative charges accumulate is called the accumulation region (Figure 5). The thickness of an accumulation region is therefore far smaller than that of a depletion region, for the same material and same amount of charge transferred across the interface. The width of an accumulation layer is typically less than 100 Å,[19] while the width of the depletion region is usually on the order of micrometers.[1]

Experimentally, the thin width of an accumulation layer implies that the electric potential gradient will not extend significantly into the semiconductor. The discussion in Section 3 will demonstrate that semiconductors in depletion act as rectifiers to current flow, selectively passing charge carriers in one direction while impeding their flow in the opposite direction. In accumulation, however, the lack of a significant barrier to charge flow implies that the semiconductor contact will be resistive, but not rectifying, to current flow. Thus, semiconductor/metal interfaces in accumulation are not useful for applications that require rectification. They are quite useful, however, for a variety of devices in which ohmic electrical contacts are required. They are also useful for basic investigations of the electrostatics of junction formation.[20]

2.3 Fermi Level Pinning

In discussing the behavior of semiconductor/metal junctions in depletion, it has been assumed that if the energy of the conduction band edge, E_{cb}, and the electrochemical potential of the contacting phase were known, their difference would yield a quantitative prediction of the barrier height for a given interface (Figure 4). Furthermore, even if the absolute magnitude of ϕ_b is not known, it should still be the case that a change in the electrochemical potential of the contacting phase should yield a defined change in the barrier height, and also in the built-in voltage, of the resulting semiconductor junction. The scenario in which these conditions apply is often called the 'ideal' behavior of a semiconductor contact. However, for many semiconductor contacts, this ideal behavior is not observed experimentally. In fact, in some systems, especially semiconductor/metal contacts, changes in the electrochemical potential of the contacting phase do not yield *any* change in properties of the junction. In the remainder of this section we describe how this important class of exceptions to ideal behavior can be understood, and we also describe the implications of this nonideal junction behavior for chemical control of device properties.

The key experimental observation is that the built-in voltage in the semiconductor, V_{bi}, often does not change as the electrochemical potential of the contacting phase is varied.[21] Attaining equilibrium between two phases requires that different degrees of interfacial charge transfer must occur when the initial electrochemical potential difference between these phases is changed. The experimental observation therefore indicates that another source or sink for charge must exist in the real interfacial system. These sources and sinks for charges are often referred to as surface states. Their ability to 'buffer' the semiconductor from changes in the electrochemical potential of the contacting phase is referred to as Fermi level pinning.

Surface states can arise simply because the atomic bonding at a semiconductor surface is necessarily different from that in the bulk. For example, in a Si lattice, the bonds at the Si surface are not fully coordinatively saturated. To relieve this unsaturation, either a surface reconstruction can occur and/or bonds to the metallic material can be formed. This distinct type of surface bonding results in a localized electronic structure for the surface which is different from that in the bulk. The energies of these localized surface orbitals are not restricted to reside in the bands of the bulk material, and can often be located at energies that are inside the band gap of the semiconductor. Orbitals that reside in this forbidden gap region are particularly important, because they will require modifications of our ideal model of charge equilibration at semiconductor/metal interfaces.[12]

To understand Fermi level pinning, we need to reconsider the charge equilibration process when the semiconductor/metal junction has a high density of surface states. As an example, we will consider a situation in which the surface states are half-filled when in equilibrium with a given metal and a semiconductor. The relevant question in this example concerns the change in V_{bi} when the electrochemical potential of the metal is made more positive. In the ideal model, the required charge had to be transferred by removing electrons from dopant atoms further into the semiconductor (Figure 2). As described above, this process required increases in both W and V_{bi}.

However, owing to the presence of occupied surface states, another source of charge is available in our nonideal system. If the charge required to equilibrate the junction is extracted from the surface states, and if the surface state density is sufficiently high to supply all of the required charges, then the junction can come to equilibrium without producing any change in V_{bi}. This situation occurs because no additional dopants have been ionized in the semiconductor. Instead, the additional charge is provided by the surface states. This situation is called Fermi level pinning; such terminology is used when the position of the semiconductor Fermi level is controlled by the occupancy of the surface states, as opposed to being controlled by the electrochemical potential of the metal.[12]

Quantitative calculations of the number of surface states that are needed to achieve Fermi level pinning will not be described here. However, such calculations show that even surface state densities as low as 10% of a monolayer (10^{14} states cm^{-2}) can provide sufficient charge to induce complete

Fermi pinning at semiconductor/metal contacts.[21] In other words, for a 1–2 V change in the work function of the metal, this density of surface states is sufficient that the values of W and V_{bi} will not change.

Lower surface state densities will, of course, produce less of a Fermi level pinning effect. This will result in an increased sensitivity of V_{bi} to changes in $E_{F,m}$. A quantitative measure of the degree of ideality of a junction can be obtained by plotting changes in V_{bi} (or ϕ_b) as a function of changes in $E_{F,m}$. Generally, however, as discussed above, values for $E_{F,m}$ are not available, so the work function φ is used instead. When the slope of a plot of V_{bi} versus φ is 1.0, the ideal situation is attained. When the slope of such plots is $\sim$0, complete Fermi level pinning is present. Intermediate situations, with $0 < \text{slope} < 1.0$, or nonlinear behavior of V_{bi} vs. φ, are often referred to as partial Fermi level pinning.[1,12]

Fermi level pinning is generally an undesirable feature of semiconductor contacts. Its presence implies that there is a lack of chemical control over the electric field strength in the semiconductor. Some reports have appeared in the literature describing the preparations of semiconductor surfaces with acceptably low levels of deleterious surface states.[22] In others, surface modification procedures have been explored with the aim of forming bonds to the defects to remove the surface states.[23,24] Such efforts are extremely important, as the problem of Fermi level pinning remains a key challenge to chemists interested in manipulating the properties of semiconductors.

3 CHARGE TRANSFER AT A SEMICONDUCTOR JUNCTION

Up to this point, we have considered the charge flow that occurs to produce the equilibrium state between a semiconductor and a contacting phase. This type of charge flow is a prerequisite for the use of semiconductor junctions in essentially any technological application. However, understanding this transient charge flow is not sufficient to describe the electrical properties of semiconductor junctions under steady state, nonequilibrium conditions. Ultimately, the steady-state current–voltage behavior is the practical characteristic that generally determines the figure of merit of a particular semiconductor device, and therefore determines its suitability for a particular application. For instance, excellent steady-state rectification is desired for energy conversion devices, photonic detectors, and some other devices, while ohmic contacts are necessary for most transistor applications as well as for various other devices.[1] Our goal in this section is to establish a framework for describing the current–voltage behavior of a given semiconductor contact, and to establish a basis for choosing a particular type of contact for a particular type of application.

3.1 Current–voltage Behavior of a Semiconductor/metal Junction

In describing the steady-state current–voltage properties of semiconductor contacts, we will use, with no loss of generality, n-type semiconductor/metal contacts as our specific example for discussion. A balanced chemical equation that represents the interfacial charge transfer at a semiconductor/metal contact is

$$\begin{aligned}&\text{electron in the semiconductor} + \text{acceptor state in the metal}\\&= \text{electron vacancy in the semiconductor} + \text{donor state in the metal}\end{aligned} \tag{9}$$

In equation (9), the forward reaction represents the transfer of electrons from the semiconductor into the contacting phase, and the reverse reaction represents the transfer of charge in the opposite direction. This equation, in combination with a simple kinetic model, can be used to obtain an expression for the current–voltage properties of a semiconductor contact.

In any chemical system, no net formation of products or net destruction of reactants occurs at equilibrium. There is, however, always some rate of conversion of an individual set of reactant molecules into a set of product molecules, and vice versa. At equilibrium, these rates cancel each other exactly. An analogous situation holds for charge transfer at a semiconductor/metal interface: at equilibrium, the rate of electrons flowing from the semiconductor into the metal must exactly equal the rate at which electrons flow into the semiconductor from the metal. Away from equilibrium, the rate constants for these processes will remain fixed for the interface of interest. However, the concentrations of the reactants and products will differ from their equilibrium values, and a net current can therefore be sustained through the interface. Our strategy in describing current flow is to evaluate the currents at equilibrium in accord with equation (9), and then to modify this treatment to include nonequilibrium conditions.

3.1.1 *Charge Transfer at Equilibrium*

The simplest model of electron transfer across a semiconductor/metal interface assumes that the current depends linearly on the concentration of electrons at the semiconductor surface, n_s. It also assumes that the concentrations of acceptor and donor states in a metal are extremely large;[9] thus, these variables can be assumed to be constant and can be incorporated as time-independent quantities into the appropriate rate equations. This assumption is extremely reasonable for the moderate current densities that flow through typical semiconductor/metal interfaces.[1]

At a semiconductor/metal contact, the rate of direct electron transfer from an n-type semiconductor to the metal can therefore be expressed as

$$\text{rate of electron injection into the metal} = k_n n_s \tag{10}$$

where k_n is the rate constant for the electron transfer. This expression represents the rate law for the forward chemical rate, that is, it represents the rate of formation of products for the chemical reaction in equation (9).

To maintain equilibrium, there must also be a current in the opposite direction that opposes this forward rate, that is, electrons must also be able to leave the metal phase and enter the semiconductor conduction band. Because the electrons enter the empty states of the semiconductor, the concentration of these empty states can be taken as a constant. This leads to the expression

$$\text{rate of electron transfer from the metal} = k_n^{-1} \tag{11}$$

In equation (11), k_n^{-1} is the reverse reaction rate constant, and it is independent of n_s. The concentration of vacant states in the semiconductor and the concentration of filled states in the metal has been incorporated into the value of k_n^{-1}. This rate is called the reverse rate, because it represents the formation of the species on the left-hand side of the reaction represented in equation (9). At equilibrium (when $n_s \equiv n_{so}$), these rates must be equal to each other ($k_n^{-1} = k_n n_{so}$).

The net rate of electron transfer into the metal, $-\mathrm{d}n/\mathrm{d}t$, is always the forward rate minus the reverse rate. From equations (9–11), we then obtain the general relationships

$$-\frac{\mathrm{d}n}{\mathrm{d}t} = k_n n_s - k_n^{-1} \tag{12}$$

$$-\frac{\mathrm{d}n}{\mathrm{d}t} = k_n(n_s - n_{so}) \tag{13}$$

Equations (12) and (13) were obtained by treating charge transfer across a semiconductor/metal interface as we would treat any other simple chemical kinetics problem. It states that the net rate at which charge crosses the semiconductor/metal interface is the rate of product formation minus the rate of reactant formation. Although equation (13) is exactly equivalent to equation (12), the form that we have adopted for equation (13) will be extremely useful in deriving concise expressions for the current–voltage relationship of a semiconductor/metal contact. This is because equation (13) expresses the net rate of charge transfer relative to the situation at equilibrium, where no current flows across the interface. According to equation (13), $-\mathrm{d}n/\mathrm{d}t = 0$ at equilibrium (as must be the case, because $n_s = n_{so}$ by definition). Away from equilibrium, $n_s \neq n_{so}$, so charge will cross the interface, and thus $-\mathrm{d}n/\mathrm{d}t \neq 0$.

3.1.2 The Current–voltage Characteristics of a Junction

It is now a simple task to describe the interfacial current as a function of applied voltage. Since the current is merely the electron transfer rate multiplied by the charge on an electron and by the surface area of the electrode, A_s, the interfacial electron transfer current can be written as:

$$I = -qA_s\left(-\frac{\mathrm{d}n}{\mathrm{d}t}\right) = -qA_s k_n(n_s - n_{so}) \tag{14}$$

In this notation, the current, I, is defined to be negative when electrons flow from the semiconductor to the metal. This notation is consistent with the electrochemical definition of a reduction current (electrons leaving the electrode). The dependence of the current on the applied voltage is implicit in n_s. To obtain this voltage dependence explicitly, we need to remember that the electron concentration at the surface of a semiconductor is related to the electron concentration in the bulk. As given in equation (7), the surface electron concentration at equilibrium is given by

$$n_{so} = n_b \exp\left(-\frac{qV_{bi}}{kT}\right) \tag{15}$$

Similarly, when a voltage V is applied across a semiconductor/metal junction, the total voltage drop in the semiconductor depletion region is $V_{bi} + V$, so we obtain an analogous Boltzmann relationship away from equilibrium:

$$n_s = n_b \exp\left[-\frac{q(V_{bi} + V)}{kT}\right] \tag{16}$$

This equation represents the physical situation that the electron concentration at the semiconductor surface can be either increased or decreased through the use of an additional voltage. This applied voltage controls the surface carrier concentration in the same fashion as the built-in voltage, so the same Boltzmann relationship applies.

Substituting equations (15) and (16) into equation (14), we obtain the desired relationship between the current and the voltage of a semiconductor/metal junction:

$$I = -I_0\left[\exp\left(-\frac{qV}{kT}\right) - 1\right] \tag{17}$$

where $I_0 = qA_s k_n n_{so}$. I_0 is called the exchange current, because it is the value of the current that is present at equilibrium. I_0 is responsible for transforming reactants into products, and vice versa, at a semiconductor/metal interface at equilibrium. For convenience, I_0 is defined as a positive quantity. I_0 is clearly dependent on the value of the equilibrium surface electron concentration, because a smaller exchange current should flow at equilibrium if there are fewer electrons available to exchange with a particular contacting phase.

We are now in a position to examine the properties of the current–voltage (I–V) behavior of a semiconductor/metal contact in detail. Equation (17) predicts that the current is exponentially dependent on the voltage for $V < 0$, but is independent of voltage, and of opposite sign, when $V > 0$. This can be understood qualitatively by reference to the elementary rate processes that result from equations (12)

and (13). The net current across the semiconductor/metal interface is always given by the difference of the forward and reverse interfacial charge transfer rates, that is, by the rate of the reaction going to the right minus the rate going to the left, as written in equation (12). For voltages that reduce the surface electron concentration below its equilibrium value, Le Chatelier's principle implies that the reaction should proceed to the left as written in equation (9). Physically, a value of $V > 0$ will yield a larger electric potential drop in the semiconductor, which will exponentially reduce the surface concentration of electrons. This lower surface electron concentration will reduce the rate of electrons leaving the semiconductor (Figure 6a). However, the rate of electrons entering the semiconductor, that is, the rate of reactant formation, will remain unchanged. Therefore, for this direction of voltage change, the net current will be independent of voltage. This direction of the applied voltage is called reverse bias. In reverse bias, the reaction proceeds to the left as written in equation (9), and electrons are injected into the semiconductor from the metal.

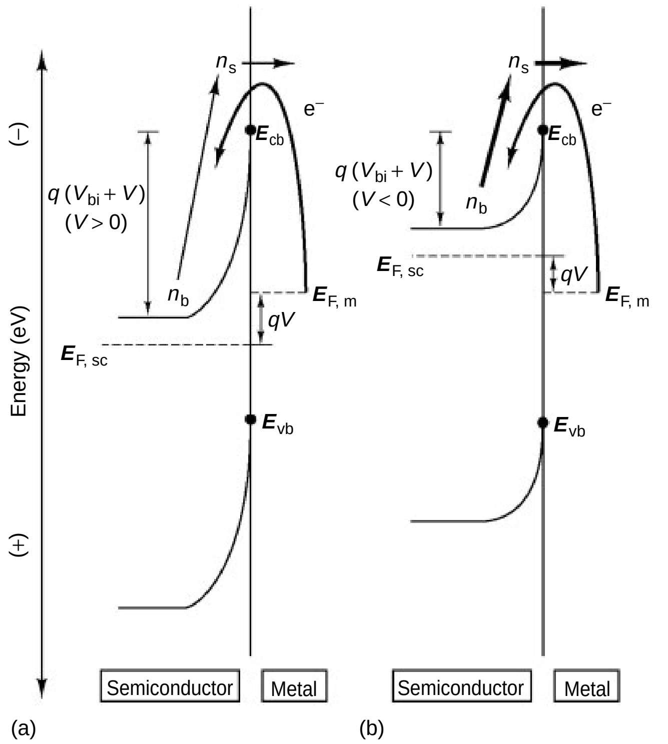

Figure 6 An energy diagram of the charge-transfer process at an n-type semiconductor/metal interface when an external potential (V) is applied across the semiconductor electrode. The applied potential changes the electric potential difference between the semiconductor surface and the bulk region. This perturbs the concentration of electrons at the surface of the semiconductor (n_s), and a net current flows through the semiconductor/metal interface. The forward reaction represents the transfer of electrons from the semiconductor to the metal and the reverse reaction represents the injection of electrons into the semiconductor from the metal. The width of the arrows indicates schematically the relative magnitude of the current. (a) The reverse bias condition for an n-type semiconductor ($V > 0$). The forward reaction rate is reduced relative to its equilibrium value, while the reverse reaction rate remains constant. A net positive current exists at the electrode surface. (b) The forward bias condition ($V < 0$), the forward reaction rate increases compared to its equilibrium value, while the reverse reaction rate remains unaffected. A net negative current exists at the electrode surface

For voltages that increase the surface electron concentration above its equilibrium value ($V < 0$), the sign of the current will be opposite to that of the current obtained at reverse bias. Le Chatelier's principle now implies that the reaction will go to the right as written in equation (9), so there will be a net transfer of electrons to the metal phase. Through the Boltzmann relationship, in forward bias ($V < 0$ for our n-type semiconductor example) the surface concentration of electrons increases exponentially with increased bias. This increased concentration of reactants results in an exponential increase in the forward rate of interfacial charge transfer, but has no effect on the reverse rate of charge transfer (Figure 6b). Because the rate of electrons leaving the semiconductor at high forward bias dominates the rate at which they enter it, the net current will depend exponentially on the applied voltage (specifically, when $\exp(-qV/kT) \gg 1$), as indicated by equation (17).

The current–voltage characteristic described by equation (17), where the current can flow predominantly in only one direction under an applied potential, is called rectification. The rectification characteristic is typical of electrical diodes.[1] Equations that have the form of equation (17) are therefore generally called diode equations. We have shown that a semiconductor/metal interface is expected to obey the diode equation when interfacial electron transfer is the rate-determining step for charge movement. In this situation, the applied voltage changes the electron concentration at the interface of the semiconductor, and this is directly reflected in the current versus voltage relationship of a semiconductor/metal interface (Figure 7). This behavior is a direct result of the Boltzmann relationships of equations (15) and (16).

Up to this point, there has been no explicit discussion of the role of the metal phase in the current–voltage behavior. For ideal semiconductor/metal junctions, it is relatively straightforward to evaluate I_0 in terms of the thermodynamic properties of the metal contact. Referring to equations (12–17), knowledge of either k_n or k_n^{-1} is sufficient to fully describe I_0. It is intuitively easier to appreciate the quantities incorporated into k_n^{-1}, which represents the rate constant for injection of electrons from the metal into the semiconductor. This charge-transfer process can be broken down conceptually into two steps. First, electrons in the metal must overcome the activation energy to enter the conduction band of the semiconductor. Because the highest occupied state in the metal is at the Fermi level, $E_{F,m}$, and the lowest unoccupied state at the semiconductor surface has an energy of E_{cb}, the electron transfer process will have an activation energy of $E_{F,m} - E_{cb} = q\phi_b$. Using a simple Arrhenius treatment of

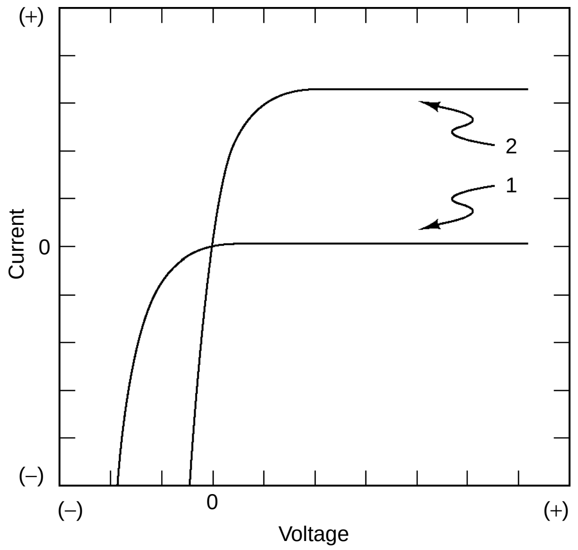

Figure 7 The current–voltage (I–V) behavior of an n-type semiconductor/metal junction in the dark. The shape of the I–V curve is described by the diode equation (equation 17); thus, such a curve is referred to as a diode curve. The difference between curves 1 and 2 is that the equilibrium exchange current, I_0, is greater for curve 2

this rate constant,[25] I_0 can therefore be written as

$$I_0 = qA_s k_n^{-1} = \text{constant} \times \exp\left(-\frac{q\phi_b}{kT}\right) \tag{18}$$

In the second conceptual step of this process, electrons with the appropriate energy must actually cross the semiconductor/metal interface, as opposed to thermalizing and remaining in the metal. A chemical analog of this event is that, once a set of reactants reaches the transition state, there is a defined probability that the reagents will proceed to form products, as opposed to reverting back to reactants. The constant in equation (18) therefore contains the probability of an actual interfacial charge transfer event. This constant also includes parameters that describe the maximum frequency for electron transfer events at the particular semiconductor/metal interface under consideration. Taken together, these two quantities closely resemble the preexponential factor in an Eyring rate expression for a chemical reaction.[25]

For a semiconductor/metal contact, it can be shown that the constant in equation (18) has a weak temperature dependence, that is, constant $\propto T^2$.[1] This temperature dependence is generally written explicitly in the expression for I_0, so the conventional form of the exchange current for a semiconductor/metal contact is

$$I_0 = A_s A^{**} T^2 \exp\left(-\frac{q\phi_b}{kT}\right) \tag{19}$$

where A_s is the area of the contact, and A^{**} is the effective Richardson constant. The constant A^{**} typically has a value of $10^2\ \text{A cm}^{-2}\ \text{K}^{-2}$.[1] The value of A^{**} is dependent on the type of semiconductor and type of metal at the particular contact of interest, but fortunately the values of A^{**} for common n-type semiconductor/metal contacts are relatively constant.[1,2] The major factor that determines the magnitude of I_0 is clearly the exponential term, which depends on the barrier height of the contact.

The role of $E_{F,m}$ in determining the electrical properties of a semiconductor/metal contact is now obvious. Physically, a more positive electrochemical potential of the metal will produce a larger barrier height and, according to equation (19), will produce a larger activation energy for electron transfer. This will produce a smaller exchange current at the semiconductor/metal contact. This effect on the exchange current can also be seen by considering the influence of $E_{F,m}$ on the semiconductor phase. In the semiconductor, a larger value of ϕ_b will produce a larger built-in voltage at an n-type semiconductor/metal interface (see Figures 2 and 4). This increased band bending decreases the equilibrium electron concentration at the surface (n_{so}), and leads to a smaller exchange current for this semiconductor/metal junction. Control over ϕ_b therefore produces control over I_0, and thus produces control over the rectification properties of semiconductor/metal contacts.

The rectification properties of semiconductor interfaces are the most important electrical characteristic of semiconductor contacts. Certain types of devices, such as transistors, require both ohmic and rectifying contacts on a given semiconductor surface, whereas other devices, such as Schottky barriers, are based on the inherent rectification properties of semiconductor/metal junctions. Numerous photonic devices, such as photon detectors and photovoltaic cells, require rectification at a semiconductor junction, and light-emitting diodes require both ohmic contacts and rectifying junctions in a well-defined geometry. Thus, successful fabrication of a desired device structure depends entirely on the electrical properties of the specific semiconductor contacts that are formed in the process. The principles described above allow the rational fabrication of contacts with the desired properties, and also describe the operation of the resulting devices within a simple, chemically intuitive, kinetic framework.

Although the discussion to this point has specifically focused on semiconductor/metal contacts, an identical formalism and analogous rate equations can also be used to describe the electrical properties of semiconductor/liquid contacts. Again the important factor is control over I_0, and again the energetic properties of the interface are the key factors that control the rectification properties of the system. In a semiconductor/liquid junction, it is the difference between the electrochemical potential of the solution and the energy of the conduction band edge ($E(\text{A/A}^-) - E_{cb}$) which defines the barrier height energy of the system.

For liquids, the only major difference in the kinetic equations lies in the analog of the Richardson constant. The probability of interfacial charge transfer at a semiconductor/liquid

interface clearly depends on the chemical nature of the donor/acceptor pair that participates in the electron transfer event. For semiconductor/liquid contacts the exchange current is typically written as $I_0 = A_s[A]n_{so}k_{et}$, where A_s is the area of the contact, [A] is the concentration of the acceptor in the solution and k_{et} is the intrinsic rate constant for electron transfer at the semiconductor/liquid interface of interest.[19] The electron transfer rate constant is a very important parameter in the kinetics of electron transfer at a semiconductor/liquid junction, and k_{et} appears in most of the equations that utilize kinetic models for I_0. Theoretical expressions for k_{et} have been derived by Morrison and by Gerischer.[19,26,27] These treatments have been reviewed extensively in the literature, and are primarily based on the Marcus theory for electron transfer at metal electrodes.[7,28–30]

The interfacial kinetics processes at semiconductor/liquid contacts for reactions with one-electron, outer-sphere, redox species can be understood in a conventional theoretical framework. The rate constant k_n can be broken down into a term representing the attempt frequency, ν_n, a term representing the electronic coupling between the electrons in the conduction band of the semiconductor and the redox acceptor state, κ_{el}, and a term representing the nuclear reorganization energy in the transition state from reactants to products, κ_n.[29] For outer-sphere electron transfer processes, the nuclear term is well-known to be:

$$\kappa_n = \exp\left[\frac{(-E_{cb} - qE^{o\prime}(A/A^-) + \lambda)^2}{4\lambda kT}\right] \qquad (20)$$

where λ is the nuclear reorganization energy.[29] The attempt frequency, ν_n, is generally on the order of $10^{13}\ s^{-1}$, being related to the vibrational frequency of the nuclear motions that drive the reaction to the transitional state. For a random distribution of nonadsorbing outer sphere acceptors in the solution, the electronic term, κ_{el}, theoretically has a value on the order of $10^{-31}\ cm^4$.[31] Hence the theoretical maximum interfacial charge transfer rate constant for a nonadsorbing, weakly coupled outer-sphere redox system to a semiconductor is expected to be on the order of $10^{-17}\ cm^4\ s^{-1}$. An alternative evaluation, using a Fermi Golden Rule approach to evaluate the maximum value expected for k_{et}, yields a similar value.[32]

Recent experimental studies have confirmed these theoretical expectations for several exemplary semiconductor/liquid interfaces.[31] Detailed rate measurements on n-Si/CH_3OH-viologen$^{2+/+}$ and n-InP/CH_3OH interfaces have validated the dependence of k_n on driving force, as predicted by equation (20), and have indicated that the value of k_n at optimal exoergicity is approximately $10^{-17}\ cm^4\ s^{-1}$. Scanning electrochemical microscopy measurements of the kinetics at p-WSe_2/H_2O-$Ru(NH_3)^{63+/2+}$ interfaces have yielded an interfacial charge-transfer rate constant of $5.7 \times 10^{-17}\ cm^4\ s^{-1}$, and estimates of the nuclear terms for this reaction result in a rate constant at optimal exoergicity of $2 \times 10^{-16}\ cm^4\ s^{-1}$. Hence it appears that these types of processes seem to be reasonably well-understood both experimentally and theoretically. In contrast, inner-sphere electron transfer processes, and processes involving adsorbed redox species, are not well-understood at present.

Even for inner sphere processes and adsorbed species, owing to the dependence of n_s on barrier height, for an n-type semiconductor, more positive redox potentials generally yield smaller values of I_0, and produce highly rectifying behavior.

The electrical behavior of semiconductor/liquid contacts is thus very similar to that of semiconductor/metal contacts. For an n-type semiconductor, more positive redox potentials will yield smaller values of I_0, and will produce highly rectifying diode behavior. In contrast, more negative redox potentials will yield larger values of I_0, and will produce poorly rectifying diode behavior. Thus, one goal in constructing semiconductor/liquid junctions is to insure that chemical control is maintained over the $I-V$ properties of semiconductor/liquid contacts. Changes in the solution redox potential are therefore one of the most important methods of manipulating the $I-V$ properties of semiconductor/liquid interfaces.

Similar behavior is also obtained for semiconductor/semiconductor interfaces. For homojunctions, the interfacial energetics are fixed by the nature of the solid, but the degree of charge transfer, and therefore the degree of rectification, is determined by the doping levels of each portion of the semiconductor device. In this situation, I_0 is a function of the dopant density of each phase. For such devices, I_0 is also a function of other physical properties of the material, such as the lifetime and diffusion coefficients of the charge carriers in the sample of interest. The particular equations that govern the current–voltage properties of homojunctions are well-known in the solid-state physics literature and will not be discussed in detail here.[1] However the fundamental operating principles of these types of devices are also readily grasped by application of the equations discussed above.

Although the diode behavior of a semiconductor/metal and a semiconductor/liquid junction have been derived by assuming that electron transfer is the important charge flow process across the interface, the diode equation is generally applicable to semiconductor/contact devices even when other processes are rate limiting, as is often the case for semiconductor/liquid junctions. A similar derivation can be performed for other possible charge flow mechanisms, such as recombination of carriers at the surface and/or in the bulk of the semiconductor. It can be shown that the $I-V$ relationships for these mechanisms almost all adopt the form of equation (17).[2,6] The major difference between the various mechanisms is the value of I_0 for each system. Mechanistic studies of semiconductor junctions therefore generally reduce to investigations of the various factors that control I_0. Such studies also involve quantitative comparisons of the magnitude of I_0 with the value expected for a specific charge transport mechanism. These types of investigations

have yielded a detailed level of understanding of many semiconductor interfaces. Recent reviews, describing more details of this work on semiconductor/liquid interfaces, have been written by Koval[7] and by Lewis.[30,31] However, regardless of mechanism, the key point is that chemical control over I_0, and over the rectification properties of semiconductor contacts, is the ultimate goal of semiconductor contact chemistry.

4 SUMMARY

Using a very simple, qualitative approach, the fundamental properties of semiconductor contacts that are responsible for the operation of rectifiers, transistors, photovoltaic devices, and light-emitting diodes have been described. The charge-transfer processes across semiconductor interfaces are ultimately responsible for this behavior; thus, control over the interfacial charge-transfer reactions is crucial to control over the properties of semiconductor contacts. The penetration of the electric field and the electric potential into a bulk semiconductor phase yields a nonuniform carrier concentration in the sample, and produces contacts that either attract or repel specific types of charge carriers. Chemical control over these electric fields is crucial to the technology of semiconductor contacts. In principle, such control can be established through a simple variation in the electrochemical potential of the contacting phase. In practice, this ideal model often does not apply, and other factors influence or completely determine the interfacial electric field strength. The basis for semiconductor contact chemistry can, however, be understood in a straightforward fashion once the nature of the interface is successfully elucidated. These principles can be applied in a quite general fashion to semiconductor/semiconductor, semiconductor/metal, semiconductor/liquid and semiconductor/polymer contacts, making the approach valuable for understanding the operational principles of a variety of technologically important semiconductor devices.

Glossary

Absorption coefficient: a parameter that characterizes the ability of a solid to absorb light of a given wavelength
Acceptor: an impurity that scavenges an electron from the semiconductor; acceptors produce a hole in the valence band and a negative charge on the dopant atom
Charge carrier: either an electron or a hole, both of which are capable of conducting electrical charge in a semiconductor
Common anion rule: a general guideline, which states that the lattice anion controls the position of the valence band edge of a semiconductor
Conduction band: the lowest unfilled energy band in a solid
Conduction band edge: the bottom of the lowest unfilled energy band in a solid
Deep dopant: a dopant whose energy level is close to the middle of the semiconductor band gap
Direct band gap semiconductors: semiconductors that display a fully allowed electronic transition between the valence and conduction bands
Donor: an impurity that is readily ionized to produce an electron in the conduction band and a positive charge on the dopant atom
Dopant atoms: chemical impurities that are deliberately introduced into the semiconductor lattice to provide control over the conductivity and Fermi level of the solid
Doping: the introduction of specific chemical impurities into a semiconductor lattice to control the conductivity and the Fermi level of the semiconductor
Effective density of states: the number of electronic states within $3kT$ of the edge of an energy band, where k is the Boltzmann constant and T is the temperature
Energy bands: a cluster of orbitals in which the individual molecular orbitals are packed closely together to form an almost continuous distribution of energy levels
Fermi level: the energy level at which the probability of finding an electron is 1/2. This quantity characterizes the tendency of a semiconductor to transfer charges to other phases
Hole: an electronic vacancy in the valence band of a solid
Indirect band gap semiconductors: semiconductors in which the lowest energy electronic transition between the valence and conduction bands is formally optically forbidden
Intrinsic semiconductor: an undoped semiconductor
Majority carrier: the predominant charge carrier in the bulk of a doped semiconductor
Minority carrier: the less abundant charge carrier in the bulk of a doped semiconductor
n-type semiconductor: a semiconductor sample, doped with donors, that has an excess of free electrons relative to the intrinsic sample
Optical penetration depth: the distance into the semiconductor at which the transmitted light intensity reaches $1/e$ of the incident light intensity at the surface of the semiconductor
p-type semiconductor: a semiconductor sample, doped with acceptors, that has an excess of free holes relative to the intrinsic sample
Semiconductor band gap: the energy difference between the top of the valence band and the bottom of the conduction band in a semiconductor
Shallow dopant: a dopant whose energy level is close to either the valence band or the conduction band
Valence band: the highest filled energy band in a solid
Valence band edge: the top of the highest filled energy band in a solid

1 INTRODUCTION

Semiconductors constitute one of the most important classes of materials of the twentieth century. Their unique optical, electronic, and thermal properties make them well-suited for a variety of applications in the modern electronics industry. Semiconductors are of increasing interest to chemists owing to their applications in solar energy conversion,[1–5] organic synthesis,[6,7] and waste water treatment.[8,9] Common semiconductors can be formed from a variety of starting materials. Si and Ge are elemental semiconductors, whereas other semiconductors may be binary compounds (e.g. GaAs, CdS, and TiO_2), ternary compounds (e.g. $Hg_{0.2}Cd_{0.8}Te$ and $Ga_{0.8}As_{0.2}P$), or quaternary materials (e.g. $In_{0.2}Ga_{0.8}As_{0.7}P_{0.3}$) (*see Compound Semiconductor*). The unifying characteristic of semiconductors is their level of electrical conductivity. A semiconductor is generally defined as a material that has an electrical conductivity, σ, between 10^{-9} ohm^{-1} cm^{-1} and 10^2 ohm^{-1} cm^{-1}.[10] Thus, semiconductors comprise the class of materials whose electrical conductivities are higher than those of insulators and lower than those of metals. Another, more useful experimental definition is that the conductivity of a semiconductor increases exponentially with increasing temperature. As described below, the conductivity of a semiconductor is ultimately determined by its chemical and electronic structure. The focus of this chapter is to describe the important chemical structures, optical characteristics, and electrical properties of semiconducting solids.

The conductivity of semiconductors can be deliberately manipulated through the introduction of specific chemical impurities. This process is known as doping. These chemical impurities, or dopants, can either donate additional charges to the semiconductor, or can accept charges from the solid. The introduction of dopants can greatly modify the electrical properties of semiconductors. In fact, in some cases, doping can effect changes of over eight orders of magnitude in the electrical conductivity of a semiconductor![11] The factors involved in the choice of a particular dopant, and understanding the behavior of different dopant atoms in semiconductors, are two other chemical issues that will be discussed in this chapter.

Another important characteristic of semiconductors is their optical absorption properties. The optical properties of semiconductors are crucial to their uses as photovoltaic energy conversion devices, photonic detectors, light-emitting diodes, solid state lasers, and optical switches[11] (*see* ***Semiconductor Interfaces***). Some semiconductors absorb both visible and ultraviolet light, while others only absorb photons in the near-ultraviolet portion of the electromagnetic spectrum. The thickness of material required to absorb photons effectively can also vary widely in semiconductors, with strong absorbers requiring as little as 100 Å of material and weak absorbers requiring as much as 0.1 cm of material. The important optical properties of a semiconductor can also be understood from their chemical and electronic properties. Thus, a final goal of this chapter is to elucidate the chemical basis of the optical characteristics of semiconducting solids.

2 CRYSTAL STRUCTURES OF SELECTED SEMICONDUCTORS

To discuss the properties of semiconductors from a chemical perspective, it is important to first understand the structures of semiconducting solids. Semiconductors comprise a diverse group of inorganic materials and exhibit a variety of different *Crystal Structures*. The most basic semiconductor structure is based on the interpenetration of two face-centered cubic (fcc) lattices. A familiar, nonsemiconducting solid that adopts this structure is NaCl, where the Na^+ cations constitute one fcc lattice and the Cl^- anions constitute the other (Figure 1(a)). Many specific crystal structures of semiconductors are related to this basic face-centered cubic lattice.

Covalent semiconductors, such as the elemental semiconductors Si and Ge, have structures in which the atoms achieve maximum bonding between nearest neighbor atoms. For Si and Ge, each atom prefers sp^3-based tetrahedral bonding. Thus, these atoms will prefer a lattice in which tetrahedrally bonded atoms are positioned as closely as possible within the face-centered cubic structure. Si and Ge therefore adopt the cubic diamond lattice, in which half of the tetrahedral positions in the face-centered cubic lattice are filled with atoms (Figure 1(b)). A related structure is adopted by covalent, binary semiconducting solids having elements of similar electronegativities. For example, GaAs adopts the zinc blende structure, which is simply the cubic diamond structure with adjacent atoms throughout the structure alternating in type (Figure 1(c)). InAs, InP, and GaP are other examples of common covalent binary semiconductors that adopt the zinc blende structure.

In certain cases, when the semiconductor is composed of elements with very different radii and electronegativities, the lattice site in the tetrahedral position of a face-centered cubic structure becomes too small to accommodate one of the ions in the semiconductor. To maintain a lattice with a 1:1 cation:anion stoichiometry, the solid adopts a structure in which the atoms are instead hexagonally close-packed. As in the zinc blende structure, only half of the possible tetrahedral sites in this hexagonal structure are filled with atoms. This arrangement, which is adopted by semiconductors such as ZnO and CdSe (Figure 1(d)), is called the wurtzite structure.

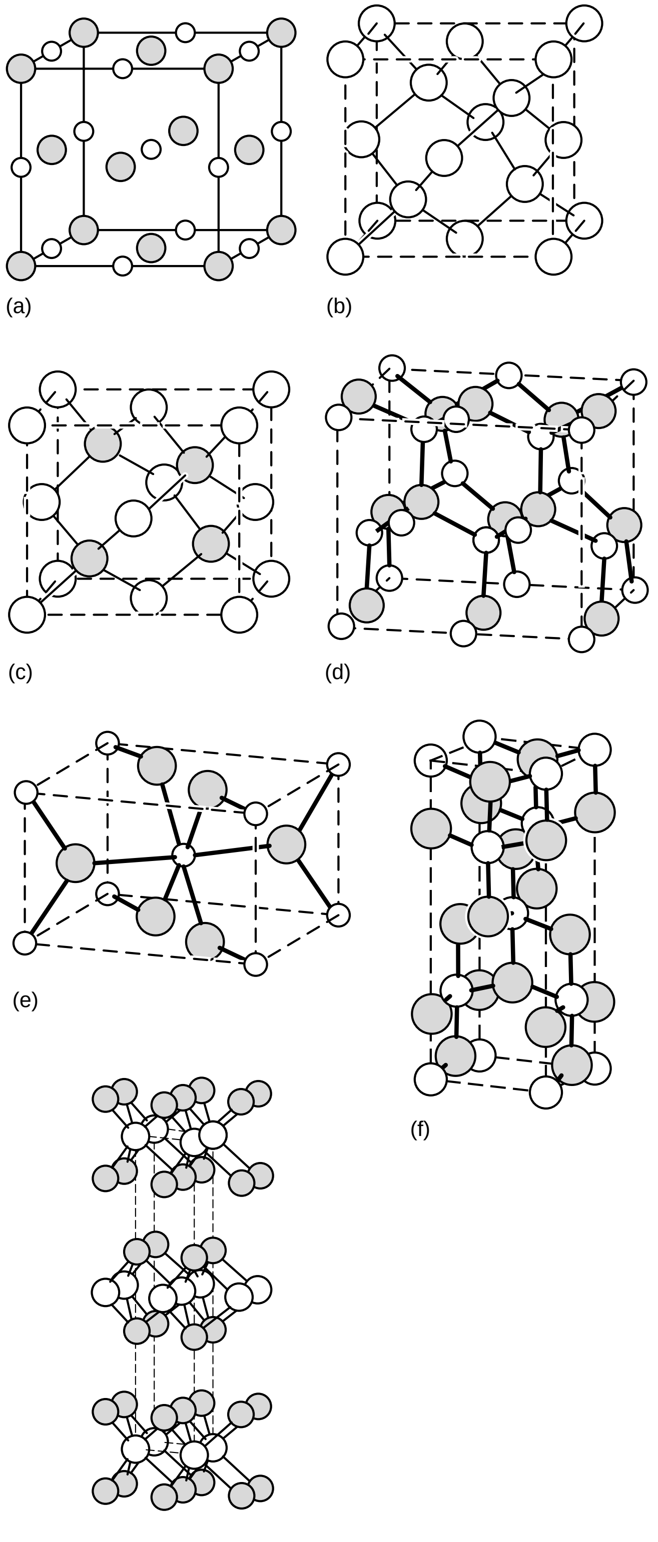

Figure 1 Structures of some common crystal lattices: (a) NaCl, (b) Si, (c) GaAs, (d) ZnO wurtzite, (e) TiO_2 rutile, (f) TiO_2 anatase, (g) MoS_2. For the binary materials, the shaded circles represent the more electronegative elements (i.e. Cl, As, O, and S) and the empty circles represent the less electronegative elements (i.e. Na, Ga, Zn, Ti, and Mo)

Some materials, such as ZnS, can be found in either the zinc blende or the wurtzite structure. Comparison between these lattices shows that the wurtzite structure is more open, and the bonding more ionic, than is the zinc blende structure.

Taken together, these three structures (cubic diamond, zinc blende, and wurtzite) encompass the majority of the common semiconductor materials in use today. These structures, which share the common feature of having an average of four valence electrons per atom, are called adamantine solids.[12]

In several semiconducting solids, steric, or electronic factors can result in the adoption of nonadamantine structures. Semiconductors that adopt nonadamantine structures include metal oxides such as TiO_2 and $SrTiO_3$, and transition metal dichalcogenides such as MoS_2, WS_2, and WSe_2. TiO_2, an important semiconductor, occurs in three forms: brookite, rutile, and anatase, but only rutile and anatase are commonly used.[2] Figures 1(e),(f) show the structures of the two common forms of TiO_2. The rutile lattice is derived from a body-centered cubic structure, where one-half of the trigonal-planar sites are occupied by anions to maintain a 1:2 cation:anion stoichiometry. The anatase lattice is derived from the NaCl structure with only one-half of the sites in one fcc lattice occupied by the Ti^{4+} cations. To date, large single crystals of TiO_2 have only been prepared in the rutile structure, while TiO_2 powders commonly contain both anatase and rutile components.[2]

Figure 1(g) illustrates a structure that is commonly found for transition metal dichalcogenide compounds such as MoS_2, WS_2, and WSe_2. These semiconductors adopt a layered structure in which the transition metal is 'sandwiched' between two layers of chalcogenide atoms. This arrangement produces a van der Waals structure, because there is no covalent bonding between adjacent chalcogenide layers. A useful feature of this structure is that the weak interactions between these planes allow high quality surfaces of van der Waals crystals to be prepared merely by peeling layers of the crystalline sample apart, as opposed to the extensive chemical and/or mechanical etching procedures that are required to produce desired surfaces in the more covalent semiconductor structures.

The surface properties of semiconductors often depend on the nature of the exposed crystal face. By convention, the orientation of a semiconductor surface is defined by the crystal plane that lies perpendicular to the normal of the surface. The conventional notation for this plane is obtained using Miller indices.[10,13] First, it is necessary to identify the intercepts of the surface plane with the crystallographic axes. The reciprocals of these intercepts are then reduced to Miller indices, which are integers that have the same ratios as the reciprocals themselves. For example, the plane ABCD in Figure 2 has formal intercepts of $\{1, \infty, \infty\}$ on the axes; thus, in the Miller index notation it is designated as the (1/1, $1/\infty$, $1/\infty$), or (100) plane. When a plane has a negative axis intercept, a bar is placed over the corresponding Miller index. For example, the plane that intercepts the axes at $x = -1$, $y = \infty$, $z = \infty$ would be designated as the $(\bar{1}00)$ plane.

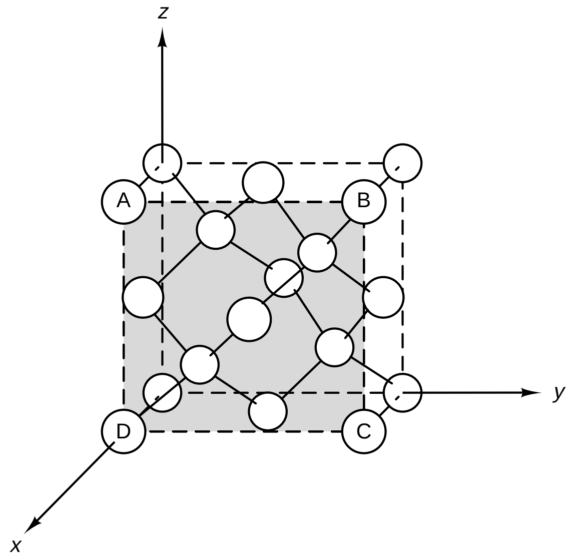

Figure 2 A schematic representation of Miller indices, imposed upon the Si crystal lattice. The x-, y-, and z-axes are indicated on the Si lattice, with the Si (100) face shaded

In the Miller index notation, the convention for denoting a direction perpendicular to a particular plane is to put square brackets around the numbers denoting that plane. The x-axis in Figure 2, for instance, is the [100] direction.

In some structures, several planes and directions may be equivalent by symmetry. For example, this is the case for the (100), (010), (001), ($\bar{1}$00), (0$\bar{1}$0), and (00$\bar{1}$) planes in the diamond cubic structure. Equivalent directions are denoted concisely as a group by using angular brackets. Thus, the ⟨100⟩ directions in a diamond cubic lattice include all of the directions that are perpendicular to the six planes noted above. The Miller index notation thus provides a concise designation for describing the surfaces of semiconductor crystals.

3 BAND STRUCTURE AND OPTICAL PROPERTIES OF SEMICONDUCTORS

The structure of semiconducting solids provides a convenient basis for understanding the important electronic properties of these materials. The important optical and electrical characteristics of semiconducting solids arise from the delocalized electronic properties of these materials. To understand the origin of this electronic delocalization, we must consider the nature of the bonding within semiconductor crystals. The basic model that has been successfully used to describe the electronic structure of semiconductors is derived from the *Band Theory* of solids. Our treatment of band theory will be qualitative, and the interested reader is encouraged to supplement our discussion with the excellent reviews by Hoffmann,[14–16] and with the classic texts by Ashcroft and Mermin,[17] Harrison,[18] Kittel,[10,19] Seitz,[20] and Goodstein.[21]

3.1 Molecular Orbital Description of Semiconducting Solids

The process of obtaining delocalized molecular orbitals for solids is similar to the approach that chemists use to describe the bonding in simple diatomic molecules. However, when orbital theory is used to describe the electronic properties of a collection of atoms within a solid lattice, a different terminology is generally used. The process is first illustrated on a chemically familiar system consisting of polyenes of varying chain lengths. This methodology is then generalized to include the bonding description of inorganic semiconducting solids.

3.1.1 Band Structure in Linear Conjugated Polyenes

An orbital description of the bonding in ethylene, which is the repeating unit in a straight chain polyene, is described first. In the Hückel molecular orbital (MO) description of ethylene (*see Hückel Theory*), the carbon atoms are sp^2 hybridized into a σ-orbital framework. The remaining carbon p-orbitals interact to yield two orbitals of π-symmetry, one of which is bonding and the other antibonding with respect to the C–C interaction. This situation is qualitatively represented in Figure 3. In the ground state of ethylene, the bonding π-orbital is occupied by two electrons, and this orbital is lower in energy than the empty antibonding orbital. A discrete optical transition exists between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of ethylene, because a well-defined energy gap separates these two orbitals (*see HOMO–LUMO Gap*).

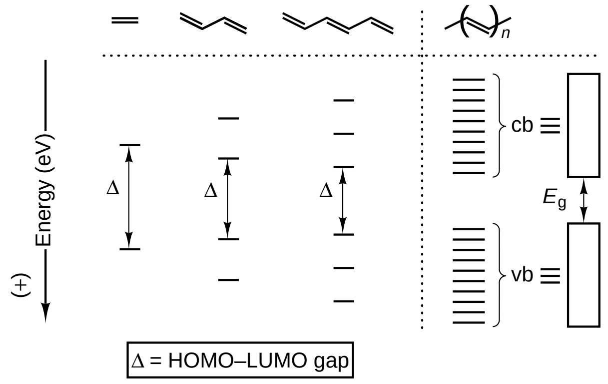

Figure 3 The development of a polyene band structure from the molecular orbitals (MOs) of ethylene.[14,15] From left to right, the molecular orbitals progressively develop into a band structure as the length of the conjugated chain is increased. For shorter polyene chains, Δ represents the HOMO–LUMO gap. For the infinite polyene chain, vb and cb denote the valence band and the conduction band, respectively, and E_g is the band gap

As the basic ethylene units are coupled together to form a larger molecule, the π-bonding will become more delocalized, and more atomic orbitals must be included in the overall molecular orbital description (Figure 3). When an infinite one-dimensional polyene chain is formed, it will contain an infinite number of bonding and antibonding molecular orbitals. In this infinite chain, the bonding orbitals will tend to cluster together into a tightly packed group, while the antibonding orbitals will cluster into another tightly packed group. It can be shown that these orbital clusters are separated by a well-defined HOMO–LUMO energy gap, just as in the cases of ethylene, 1,3-butadiene, 1,3,5-hexatriene, and other molecular oligomers that are precursors to the infinite chain polyene (Figure 3).[14,15]

Because the fully developed polyene has an extremely large number of molecular orbitals, a description of the π-bonding in this molecule can be simplified by considering groups of orbitals together as sets. Even though each of the molecular orbital distributions in the polyene consists of a large number of orbitals that are packed tightly together into a finite energy interval, we can ignore the energy spacing between the individual orbitals for most purposes. We can therefore consider the orbitals to form ‘continuous’ bands of energy levels (*see Energy Bands*). A shorthand notation for this assumption is to draw each band as a single block in energy. In this notation, there is an implicit understanding that there are actually a large number of states clustered together within this block (Figure 3). Under this scheme, the HOMO–LUMO gap is called the *Band Gap*.

3.1.2 Band Structure in Semiconducting Crystals

The band structure of a three-dimensional solid, such as a semiconductor crystal, can be obtained in a similar fashion to that of a polyene. Localized molecular orbitals are constructed based on an appropriate set of valence atomic orbitals, and the effects of delocalization are then incorporated into the molecular orbital as the number of repeat units in the crystal lattice is increased to infinity. This process is widely known to the chemical community as extended Hückel theory (*see Extended Hückel Molecular Orbital Theory*). It is also called tight binding theory by physicists who apply these methods to calculate the band structures of semiconducting and metallic solids.

We will not describe this process in detail for semiconducting solids, because there are complications that result from the different symmetry types of various unit cells, as well as from spin–orbit coupling considerations. These factors tend to increase the complexity of the MO description of inorganic solids relative to the simple MO treatment of polyenes. However, the principles of the procedure are the same as those outlined for the polyene example, with each individual atom in the lattice contributing a set of atomic orbitals toward the formation of crystal orbitals. These crystal orbitals will extend throughout the solid, and will yield discrete energy bands when represented on an energy diagram, just as in our polyene example (Figure 4). By definition, the highest filled band is called the valence band of the semiconductor. Similarly, the lowest unfilled band is called the conduction band. Thus, we obtain energy diagrams for semiconductor crystals that are similar to the one presented in Figure 3 for the organic polyenes, with bands of orbitals representing the HOMO and LUMO for the material of concern (Figure 4).

In semiconductor terminology, the top of the valence band and the bottom of the conduction band are called the valence band edge and the conduction band edge, respectively. The energy of the conduction band edge is denoted as E_{cb}; similarly, the energy of the valence band edge is denoted as E_{vb}. The energy difference between these levels is called the semiconductor band gap. The size of this band gap, E_g, is perhaps the most important characteristic of a semiconducting solid, as it influences many electronic properties of semiconductors. In general, semiconducting solids have band gaps that range from 0.5 to 3.5 eV; Table 1 lists the values of E_g for a variety of common semiconductors.

It should be noted that the positions of the crystal orbitals on the energy scale in Figures 3 and 4 are located with respect to the vacuum level as reference. The vacuum level is defined

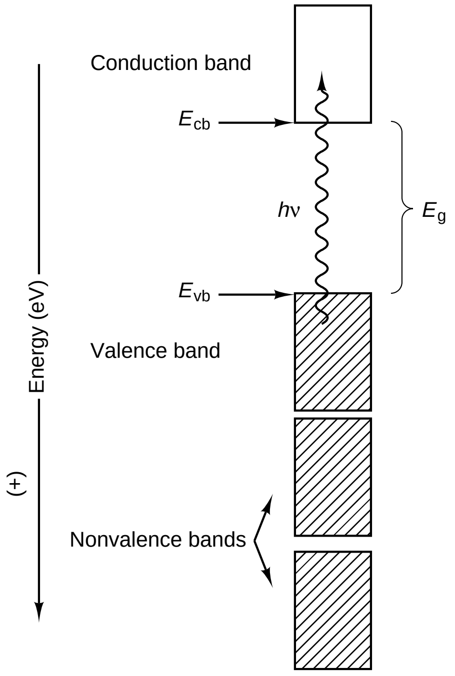

Figure 4 A schematic representation of the band structure of a semiconductor. The shaded area denotes a fully occupied band and the unshaded area denotes an empty band. Two nonvalence bands are also drawn to stress the point that the valence band of a semiconductor is the highest occupied band. E_{cb} and E_{vb} represent the conduction band edge and the valence band edge, respectively, and E_g is the band gap. When photons with energy greater than the band gap are absorbed by the semiconductor, electrons are excited from the semiconductor valence band into the conduction band

Table 1 Properties of some common semiconductors[a]

Semiconductor	Crystal structure	Band gap (eV)[b]	Type of band gap
Si	Diamond	1.12	Indirect
Ge	Diamond	0.66	Indirect
Se	Hexagonal	1.77	Direct
GaP	Zinc blende	2.26	Indirect
GaAs	Zinc blende	1.42	Direct
InP	Zinc blende	1.35	Direct
InAs	Zinc blende	0.36	Direct
ZnS	Zinc blende	3.58	Direct
	Wurtzite	3.70	Direct
ZnSe	Wurtzite	2.67	Direct
ZnTe	Wurtzite	2.26	Direct
CdS	Wurtzite	2.42	Direct

WO_3	Perovskite	2.7	Indirect

[a]Data compiled from Refs. 2,11,22–24, and 25. [b]At 300 K.

as the energy level of an electron in vacuum, and is taken to be zero eV on the energy scale. Note also that although the physics convention assigns more negative energies to electrons that are more tightly bound relative to vacuum (for example, the energy of a 1s orbital in the H atom is −13.6 eV), the energy scale used by most electrochemists is opposite in sign, with more tightly bound electrons having more positive energies relative to the vacuum level. The assignment on the electrochemical energy scale is based on a 'work function' convention, which refers to the energy required to remove an electron from a particular electronic state in the solid.

3.1.3 *Density of States in the Energy Bands of a Semiconductor*

An important numerical quantity that describes the electronic structure of a semiconductor is the density of electronic states within a band. The density of electronic states per unit of energy can be obtained in a qualitative fashion by assuming that the crystal acts like a potential well and by treating the electron as a particle in a box.[11,17,19] Since the motions of electrons in a crystal are restricted by the delocalized orbital structure of the solid, the apparent mass of the electron is different from its mass in a vacuum. This 'effective' mass, m_e^*, describes the movement of an electron under the influence of the periodic potential in the lattice. The value of m_e^* can be calculated from the band structure of the semiconducting solid, and can also be measured experimentally using cyclotron methods.[10]

When the value of the effective electron mass is known, the resulting expression for the density of states in the conduction band is

$$N_{cb}(E) = \frac{4\pi(2m_e^*)^{3/2}}{h^3}(E_{cb} - E)^{1/2} \qquad (E \leq E_{cb}) \tag{1}$$

where h is Planck's constant and $N_{cb}(E)$ describes the density of electronic states in the conduction band as a function of energy, E. In this formalism, the influence of the periodic lattice potential on $N_{cb}(E)$ is contained in the value of the effective mass, m_e^*. A similar expression can be obtained to describe the density of electronic states in the valence band, and in all other bands, of the semiconducting solid.

The density of states is useful to our discussion because it allows the calculation of an extremely important numerical quantity, the effective density of states in the conduction band of the semiconductor, N_c. As a first approximation, N_c can be considered to be the number of electronic states in the conduction band of the semiconductor that are available to accept electrons from a donor. N_c is more formally defined as the number of electronic states, $N(E)$, for all energy E within $3kT$ of the conduction band edge $[|(E_{cb} - E)| < 3kT]$. Given the density of states per unit energy (equation 1), and using Fermi–Dirac statistics to describe the distribution of electrons as a function of energy, it can be shown that[10,11,17]

$$N_c = 2\left(\frac{2\pi m_e^* kT}{h^2}\right)^{3/2} \tag{2}$$

Typically, $N_c \approx 10^{19}$ states cm^{-3}. A similar equation can be derived for the valence band, and the effective density of states in the valence band, N_v, is also $\approx 10^{19}$ states cm^{-3}.

3.1.4 *Chemical and Electronic Properties of Semiconductors*

In general, semiconductors can have different types of valence band and conduction band structures. These differences can affect the chemical reactivity of the various types of semiconducting solids. For example, in a covalent solid such as Si, the valence and conduction bands can be considered as crystal orbitals that are either bonding or antibonding combinations of hybridized Si atomic orbitals. This situation is closely related to our polyene example, where the valence band consisted of bonding π-orbitals and the conduction band consisted of antibonding $\pi*$-orbitals. However, in an ionic crystal such as TiO_2, the valence band is composed of crystal orbitals that are derived from the filled O^{2-} 2p orbitals, while the conduction band is composed of crystal orbitals that are

derived from the empty 3d orbitals of Ti^{4+}.[26–29] In this case, the band gap is not an energy gap between bonding and antibonding bands of the same symmetry. Rather, it is the energy gap between two very different types of bands.

The electronic band structure of solids is also useful in explaining many chemical properties of semiconductors. For example, ionic semiconductors are generally more stable towards corrosion and passivation than covalent semiconductors. This observation can easily be rationalized using the frontier molecular orbital argument (*see Frontier Orbitals*), which states that chemical reactivities are often controlled by the size of the HOMO–LUMO gap.[30,31] For semiconductors, the HOMO–LUMO gap is the band gap, and therefore the chemical reactivity of semiconductors should be related to the value of E_g. In a covalent semiconductor, the crystal orbitals that comprise the valence band and the conduction band are reasonably close in energy. The band gaps of these materials are relatively small, and these semiconductors are thus expected to be chemically reactive. This prediction is in agreement with experiment. In fact, one of the key problems in using small band gap semiconductors in energy conversion applications is their tendency to undergo corrosion and passivation reactions.[2] In contrast, the crystal orbitals that make up the valence and conduction bands of ionic semiconductors (TiO_2, $SrTiO_3$, etc.) are generally very different in energy, so their band gaps are usually very large. These solids should therefore be less prone to undergo oxidation or corrosion reactions. This prediction is also consistent with experimental results, and accounts for the emphasis on the use of metal oxides in water photoelectrolysis.[32–34]

The orbital character of the valence and conduction bands can also be used to understand trends in the electronic properties of semiconductors. For example, even though the value of E_g varies a great deal in metal oxide semiconductors (Table 1), the energies of the valence band edges are quite similar throughout this series of solids. This similarity can be understood from our MO/band structure treatment, as the valence bands of these semiconductors are constructed predominantly from the 2p orbitals of O^{2-}. The MOs that arise from these atomic orbitals should therefore be similar in bonding character and in energy. Within this framework, changes in the lattice cation will primarily affect the energy of the conduction band edge. This prediction is consistent with experimental data for metal oxide semiconductors.[35–39]

This latter behavior has been generalized to extend beyond the metal oxide semiconductor series. A general guideline has been proposed that the valence band character of most semiconductors is dominated by orbitals that are derived from atomic orbitals of the lattice anion.[40] To the extent that this generalization is valid, it predicts that semiconductors with a given lattice anion will have valence band edge energies similar to other materials with the same lattice anion. This rule also predicts that changes in the lattice cation will be reflected primarily in the energy of the conduction band edge (and therefore also in the band gap energy). This generalization is called the *Common Anion Rule*.[40] Although the common anion rule has received some experimental and theoretical support,[38,41–48] it is at best a rough generalization of chemical and electronic behavior. This generalization is not expected to be rigorously valid for any wide series of materials, especially for solids with different crystal structures or lattice stoichiometries.

Another analogy to chemical systems can be made when considering the reactivity of excited states of semiconductors. In molecular systems, it is well known that the types of orbitals in the HOMO and LUMO can determine the chemical reactivity of the excited electronic states of a molecule. A similar argument can be applied to predict the reactivity of different semiconductors. For example, it has been suggested that van der Waals semiconductors such as MoS_2 should be more stable towards corrosion and passivation reactions than II–VI semiconductors such as CdS.[49,50] This prediction was based on calculations that revealed that the valence and conduction bands of MoS_2 are both largely Mo 3d in character. For MoS_2, excitation of an electron is expected to result in the transfer of an electron from one metal-derived orbital set (in the valence band) to another metal-derived orbital set (in the conduction band), so no photocorrosion processes should be initiated. In contrast, the valence band of CdS is S^{2-} in character, and the conduction band is Cd^{2+} in character. For CdS, excitation of an electron from the valence band to the conduction band is expected to remove an electron from the S^2-derived orbitals, and should provide an initial step towards the dissolution of the lattice anion as the neutral S^0 species. These predictions have been partially verified by experiment, as metal dichalcogenide electrodes are often more stable in contact with aqueous solutions than are II–VI compounds.[2]

3.2 Optical Characteristics of Semiconductor Materials

In a semiconductor, some of the most important electronic transitions arise from the optical excitation of an electron across the semiconductor band gap. This excitation leads to the promotion of an electron from an orbital in the valence band to an orbital in the conduction band. This fundamental and extremely important process is crucial to the use of semiconductors as photovoltaic devices, photonic detectors, and optical switches. It is possible to understand the optical properties of semiconductors using the band structure formalism described above.

The light absorption process in semiconductors has an energy threshold. The value of this threshold is the band gap energy, E_g. Only photons with energies greater than or equal to the band gap energy can induce an electronic transition in the semiconductor. Large band gap materials such as TiO_2 will therefore only absorb light at short wavelengths, whereas small band gap materials such as Si and GaAs will respond to larger portions of the electromagnetic spectrum.

The band gaps of common semiconductors can vary from near-zero ($E_g = 0.1$ eV for $Hg_{0.8}Cd_{0.2}Te$) to greater than 3 eV ($E_g = 3.2$ eV for $SrTiO_3$).

From Beer's law, the absorbance and transmittance of a material can be expressed as

$$A = \ln \frac{I_0}{I} = \varepsilon c l \text{ and } T = \frac{I}{I_0} = \exp(-\varepsilon c l) \quad (3)$$

where I is thetransmitted light intensity, I_0 is the incident light intensity, ε is the molar extinction coefficient, l is the optical path length, and c is the concentration of absorbing material. For solids, the concentration of the absorber is a constant, so Beer's law can be rewritten as

$$A = \ln \frac{I_0}{I} = \alpha l \text{ and } T = \frac{I}{I_0} = \exp(-\alpha l) \quad (4)$$

where $\alpha \equiv \varepsilon c$ is the absorption coefficient of the material. This latter expression is usually used for expressing light absorption in solids. In this expression, α is a function of the wavelength at which the light absorption is measured.

For molecules, the extinction coefficient, ε, of an electronic transition can vary over a wide range of values, depending on whether the transition is optically and/or spin allowed. For semiconductors, the same restrictions apply. At the wavelength of interest, the electronic transition from one band to another must be optically and spin allowed to have a high extinction coefficient, that is to have a large absorption coefficient, α. Semiconductors that display a fully allowed transition between the valence band and the conduction band are referred to as direct band gap semiconductors. In these materials, such as GaAs and CdTe, the absorption coefficients are large, and the light is strongly absorbed close to the surface of the solid. Typical values of α for these materials are 10^4–10^5 cm^{-1}. Figure 5 depicts a plot of the absorption coefficient versus wavelength for a typical direct band gap semiconductor, GaAs.

For other semiconductors, such as Si, the lowest energy electronic transition between the valence band and the conduction band is formally optically forbidden. These materials are said to have an indirect band gap. Indirect band gap materials generally display small absorption coefficients for photons near the band gap energy. This behavior is analogous to a d–d electronic absorption band in an octahedral transition metal complex, which is formally optically forbidden owing to the inversion symmetry of the d orbitals. In such complexes, d–d transitions are generally observed experimentally, albeit with weak extinction coefficients, because other mechanisms allow the light absorption process to conserve momentum when the entire molecular wavefunction is considered. Similarly, for indirect band gap semiconductors, light absorption is allowed only when the momentum of the photon is coupled to vibrations of the crystal lattice and to the lowest energy electronic transition. Because of this requirement, the photon absorption process

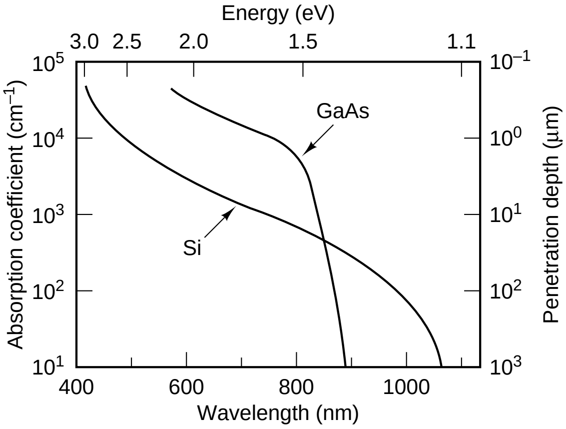

Figure 5 A plot of absorption coefficient versus photon wavelength for Si and GaAs.[24] A direct band gap semiconductor, such as GaAs ($E_g = 1.42$ eV), has a sharp onset of absorption at photon energy $= E_g$ and a large absorption coefficient for $h\nu > E_g$. The indirect band gap semiconductor Si ($E_g = 1.12$ eV) has a broad, weak onset of absorption, which begins at photon energies $\leq E_g$ owing to vibrational coupling with the crystal lattice. For Si, note the low value of the absorption coefficient at photon energies substantially higher than the band gap energy

is less likely to occur, and indirect band gap semiconductors therefore have small absorption coefficients. For example, although the band gap energy for Si is 1.12 eV, the absorption coefficient at photon energies of 1.3 eV is still only 10^2 cm^{-1} (Figure 5). This contrasts with the value of 10^4 cm^{-1} that is typically displayed by direct band gap materials at photon energies 0.1–0.2 eV higher than E_g.[11] Examples of other indirect band gap semiconductors include GaP and TiO_2.

For direct band gap materials, the absorption coefficient generally increases rapidly when $h\nu$ is approximately equal to E_g, and it then remains at large values when $h\nu$ is much greater than E_g. For indirect band gap materials, the absorption coefficient is generally a much more slowly rising function of energy, with $\alpha \propto (h\nu - E_g)^2$ (for $h\nu \geq E_g$) being a typical dependence of the absorption coefficient on the energy of the incident photon.[11] In both cases, all of the incident light can be absorbed if the sample is sufficiently thick, because, as indicated by equation (4), increases in l will produce increases in absorbance. Note, however, that as the photon energy increases, the indirect band gap material will eventually enter a regime where it absorbs light almost as effectively as a material with a direct band gap.

A related, useful quantity for characterizing the absorption of light by semiconductors is the optical penetration depth (Figure 5). This quantity is defined as the inverse of the absorption coefficient; that is, penetration depth $\equiv \alpha^{-1}$. From equation (4), it can be seen that the penetration depth is the distance into the semiconductor at which the transmitted light intensity reaches $1/e$ of the incident light intensity at the surface of the solid. In general, when compared to direct

band gap semiconductors, indirect band gap semiconductors have larger penetration depths, and therefore require thicker samples to fully absorb the incident light.

One important optoelectronic application of semiconductors is as photovoltaic energy conversion devices. For efficient solar energy conversion, a semiconductor needs to be thick enough to absorb essentially all the incident photons with energies greater than E_g. For example, Si, an indirect gap semiconductor, has a value of α equal to $10^2\ cm^{-1}$ for photon energies near E_g (Figure 5). This value implies that greater than 100 µm of Si must be used to absorb the incident light effectively in this energy range. This value places severe restrictions on the type of cells, and on the quality of crystals, that must be used in any efficient Si-based solar energy conversion device. This situation contrasts with that for the direct band gap semiconductor GaAs, in which α is approximately $10^4\ cm^{-1}$ near E_g (Figure 5). The large absorption coefficient of this direct band gap semiconductor implies that only 1–2 µm of GaAs are needed to harvest the incident photons effectively near the GaAs band gap energy. Similar considerations apply, of course, to the use of semiconductors in other optical applications, such as in photonic detectors and optical switching applications.

4 CARRIER STATISTICS FOR SEMICONDUCTORS

With the above description of the band structure and optical properties of semiconductors, it is now possible to describe the remaining key characteristic of semiconductors: electrical conductivity. The electrical conductivity of semiconductors forms the basis for most of the modern electronics industry. Without precise control over the electrical conductivity of semiconductors, many modern electronic devices would not perform satisfactorily. The goal of this section is to understand the chemical basis for the electrical properties of semiconducting solids.

4.1 Carrier Concentrations in an Intrinsic Semiconductor

First, the properties of the undoped, intrinsic semiconductor (i.e. the pure semiconductor) must be considered. Although semiconductors have been described as having a filled HOMO (the valence band) and an empty LUMO (the conduction band), this condition is only rigorously true at absolute zero. At any finite, nonzero temperature, thermal excitation within the solid will result in promotion of carriers from one band to the other. This promotion of carriers produces a nonzero conductivity of the semiconductor. This situation is described quantitatively in this section.

Before proceeding with this discussion, it is important to realize that there are two different types of charge carriers in a semiconductor: electrons and holes. The promotion of an electron from the valence band into the conduction band, either by thermal or optical excitation, produces a free electron in the conduction band and an electronic vacancy in the valence band. This electronic vacancy is commonly referred to as a hole. Although the motion of holes is actually a representation of the motion of the remaining collection of valence band electrons, a hole can formally be treated as a discrete particle with a positive electronic charge. In general, most of the properties of electrons in the valence band can also be calculated formally as properties of holes. For example, the effective mass of a hole can be calculated similarly to that of an electron. However, owing to differences between the electronic structures of the valence and conduction bands, it is important to realize that the effective mass of a hole in the valence band may be quite different from the effective mass of an electron in the conduction band. The hole formalism is, however, quite useful in concisely describing the charge carrier motion in the valence band of a semiconductor.

Like an electron, a hole can act as a charge carrier. For example, a hole moving towards a contact is physically identical to an electron in the valence band moving away from that contact. Because both electrons and holes contribute to the current in a semiconductor sample, we will use the more general term charge carriers to refer to either electrons or holes in a semiconductor.

To describe the conductivity of an intrinsic semiconductor sample quantitatively, we need to calculate the concentrations of both types of charge carriers in the solid. The key quantity that controls the equilibrium concentration of electrons and holes in an intrinsic semiconductor is the band gap. Because the thermal excitation energy required to produce an electron and a hole is equal to E_g, the intrinsic carrier concentrations can be related to E_g using the Boltzmann relationship:[51]

$$n_i p_i = \text{constant} \times \exp\left(-\frac{E_g}{kT}\right) \tag{5}$$

In this equation, k is the Boltzmann constant, T is the absolute temperature, and n_i and p_i are the electron and hole concentrations at equilibrium in the intrinsic semiconductor, respectively. Both n_i and p_i are expressed as particles cm^{-3}, which is often abbreviated as 'cm^{-3}'. The constant in equation (5) is actually a function of the band structure of the solid and is numerically equal to the product of N_c and N_v.[51] It is clear that this type of Boltzmann relationship should correctly describe the concentrations of electrons in the conduction band and of holes in the valence band that exist as a result of thermal excitation across the band gap at any given temperature.

Realizing that the thermal excitation to promote an electron into the conduction band must also result in the formation of a hole in the valence band, we can set $p_i = n_i$. This equivalence

leads to the following relationship between n_i and E_g:

$$n_i{}^2 = N_c N_v \exp\left(-\frac{E_g}{kT}\right) \quad (6)$$

This equation is essentially an equilibrium constant relationship between the electron and hole concentrations in the semiconductor. It is much like the ionization constant expression for the dissociation of water, which can be related to the concentrations of H^+(aq) and OH^-(aq) through the relationship $[H^+][OH^-] = K_w = 1 \times 10^{-14}$ M^2. The only difference between these two expressions is that the temperature dependence of the water dissociation equilibrium constant is contained implicitly in the value of K_w, but is explicit in the relationship expressed by equations (5) and (6). The most important point to remember is that increases in the sample temperature will produce exponential increases in the electron and hole concentrations for an intrinsic semiconductor. Thus, the conductivity of intrinsic semiconductors increases exponentially with temperature. In contrast, the conductivity of metals decreases with increasing temperature.[10]

We can now estimate the intrinsic carrier concentrations for many semiconductors. We merely use equation (6) with the appropriate values of N_c and N_v for each material. As described above, N_c and N_v have similar values and are typically $\approx 10^{19}\,\text{cm}^{-3}$. If these values are not known, they can be calculated from the band structure according to equation (2). For Si ($E_g = 1.12\,\text{eV}$), n_i is only $1.45 \times 10^{10}\,\text{cm}^{-3}$. In general, samples with higher band gap energies will typically have lower values of n_i^2. For example, considering GaAs ($E_g = 1.42\,\text{eV}$) and using the actual values of N_c and N_v for GaAs at $T = 300\,\text{K}$ in equation (6), we calculate that the equilibrium concentrations of electrons and of holes at room temperature are $1.79 \times 10^6\,\text{cm}^{-3}$.

For most semiconductors, kT (0.0259 eV at 300 K) is much smaller than E_g. Thus, few electrons and holes are produced at room temperature in such semiconductors. Intrinsic samples are far too resistive for many applications; additionally, in actual semiconductor samples, the concentration of unwanted impurities often exceeds the intrinsic carrier concentrations. Under these conditions, it is difficult to maintain quality control over the electrical properties of semiconductors. For these reasons, the conductivity of semiconductors is generally deliberately controlled through a process known as doping.

4.2 Carrier Concentrations in a Doped Semiconductor

Because the intrinsic carrier concentrations in semiconductors are so low, even impurity concentrations at the level of one part per billion can have a profound effect on the electrical properties of a semiconductor sample. To increase the sample conductivity and to control other electronic properties of the semiconductor, low concentrations of specific impurity atoms are often introduced into the crystal lattice. This process, which is called doping, serves to decrease the resistance of the crystal. Doping also allows control over the Fermi level (i.e. the electrochemical potential) of the semiconductor phase. The strategy for introducing dopant atoms, as well as some quantitative properties of doping statistics, is described in this section.

4.2.1 Chemistry of Dopants: Donors versus Acceptors

Dopant atoms can be either donors or acceptors. Donors are readily ionized to produce electrons in the conduction band and positive charges on the dopant atoms; acceptors scavenge electrons to produce holes in the valence band and negative charges on the dopant sites. A material that has been doped with donors is called an n-type semiconductor, while one that has been doped with acceptors is called a p-type semiconductor. These designations can be easily remembered by the sign of the predominant charge carrier. Donors create free electrons, which have a *n*egative charge, so the sample is denoted n-type. Similarly, acceptors create holes, which have a *p*ositive charge, so the sample is denoted p-type. The predominant charge carrier is called the majority carrier, so electrons are the majority carriers in an n-type sample and holes are the majority carriers in a p-type semiconductor.

Figure 6 displays the energy levels of common donors and acceptors with reference to the band edges of two semiconductors. If the energy levels of these donors and acceptors are close to the conduction or valence bands, respectively, they are called shallow donors or acceptors. Dopants with energy levels that are further away from either band are called deep dopants. While ionization of shallow dopants is usually complete at room temperature, ionization of deep dopants generally does not occur at room temperature. Shallow dopant materials are considered primarily in the remainder of this section.

The properties of most common dopants can be surmised from simple atomic ionization energies and from trends in the periodic properties of the elements. For example, in Si, which is a group 14 element, group 15 elements such as P or As (which have lower ionization energies than Si) will act as donors. Since only four of the five valence electrons in P are required for tetrahedral bonding in the crystal, the fifth valence electron will be donated to the conduction band at room temperature. This situation will produce an n-type semiconductor, in which the majority carriers are electrons. To a good approximation, the group 15 atom in the Si lattice could be considered as being a positively charged P core with a loosely bound electron, as depicted in Figure 7(a).

Conversely, group 13 elements such as B or Al are acceptors in Si, since they require an additional electron from the valence band to satisfy the tetrahedral bonding requirement. The group 13 atom in the Si lattice can be considered as a negatively charged B core with a loosely bound hole (Figure 7(b)). Since the trapping of an electron by the group 13 dopant atom results in the ionization of an electron from a lattice Si site, the doping process with the group 13 element produces an excess number

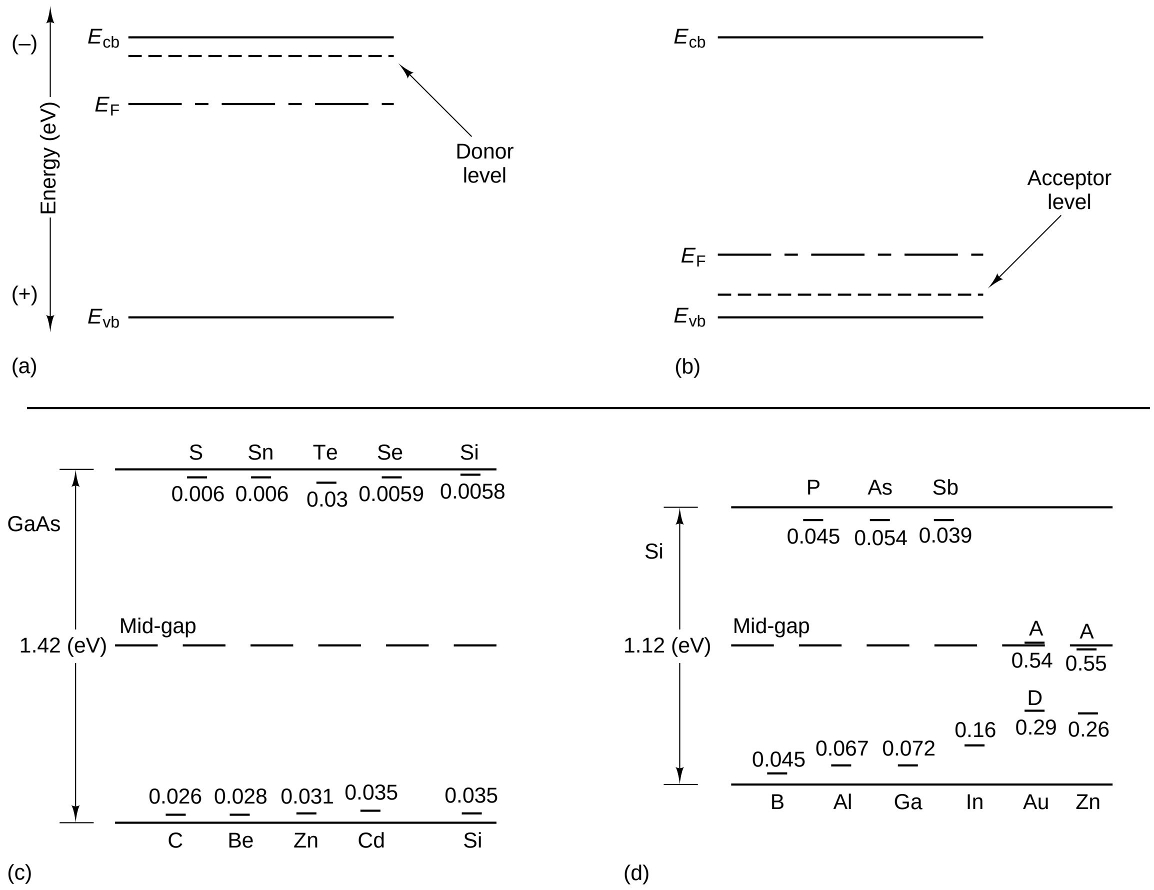

Figure 6 Above: schematic drawing of the energy levels of 'shallow' (a) donor and (b) acceptor dopants. E_{cb} and E_{vb} represent the conduction band edge and the valence band edge, respectively. E_F is the Fermi level. For a semiconductor doped with donors, the Fermi level is closer to the conduction band edge, while E_F is closer to the valence band edge for a semiconductor doped with acceptors. Below: representation of typical dopant levels for (c) GaAs and (d) Si in relation to the band edges.[11] The numbers near these levels denote the difference in energy (eV) away from the nearest band edge. Dopant levels that are close to the middle of the band gap are referred to as 'deep' dopant levels. In (d), an example of a compensator, Au, is shown, with an acceptor energy level above the donor, so that any Au dopant renders the Si crystal 'more intrinsic'. The two dopant levels of Zn are also represented

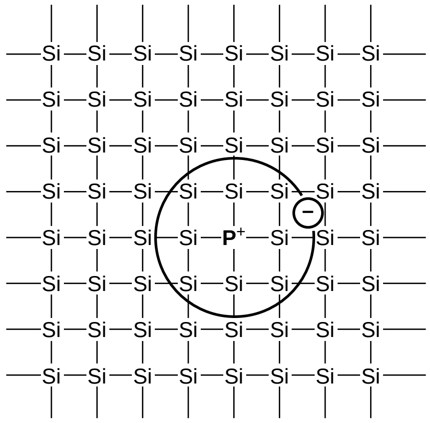
of holes in the valence band. Doping Si with B thus leads to a p-type Si sample. In such a p-type sample, the holes are the majority carriers, while the electrons are the minority carriers.

In some special cases, such as when Si is used as a dopant in GaAs, dopants are amphoteric. Amphoteric dopants can either be donors (Si in Ga sites of GaAs) or acceptors (Si in As sites of GaAs), depending on the crystal growth conditions (Figure 6(c)). Au in Si can best be described as a compensator, because its incorporation always reduces the number of free carriers in the sample. This occurs because Au has both a donor level and an acceptor level, with the acceptor level higher in energy (closer to vacuum) than the donor level (Figure 6(d)). Ionization of the gold dopant levels will therefore tend to make Si samples more intrinsic, regardless of whether the Si is initially n-type or p-type.

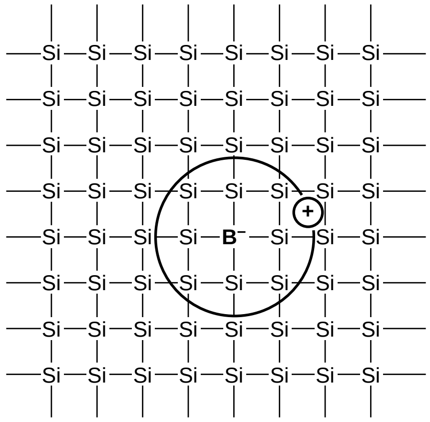
Other impurity atoms, such as transition metals, can have deep levels or multiple levels. An example of this situation is Zn in Si. Zn differs from Si by two valence electrons, so the Zn dopants can accept either one or two electrons from the Si valence band. However, owing to Coulombic repulsion and reorganization of the lattice atoms around the dopant, the energy of the singly charged state is different from that of the doubly charged state. This difference produces two distinct dopant energy levels for Zn in Si (Figure 6(d)).

Interstitial atoms and crystal defects can also behave as dopants. This type of doping is important for n-type CdS. Typical growth conditions for CdS yield S vacancies in the lattice, and the excess Cd then acts as an n-type dopant. For this reason, no p-type CdS has yet been prepared. CdSe and CdTe, however, have been grown in p-type forms, because they can be obtained in more defect-free crystalline phases and thus doping is more effective in controlling the carrier concentration of these purer solids.

The introduction of crystal defects such as oxygen vacancies is also an important mechanism for doping metal oxides. In fact, many of the n-type doping processes for



(a)



(b)

Figure 7 A schematic representation of dopant atoms in a Si lattice: (a) P-doped Si lattice, and (b) B-doped Si lattice. The dopant atoms are shown as replacing a Si atom in the crystal lattice. The circles represent schematic Bohr radii of the carrier (i.e. an electron (−) or a hole (+)) around the dopant atom. Note that these orbits are not drawn to scale; in reality, the first Bohr radius of these carriers is about 12 Å,[57] and a single carrier is spread over about 10^3 Si atoms

materials such as ZnO and TiO_2, which involve 'reduction' with H_2, actually create oxygen vacancies in the lattice.[2] The actual role of the H_2 is to combine with the lattice anions to form H_2O, which is expelled from the crystal. The reaction with H_2 creates the desired oxygen vacancies in the metal oxide lattice. These anion vacancies leave the surrounding lattice cations uncompensated. The electrons from these uncompensated metal ions then act as dopants, and make the entire crystal n-type in electrical properties. Formation of interstitials is also a possible mechanism for doping oxide semiconductors such as TiO_2. However, oxygen vacancies are generally viewed as the dominant doping process at low temperatures and higher oxygen partial pressures, while Ti interstitials may dominate the TiO_2 doping process at high temperatures and lower oxygen partial pressures.[2]

All of these factors can significantly affect the electronic properties of a semiconducting material, even if the dopant atoms exist in the crystal in concentrations of parts per billion. The manufacturing and processing of most semiconductor materials and devices are therefore conducted under conditions of excruciating cleanliness in order to minimize the incorporation of unwanted impurities. For most samples of technological importance, doping is performed using the straightforward concepts that have been described above. For certain applications, impurities with deep levels are incorporated into the semiconductor to control properties that cannot be easily manipulated by shallow dopants.[11,23,52]

4.2.2 Carrier Concentrations in a Doped Semiconductor

Because shallow dopant atoms are readily ionized at room temperature, the electron concentration, n, in an n-type semiconductor is closely approximated by the concentration of donor atoms, N_d, in the lattice. Rigorously, the electron concentration is given by the sum of the electrons thermally generated from the Si atoms and those generated by the thermal ionization of dopants. However, because n_i is so small for most common semiconductors, $n = n_i + N_d \approx N_d$ for any reasonable dopant concentration (10^{14}–10^{18} dopant atoms cm^{-3}). Similarly, for a p-type semiconductor, the hole concentration is approximately equal to the acceptor concentration, N_a. This approximation holds because shallow acceptors are essentially all ionized at room temperature, and the intrinsic hole concentration, p_i, is generally negligible compared to the number of holes that are generated by the dopants. Clearly, control over the dopant density of a semiconductor allows the manipulation of the carrier concentrations.

It is also important to calculate the equilibrium concentration of holes in a doped n-type semiconductor and of electrons in a doped p-type semiconductor. These minority carrier concentrations are readily obtained using the concepts described above, because equations (5) and (6) are actually more general than has been indicated. As mentioned above, the relationship between n_i and p_i in equation (5) is actually an equilibrium constant relationship between the electron and hole concentrations in the solid. In the discussion above, this expression was derived under the special constraint that $n_i = p_i$, that is under thermal excitation conditions. However, the equilibrium constant relationship on the right-hand side of equations (5) and (6) must hold regardless of the source of electrons and holes, so it applies to both doped and intrinsic semiconductor samples. We thus obtain

$$np = n_i^2 = N_c N_v \exp\left(-\frac{E_g}{kT}\right) \tag{7}$$

as the general relationship between the electron and hole concentrations in any given semiconductor. In equation (7), n and p denote the equilibrium majority and minority carrier concentrations, respectively, in an n-type semiconductor, or vice versa in a p-type semiconductor.

This relationship is often called the *law of mass action* when applied to semiconductor doping statistics.[11] The situation is again conceptually identical to that for the equilibrium constant relationship for aqueous acid/base dissociation. The relationship $K_w = [H^+(aq)][OH^-(aq)]$ holds not only for the neutral liquid (i.e. the 'intrinsic', pH = 7 sample), but also for the proton and hydroxide concentrations in the presence of externally added sources of H^+ (aq) or OH^-(aq) (i.e. the extrinsic or 'doped' liquid). In the doped semiconductor, we are merely adding electrons or holes to control the carrier concentrations in the same way that the pH of water can be manipulated through the addition of acid or base.

4.2.3 Conductivity

The most important feature of the doping process is that it affects the electrical conductivity of the semiconductor sample. However, the doping process directly produces changes in the concentration of free charge carriers in the semiconductor, and indirectly produces changes in the electrical conductivity of the specimen. To understand the relationship between the charge carrier concentration and the electrical conductivity of a semiconductor, it is necessary to describe the macroscopic motion of charge carriers through the semiconducting solid. To describe this process, we first need to consider the motion of charge carriers when no electric field is present in the solid. We will then modify this discussion to incorporate the effects of electric fields in the system.

As described above, the electrons in a semiconductor can be described classically with an effective mass, m_e^*, which is usually less than the free electron mass. When no gradients in temperature, potential, concentration, and so on are present, the conduction electrons will move in random directions in the crystal. The average time that an electron travels between scattering events is the mean free time, τ_m. Carrier scattering can arise from the collisions with the crystal lattice, impurities, or other electrons. However, during this random walk, the thermal motion is completely random, and these scattering processes will therefore produce no net motion of charge carriers on a macroscopic scale.

Now we consider the charge carrier motion when an electric field is applied to the semiconducting solid. The electric field, $\mathcal{E}$, will result in a force, $F = -q\mathcal{E} = m_e^*$a, on the electron, where a is the acceleration of the electron due to the electric field. Under these conditions, the electron will still move with its average thermal velocity. However, in the presence of the electric field, the electron will also acquire a drift velocity, v_d. The drift velocity will be directed in the opposite direction from the electric field, and this directed motion will propel the electrons through the crystal even though they still undergo scattering events (Figure 8).[51] The drift velocity and the electric field can be related through the mean free time between scattering events, τ_m:

$$v_d = a\tau_m = -q\left(\frac{\tau_m}{m_e^*}\right)\mathcal{E} \tag{8}$$

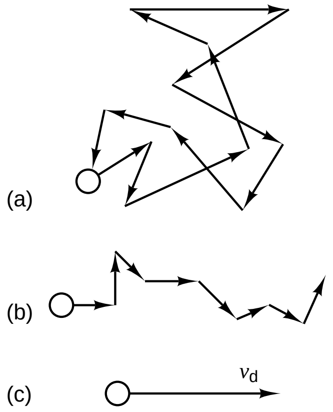


Figure 8 A schematic representation of the motion of charge carriers in a semiconductor lattice.[51] (a) A charge carrier in the absence of any external field. The thermal motion is random, and will not lead to any motion of the charge carrier on a macroscopic level. (b) A charge carrier in the presence of an electric field. The charge carrier motion due to the electric field is imposed upon its thermal motion. (c) The carrier drift shown at the macroscopic level. The random thermal motion of the charge carrier again leads to no motion on the macroscopic level. The charge carriers are propelled by the electric field at a constant velocity, v_d, either parallel or antiparallel to the applied field

A similar equation can be used to describe the motion of holes, except that holes will move toward the electric field rather than away from it.

The proportionality constant between the applied electric field and the resulting drift velocity is called the charge carrier mobility, μ. For electrons, $\mu_n = q(\tau_m / m_e^*)$; for holes, $\mu_p = q(\tau_m / m_h^*)$. It should be noted that, owing to differences in the effective masses of electrons and holes, their mobilities within a semiconductor may be markedly different. The electrical conductivity, σ, of a semiconductor is related to the free carrier concentrations by:

$$\sigma = qn\mu_n + qp\mu_p \tag{9}$$

This equation states that the electrical conductivity due to a free carrier is the product of the charge on the carrier, q, its concentration in the solid, and its mobility, μ. Since semiconductors have two different types of mobile charge carriers, electrons, and holes, the total sample conductivity, σ, is simply the sum of the individual conductivities due to each carrier type. It should be noted that the conductivity depends only on the absolute number of carriers, and therefore is not affected by the signs of the carriers themselves. Carrier mobilities for electrons and holes in a variety of semiconductors can be measured experimentally. These values have been tabulated in various reference books[10,11,22,23] and are available for many semiconductors of interest. Doping of a semiconductor therefore allows precise control over the conductivity of the semiconductor sample.

4.3 Fermi Levels and the Energetics of Semiconductor Samples

The last quantity that is needed to describe the important properties of an isolated semiconductor phase is the electrochemical potential, or *Fermi Level* (E_F), of the material. The Fermi level determines the tendency of the semiconductor to transfer charges to other phases. As formally defined in statistical mechanics, the Fermi level of any phase is the energy level where the probability of finding an electron is 1/2. In an intrinsic semiconductor crystal at absolute zero, the Fermi level would be located near the middle of the band gap (Figure 9(a)). At absolute zero, the energy states in the valence band would be totally occupied, while the states in the conduction band would be completely empty. The probability of finding an electron would therefore go from 1.0 in the valence band to 0.0 in the conduction band, and would reach a value of 1/2 at mid-gap (even though there are no actual electronic states at this energy).

For a doped semiconductor, the Fermi level position will be shifted from mid-gap, because the doping process will vary the tendency of the solid to either gain or lose electrons. For example, if donors are added to an intrinsic semiconductor, the material will be more likely to lose electrons. The Fermi level of an n-type semiconductor will thus move closer to the vacuum level (i.e. will become more negative on the electrochemical potential scale) (Figure 9(b)). Similarly, if acceptors are added to an intrinsic material, the Fermi level will become more positive, because this phase will now have an increased tendency to accept electrons from another phase (Figure 9(c)).

The Fermi level of a semiconductor phase can be written as

$$E_F = E_{Fi} - kT \ln\left(\frac{n}{n_i}\right) \quad (10)$$

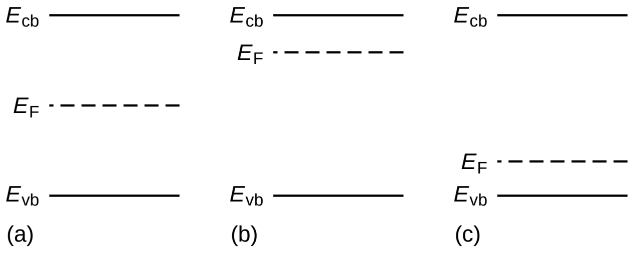

Figure 9 A schematic representation of the Fermi level position in a semiconductor. (a) The Fermi level in an intrinsic semiconductor at absolute zero is approximately at mid-band gap. (b) In an n-type semiconductor, the electron concentration in the conduction band is greater than in an intrinsic sample. The Fermi level is thus closer to the conduction band for an n-type sample. (c) In a p-type semiconductor, the Fermi level position is moved closer to the valence band. Thus, a p-type semiconductor is more likely to accept electrons from another phase than is the corresponding n-type semiconductor

or

$$E_F = E_{Fi} + kT \ln\left(\frac{p}{p_i}\right) \quad (11)$$

In these equations, the term E_{Fi} represents the Fermi level position in the intrinsic semiconductor (i.e. when $n = n_i$ in equation (10) or $p = p_i$ in equation 11). This value serves as a reference energy, much as pH = 7 serves as a reference value for changes in the pH of a neutral aqueous solution. Physically, equation (10) states that doping a semiconductor with donors will produce a more negative Fermi level because $n > n_i$. Similarly, the doping of a semiconductor with acceptors yields a more positive Fermi level, as given by equation (11) with $p > p_i$. Of course, since $np = n_i^2$, equations (10) and (11) can be used interchangeably to solve for E_F of a doped semiconductor if either n or p is known. Both expressions will yield identical numerical values for E_F. More rigorous equations can be obtained by using Fermi–Dirac statistics on the electron occupancy of the filled and empty states of a semiconductor.[11,52] However, the final results of such a treatment are identical to equations (10) and (11) for most doping conditions.

It is often convenient to refer the Fermi level to reference levels that are close to the band edge energies. If we were to fill up the conduction band with electrons to a value equal to the effective density of states in the conduction band, N_c, then the Fermi level would shift until it was exactly equal to the energy of the bottom of the conduction band, E_{cb}. Our new reference level would then be the energy of the Fermi level at the bottom of the conduction band, that is, $E_F = E_{cb}$. That is,

$$E_F = E_{cb} - kT \ln\left(\frac{n}{N_c}\right) \quad (12)$$

In essence, this is analogous to shifting the reference level of an aqueous solution to pH = 0. Changes in pH could then be calculated relative to the amount of acid in a 1.0 M H^+ solution, as opposed to calculating pH changes relative to a 10^{-7} M H^+ solution for neutral water. The result for the Fermi level position versus electron concentration is, of course, identical no matter which formula is used. It is only a matter of convenience as to which reference level is used in the calculation of E_F. Similarly, we could choose to refer the Fermi level position to the energy of the top of the valence band, E_{vb}. In this case, the expression for E_F is:

$$E_F = E_{vb} + kT \ln\left(\frac{p}{N_v}\right) \quad (13)$$

The forms used in equations (12) and (13) are often found in the solid-state physics and chemistry literature.

4.4 Chemical and Electrical Effects of Doping Semiconductors

We have seen that doping is useful for several purposes, in that it allows both the electrical conductivity and the Fermi level position of a semiconductor sample to be controlled readily. Various types of electronic devices can be obtained when the carrier concentrations are manipulated through doping. The conductivity of Si can vary from 10^{-4} ohm^{-1} cm^{-1} for nearly intrinsic Si to greater than 10^2 ohm^{-1} cm^{-1} for highly doped n-type or p-type samples. These levels of conductivity correspond to a range of doping levels in Si, for example, from 10^{12} to 10^{21} cm^{-3}.[11] The ability to control the electrical properties of these materials allows fabrication of rectifiers, transistors, physical, and chemical sensors, and other electronic devices from semiconducting materials. Further information on the specific doping geometry of electronic devices can be found in numerous textbooks.[11,53–55] It is clear, however, that deliberate manipulation of the electrical conductivity of semiconducting solids is a key feature of doping.

Doping also affects the Fermi levels of semiconducting solids, and therefore affects the chemical reactivity of these phases. The Fermi level is the electrochemical potential of the material, and materials with differing electrochemical potentials must react differently. For example, selective etchants can etch p-type Si, while leaving n-type Si untouched. Another example is the behavior of Si electrodes in contact with aqueous HF solution. Although p-type Si anodes corrode in contact with aqueous HF in the dark, n-type Si anodes are chemically inert in this system unless they are illuminated with photons above the Si band gap energy.[56] These chemical differences are a direct consequence of the different Fermi level positions that are obtained through doping. The Fermi level position is also of importance in semiconductor contacts, and in the formation of numerous other electronic devices. Thus, doping of semiconductors is critical for numerous fundamental and technological reasons.

5 SUMMARY

To this point, we have seen how the structural, electronic, optical, and electrical properties of semiconductors can be treated within a common framework. The bonding in the lattice determines the structure of the solid, and the structure of the lattice in turn affects the band structure. This band structure then can be used to describe the chemical, optical, and electrical properties of the semiconducting solid. Thus, chemical control over the electronic properties of semiconductors is an important component of modern research in solid-state chemistry and solid-state physics. The concepts described above enable this process to be understood from a relatively qualitative, chemically based viewpoint. Further details on specific topics can be obtained in specialized textbooks in solid-state chemistry and physics, but this introduction to the relevant concepts should suffice to provide the inorganic chemist with access to the terminology and concepts of the field.

1 INTRODUCTION

Why study short-lived molecules?[1] Those who carry out such studies are perhaps driven by two main ambitions. First, to investigate the structures of compounds with unusual coordination numbers or oxidation states. We can thus make small molecules, for example, AlCl or OPCl (to take just two of very many examples), that are not stable under ambient conditions. In transition metal chemistry, it is becoming apparent that we cannot predict the structures of 'open shell' molecules simply by looking at the structures of 'closed shell' species, for example, we cannot predict what structure the unsaturated 16-electron carbonyl $Cr(CO)_5$ will adopt, simply by knowing that saturated 18-electron $Cr(CO)_6$ is octahedral. The second point is to study reaction mechanism. We must know about structures of intermediates fully to understand reaction pathways; *kinetics* alone is not enough.

In considering what we mean by 'short-lived molecules', we must be careful to distinguish between thermodynamic stability and kinetic inertness. A compound that is thermodynamically unstable need not be short-lived, provided a high activation barrier exists towards reaction. Such a molecule is said to be kinetically inert. A species that survives for only short periods is said to be *labile*. Thus most of those short-lived species that we will consider in this chapter have a degree of thermodynamic instability coupled with kinetic lability. An added complication arises when we consider photochemical systems. Here the ability of a molecule to absorb light at a particular wavelength and the quantum yield for reaction will determine, to some extent, its lifetime. The broad definition adopted in this article is that a short-lived molecule is one whose concentration decays, under ambient conditions, on a timescale ranging from nanoseconds or even picoseconds to a few seconds.

A comprehensive selection of the relevant chemistry is covered, supported by experiments that highlight two of the main areas of study of short-lived intermediates, namely photochemical reactions and high-temperature systems.

2 GENERATION OF SHORT-LIVED MOLECULES

Various means exist for the generation of short-lived intermediates. The first are 'high energy' systems such as high-temperature vapors or plasmas, the chemistry of which is often quite complex. The thermodynamics of the system under investigation must be considered carefully before predictions can be made as to what species will be present in the vapor. Thus, for example, evaporation of silica, SiO_2, yields SiO rather than SiO_2 molecules. This observation reflects the greater thermodynamic stability of the monoxide over the dioxide at the temperature (ca. 2000 K) at which vaporization takes place. Many other similar examples are known; sometimes the nature of the vapor-phase species depends upon the material of the vessel from which the species are evaporated. Thus evaporation of sodium phosphate (Na_3PO_4 or $Na_5P_3O_{10}$) from a boat made of a reducing metal such as Mo or Ta yields sodium phosphite ($NaPO_2$) molecules in the vapor. Reduction of phosphorus also occurs if $OPCl_3$ vapor is passed over silver heated to 1100 K. Here the gaseous product is OPCl.

Two other systems that produce 'high-temperature' molecules should be mentioned: shock waves and flames. Shock waves are typically formed by the rapid release of a high pressure of gas in a shock-tube apparatus. A shock wave is formed that can travel at several times the speed of sound; temperatures as high as 20 000 K have been produced in shock tubes. Thus the method is ideal for monitoring pyrolysis and oxidation reactions. Flames are gaseous systems where a flow of gas combines with a self-supporting reaction to produce a steady-state situation. Again, oxidation reactions are amenable to this approach. In particular, short-lived intermediates in hydrocarbon oxidation, such as C_2, OH, and CHO^+, have been identified in flames.

Plasmas are another example of a 'high energy' gas-phase system. The flow discharge, excited by microwave, radio frequency, or electric discharge, has been much used by chemists to generate reactive species. The system operates at low pressure and at moderate temperatures (ca. 600 K). The plasma contains electrons, ions (positive and negative), and neutral species (atoms, free *radicals* and molecules). Secondary reaction products may sometimes be formed in a plasma, for example, via the intermediacy of fluorine atoms formed when CF_4 or NF_3 gas is flowed through a discharge. Such a method has been used, for example, to generate methyl radicals:

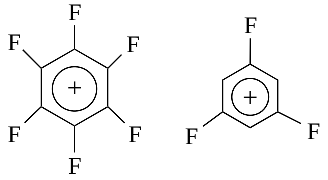
$$F(g) + CH_4(g) \longrightarrow CH_3(g) + HF(g) \quad (1)$$

A rather different route to short-lived intermediates is to irradiate a suitable precursor with radiation of an appropriate energy. Most common is UV–visible photolysis. Section 5 discusses some of the rich photochemistry displayed by transition metal carbonyls, these being very amenable to UV–visible photolysis. Thus unsaturated carbonyl fragments may be produced:[2,3]

$$Cr(CO)_6 \xrightarrow[h\nu]{\text{Ar matrix, 12 K}} Cr(CO)_5 + CO \quad (2)$$

$$Fe(CO)_5 \xrightarrow[h\nu]{\text{Ar matrix, 12 K}} Fe(CO)_4 + CO \quad (3)$$

For some reactions, however, higher energy radiation is required. Vacuum UV photolysis may be useful to initiate reactions of molecules that only absorb at short wavelengths. To form matrix-isolated radical cations of various aromatic compounds, for example, (**1**) and (**2**). Andrews and coworkers have devised a system for windowless photolysis of a low-temperature matrix (since most window materials will absorb vacuum UV light). A glow discharge of Ar or H_2 is used (the latter has strong emission centered at 121.6 nm) and the excited species emanating from the discharge are cocondensed with the molecules under investigation. The success of the method is demonstrated by the spectra shown in Figure 1. Here the yields of the *p*-dichlorobenzene cation using standard UV–visible or 'windowless' vacuum UV photolysis are contrasted. The latter approach is shown to produce an enormously enhanced yield.



(**1**) (**2**)

X-ray irradiation is another good way to produce radicals in low-temperature solids. To take just one example, the methoxyl radical MeO• is generated by X-ray irradiation of solid methanol-d_1 at 4.2 K:

$$MeOD \xrightarrow[4.2\,K]{\text{X-ray}} MeO\bullet + D\bullet \quad (4)$$

It has been the view of many chemists that ionizing radiation represents a 'sledgehammer' that will break molecules indiscriminately into a wide variety of products. However, it has become increasingly apparent that, for properly controlled systems, the products are often simpler and more readily predictable than those formed by UV light. Thus γ-rays may be used to produce a wide range of radicals and ions

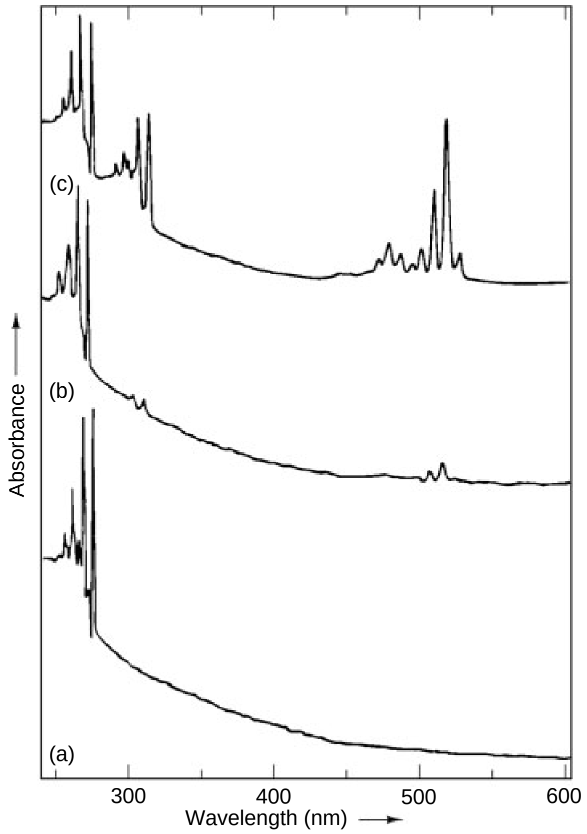


Figure 1 UV–visible absorption spectra of matrix-isolated *p*-dichlorobenzene and of its radical cation: (a) spectrum of *p*-dichlorobenzene before photolysis; (b) spectrum after 15 min photolysis at = 220–1000 nm; (c) spectrum after 15 min Ar resonance photolysis. The much increased yield of product upon vacuum UV photolysis can clearly be seen. (Reprinted with permission from Friedman *et al., J. Phys. Chem.*, 1984, **88**, 1944. © 1984 American Chemical Society)

(equation 5 for example).

$$Me_2Te \xrightarrow[CFCl_3,\ 77\,K]{\gamma\text{-ray}} Me_2Te^+ \quad (5)$$

The 'freon' $CFCl_3$ is used as the solid host here since it has an ionization potential of ca. 11.8 eV, while the ionization potential of Me_2Te is 7.9 eV. Thus ionization of the guest is favored over that of the host.

3 METHODS OF DETECTION OF SHORT-LIVED INTERMEDIATES

This section addresses the question: how is it possible to obtain spectra of species whose lifetimes are only a small fraction of a second? It is only within the past 60 or so years that direct observation of short-lived molecules has been possible.

Nowadays such studies are relatively commonplace and three quite distinct methods are typically used: (i) flow techniques, (ii) flash photolysis, and (iii) matrix isolation. The oldest of these approaches is the flow method developed independently in the 1920s by Paneth, for demonstrating the existence and reactivity of gaseous free radicals, and by Hartridge and Roughton, for studying biochemical liquid-phase processes. Flash photolysis was first reported by Norrish and Porter in 1949, while matrix isolation, an invention of George Pimentel, was first used in 1953. To complement these methods, brief mention is made of two approaches that allow the presence of a reactive intermediate to be inferred without direct observation. These are (i) kinetic measurements and (ii) chemical trapping experiments, where a reagent is added to the reaction mixture, which forms a stable product with the intermediate and which is particularly characteristic of that intermediate.

3.1 Flow Techniques

If an unstable species is generated continuously in a flow system, its decay establishes steady-state concentrations that decrease with distance downstream from the point of generation. It is thus possible to detect spectroscopically the unstable intermediate, though, of course, the spectra will necessarily be complicated by the presence of unreacted reagents or carrier material. Flow methods may be used to look at unstable species in the gas phase or in solution. They are ideally suited to kinetic measurements since, if the velocity of the flow of gas or liquid is known, it is possible to measure the rate of decay of the species under investigation. Early experiments used UV–visible absorption or emission to monitor the species in the flow; however, such methods give only limited structural data. A more modern innovation is the use of tunable IR lasers to obtain high-resolution vibrational spectra.

Flow systems lend themselves to several other methods of detection. Radicals such as Me• or MeO• have been studied by flowing them through the cavity of an ESR spectrometer. The deflection of a beam of molecules in an electric field may give information about any permanent *Dipole Moment* of the species under investigation. Mass spectrometric detection and even structural measurements by gas electron diffraction may be made on the vapor.

It is pertinent to consider briefly the supersonic molecular beam. Here, a flow of gas is expanded through a nozzle into a vacuum in such a way that the flow diverges and becomes supersonic. As the gas expands, so the temperature falls, thus molecules within the beam may be studied at very low temperatures and essentially free from molecular interactions.

3.2 Flash Photolysis

If a short-lived species is suddenly generated in a nonflowing sample it is possible to monitor the species

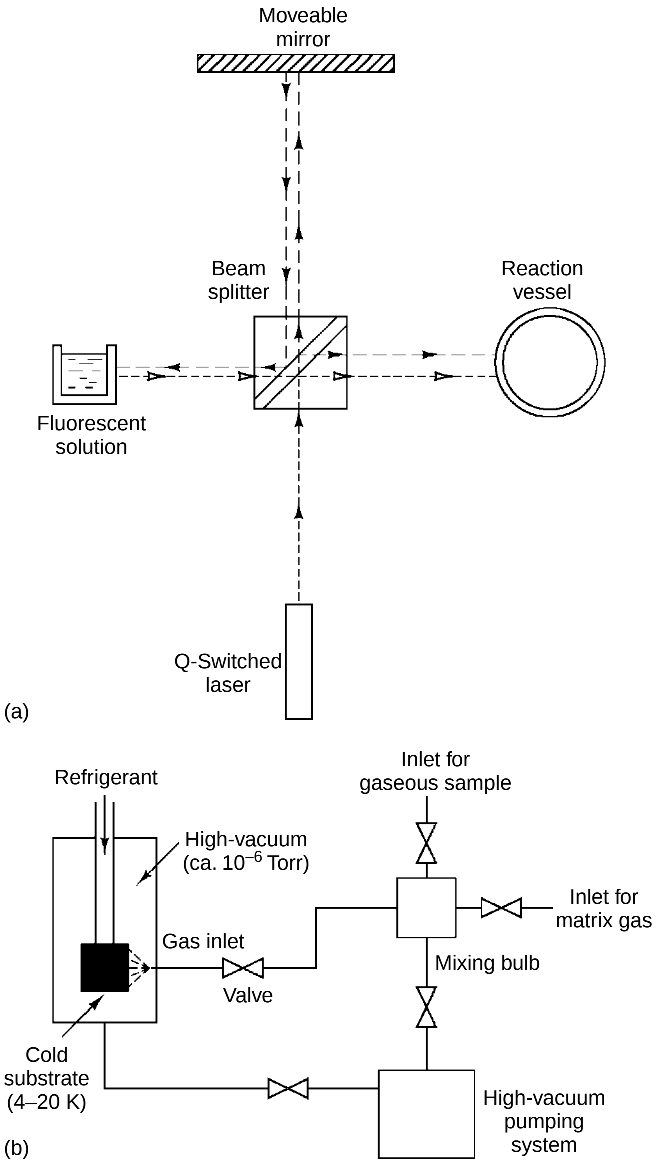

Figure 2 (a) An arrangement for nanosecond flash photolysis. (b) A schematic diagram of a matrix-isolation apparatus

spectroscopically some time after its generation, but before its decay is complete, provided that a very fast detection technique is available. Early systems used high-intensity UV lamps to generate the species and UV–visible spectroscopy to monitor their decay. Modern flash photolysis experiments generally use lasers. An arrangement for 'nanosecond' flash photolysis is shown schematically in Figure 2(a). In this case one laser only is used. Light from the laser initiates photolysis but some light is directed by means of a beam splitter to a vessel containing a fluorescent solution. Fluorescence from the solution gives a continuum of light over a region of the visible spectrum and this is used as the spectroscopic source for monitoring the decay of the reaction intermediates. It is possible to use a second (normally tunable) laser for this purpose. An IR

laser can be used; thus it is possible to build up point-by-point IR spectra of the intermediates. However, the process is laborious. A large number of points are needed to cover even a relatively small part of the spectrum such as the ν(CO) region.

3.3 Matrix Isolation

This technique consists of trapping reactive molecules in a cold, solid, inert environment, where bimolecular reactions are prevented (provided that the sample is at sufficiently high dilution) and where the low temperatures greatly reduce the possibility of unimolecular decomposition.[4] In Figure 2(b) is shown a standard arrangement for a matrix-isolation apparatus. The low temperatures are often attained by the use of microrefrigerators using helium as the working fluid. The cold substrate, the nature of which depends upon the type of spectroscopy being used to monitor the sample, is enclosed in a shroud that is maintained at high vacuum.

Preparation of matrix-isolated samples generally follows one of two routes. Either the short-lived species is formed in the gas phase (by photolysis, pyrolysis, or the action of a discharge) then condensed with a large excess (typically thousandfold) of the matrix material, or a stable precursor is trapped within the matrix and the unstable species are generated in situ by photolysis or radiolysis.

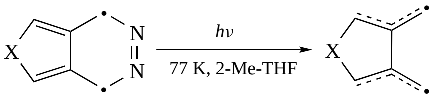
Matrix isolation has the potential of tailoring the detection method to the problem. A large number of spectroscopic techniques are employed for matrix-isolated samples. Matrix isolation is thus an excellent method for studying the structures of short-lived molecules. However, it does have its drawbacks. Firstly, it can give no kinetic information. Secondly, the question must be asked: to what extent are species seen in a matrix analogous to those in more ‘normal’ chemical environments?

It is possible to address these points by studying reactive intermediates in low-temperature liquid solution, a typical solvent being liquid xenon. Here the molecules are retarded, rather than stopped so that, while conventional spectroscopic monitoring is possible, kinetic information about the species may also be obtained. In this way a ‘bridge’ is formed between flash photolysis work and matrix isolation.

4 STRUCTURAL INFORMATION FROM SPECTROSCOPIC MEASUREMENTS[5]

4.1 Nuclear Magnetic Resonance Spectroscopy

This technique is of immense potential importance but so far has been of very limited applicability towards short-lived intermediates. It is too slow for use in flash photolysis and there are extreme problems of sensitivity in matrix-isolation experiments. Although the feat of obtaining ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra of stable matrix-isolated molecules was first achieved some time ago, it is only relatively recently that short-lived species have been detected in this way. Thus two-dimensional solid-state NMR has been used to study the intermediate 3,4-dimethylenethiophene (**4**) generated by photolysis of the parent diazo compound (**3**) in a 2-methyltetrahydrofuran glass at 77 K (equation 6).



(6)

(**3**) a, X = S; b, X = O; • = ^{13}C (**4**)

It is not pertinent here to go into details of 2D NMR spectroscopy; such material is adequately covered elsewhere.[6] Suffice it to say that, in this instance, computer simulation of the dipolar coupled ^{13}C sideband patterns allowed estimates to be made of the C–H bond distances and the H–C–H bond angles. Such information is of extreme importance. A great shortcoming of matrix isolation is the lack of *Bond Length* information. Two techniques have been developed that will give these data: one is NMR, the other is extended X-ray absorption fine structure (EXAFS) (see Section 4.6).

4.2 Electron Spin Resonance (ESR) Spectroscopy

Electron Spin Resonance (ESR) spectroscopy is a very powerful method for studying species with *unpaired electrons*. It has been used to investigate short-lived intermediates in flow systems and in matrices. The two main data of interest from an ESR Experiment are the g values and the hyperfine splittings. The latter are important in providing information about the delocalization of the unpaired electrons within the molecule. For an electron with some s character, coupling between electron and nuclear spin magnetic moments occurs by the so-called Fermi contact interaction. Coupling to a single nucleus with spin $n/2$ gives $n + 1$ lines that are of equal intensity and are equally spaced. Coupling to n equivalent nuclei of spin 1/2 again gives $n + 1$ lines but here the intensities follow the binomial distribution. Low-temperature matrices are anisotropic systems; thus the situation is complicated in that both g values and hyperfine splitting constants must be considered as tensors. Three principal terms are obtained (for g values these may be labeled g_x, g_y and g_z). For systems with cubic or spherical symmetry these are equal; for those with at least axial symmetry there are two terms (labeled $g_{\parallel}$ and $g_{\perp}$); for lower symmetries all three terms are different. In Figure 3(a) is shown the ESR spectrum of the $^{15}N_2CO^+$ cation in a neon matrix at 4 K, formed by the reaction of CO^+ with $^{15}N_2$. Both parallel and perpendicular components can be seen: each forms a doublet of doublets, which points to the interaction of the unpaired electron with two inequivalent $I = 1/2$ ^{15}N nuclei. Thus, the structure of the cation may be deduced as (**5**).

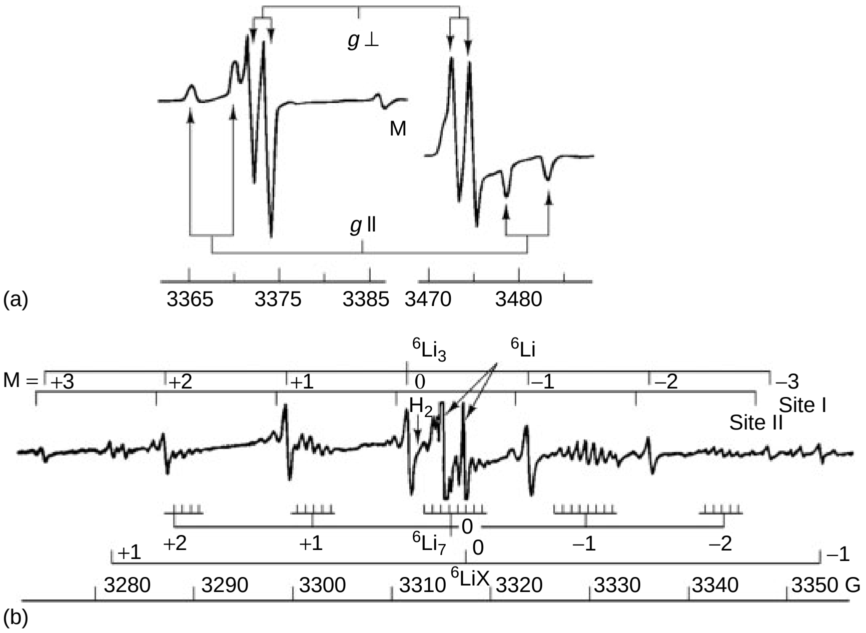


Figure 3 (a) ESR spectrum of the cation $^{15}N_2CO^+$ in a neon matrix at 4 K. (Reproduced by permission of the American Chemical Society from Knight Jr, *Acc. Chem. Res.*, 1986, **19**, 313) (b) ESR spectrum of pseudorotating $^6Li_3$ in an argon matrix at 28.5 K. (Reproduced by permission of American Institute of Physics from Garland and Lindsay, *J. Chem. Phys.*, 1983, **78**, 2814)

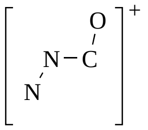

(**5**)

Figure 3(b) shows the ESR spectrum of the trimer $^6Li_3$ in an argon matrix at 28.5 K. Despite complications due to the presence of the heptamer $^6Li_7$ and an unknown impurity ^{6}LiX, seven equally spaced signals can be seen. These have the correct intensity ratio to belong to a molecule with three equivalent ^{6}Li nuclei ($I = 1$). It appears that the Li_3 trimer is rapidly pseudorotating in an argon matrix at this temperature; thus the system behaves as an isotropic one and only one set of g values are seen.

In this brief discussion, only radicals that have just one unpaired electron are mentioned. Obviously there are many systems that have several unpaired electrons but, especially for anisotropic systems, the ESR spectra for such species can be extremely complicated. More information on aspects of ESR spectroscopy of short-lived intermediates is given in two excellent reviews on the subject.[6,7]

4.3 Rotational Spectroscopy

For short-lived molecules this technique is only really of use for flow systems, where tunable lasers are employed to record high-resolution spectra; thus rotational fine structure can be seen. In Figure 4 is shown the high-resolution rotation–vibration spectrum, recorded using a tunable IR laser, of the Q-branch of the bending vibration of FO_2 prepared in a flow tube reaction. The band is centered near 578 cm^{-1} and the whole spectrum shown covers only 1.5 cm^{-1}. Analysis of the rotational fine structure of electronic bands is also possible. Much information about unstable diatomic molecules has been derived in this way: the rotation constant of a diatomic molecule may be calculated for each of many vibrational states of each electronic state involved in the transition. Much less information has been forthcoming for larger molecules, in part because it is difficult to attain the resolution needed to observe rotational fine structure on an electronic band in these cases. More fundamentally, the fine structure is often not defined because the excited state has a very short lifetime, with a consequent uncertainty in energy levels due to the uncertainty principle. By their nature, solid matrices are not amenable to rotational spectroscopy for the simple reason that all but the smallest molecules cannot rotate within these rigid media.

The most important use of rotational spectroscopy is the determination of rotation constants. A problem besetting rotational spectroscopy is centrifugal distortion; however, it is possible to take account of this if precise data over a range of quantum numbers is available.

Having once obtained rotational constants it is possible to define molecular structures via the corresponding moments of inertia. Both bond lengths and bond angles can be obtained, but the process is not always straightforward and, for polyatomics, can be laborious; detailed descriptions of these procedures are given by Hollas.[8]

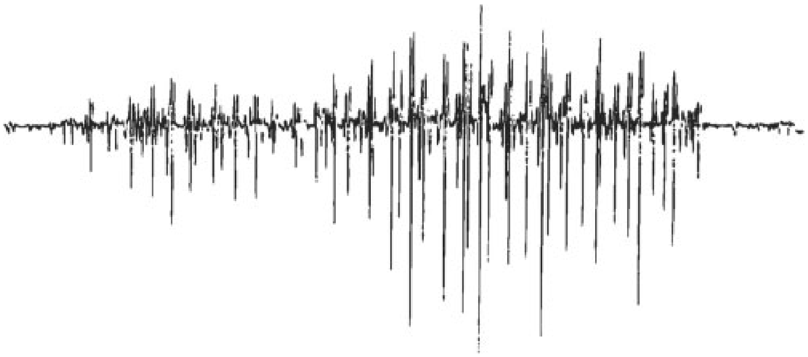

Figure 4 The Q-branch of the bending vibration of FO_2 prepared in a flow tube reaction. The band is centered near 578 cm^{-1} and the whole spectrum shown covers only 1.5 cm^{-1}. (Reproduced by permission of American Institute of Physics from Yamada and Hirota, *J. Chem. Phys.*, 1984, **80**, 4694)

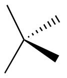
Isotopic substitution may help us to obtain rotation constants. It also allows us to define atom positions within a molecule precisely (the effect of change of mass is small if the substituted atom is close to the center of mass, and zero if it is at the center of mass, for example, the rotation constants of BCl_3 are unaffected by the boron isotopic mass), and may confirm the presence of a particular type of atom in the molecule. This latter point is of particular value in studying unstable species where elemental analysis is impracticable. For example, in order to prove that a species under investigation is an oxide we may observe a shift in the position of rotational lines when ^{18}O replaces ^{16}O.

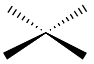
4.4 Vibrational Spectroscopy

Over the years, infrared (IR) absorption spectroscopy (*see Infrared Spectroscopy*) has been one of the mainstays of matrix isolation and it is nowadays being used increasingly (utilizing IR lasers) for monitoring the intermediates of flash photolysis reactions.

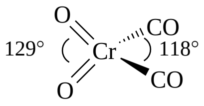
The main information to be obtained from IR spectroscopy concerns the presence of various groups within a molecule. Thus the presence of a nonclassically bound η^2-H_2 group in the complex $H_2Cr(CO)_5$ in low-temperature liquid xenon solution may be demonstrated by the presence of an IR band at ca. 3020 cm^{-1} corresponding to the ν(H–H) vibration.[9] Since the number of IR active vibrations depends upon the symmetry of the molecule under investigation, it is also possible to learn much about the number and geometry of groups within the molecule by analysis of the IR spectrum. A classical example is provided by matrix-isolated metal carbonyl fragments. Thus, for example, it should be straightforward to distinguish between C_{2v} (**6**) and D_{4h} (**7**) (*Square Planar*) symmetries for an $M(CO)_4$ fragment, since the former should show four IR active ν(CO) modes and the latter only one. However, the most unambiguous results are obtained when isotopic substitution is employed. For metal carbonyls partial enrichment in ^{13}CO is normally used, so that all isotopomers of the type $M(^{12}CO)_x(^{13}CO)_{n-x}$ are produced. For low values of n it is a relatively easy matter to determine the identity of the $M(CO)_n$ fragment from the spectra of the isotopic species. The molecule chromyl carbonyl, $O_2Cr(CO)_2$ (**8**), has a nonlinear C_{2v} $Cr(CO)_2$ fragment. Thus, the IR spectrum of the molecule, when enriched 50% in ^{13}CO, shows two triplets of bands each with a 1:2:1 intensity ratio, corresponding to the symmetric and antisymmetric ν(CO) modes of the $Cr(^{12}CO)_2$, $Cr(^{12}CO)(^{13}CO)$, and $Cr(^{13}CO)_2$ isotopomers.[10]



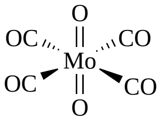
(**6**) C_{2v}



(**7**) D_{4h}



(**8**)



(**9**)

For more complex examples, it is necessary to model the IR spectrum using different possible geometries for the $M(CO)_n$ fragment and estimated stretching and interaction force constants. If the $M(CO)_n$ fragment has high symmetry, the results are usually unambiguous, for example, the square planar structure of the $Mo(CO)_4$ fragment of *trans*-$O_2Mo(CO)_4$ (**9**) is clear from the results of ^{13}CO substitution.[11] For this experiment, different degrees of ^{13}CO enrichment (33, 55, and 65%) were used. As shown in Figure 5, the spectra obtained can clearly be used to distinguish between a D_{4h} $M(CO)_4$ and D_{3h} $M(CO)_3$ fragments, either of which geometries would account for the IR spectrum of the unenriched molecule. For less symmetric species, unambiguous results may be obtained, though here it is necessary to pay careful attention to the matching of both the intensities and positions of peaks in the observed and calculated spectra.

Bond angles may be calculated from IR spectra in two distinct ways: (i) intensity measurements and (ii) isotopic shift calculations. For a molecule such as $O_2Cr(CO)_2$ (**8**), it is a relatively simple matter to calculate the C–Cr–C bond angle

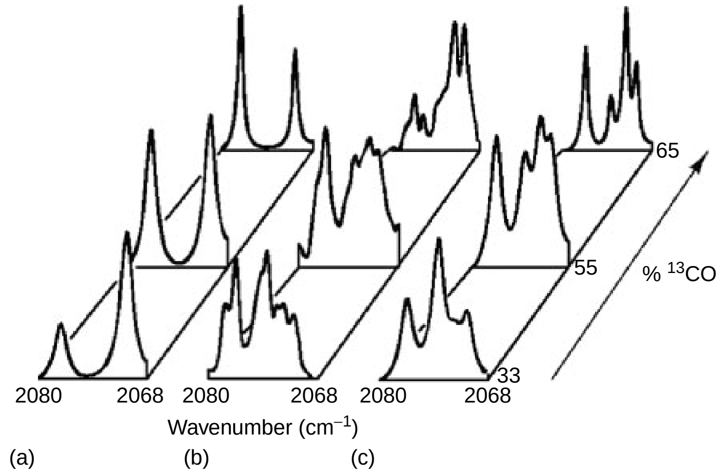


Figure 5 Stacked plot showing observed and predicted IR absorption spectra for *trans*-$O_2Mo(CO)_4$ in the region 2068–2080 cm^{-1} upon 33, 55, and 65% ^{13}CO enrichment: (a) predicted spectrum assuming a D_{3h} $Mo(CO)_3$ moiety; (b) observed spectrum; (c) predicted spectrum assuming a D_{4h} $Mo(CO)_4$ moiety. (Reprinted with permission from Ref. 11a. © 1984 American Chemical Society)

(θ). If we assume that there is no coupling between ν(CO) and any other vibration in the molecule, then we may estimate the bond angle from measured intensities of the bands arising from the symmetric and antisymmetric carbonyl stretching fundamentals using the relationship

$$\frac{I_{\text{sym}}}{I_{\text{asym}}} = \tan^2(\theta/2) \tag{7}$$

Nor is it difficult to modify this procedure to take account of the motion of a central atom, for example, to estimate the Mn–O–Mn bond angle (θ) of the O-bridged molecule Mn_2O_7. Here θ is calculated from the intensities of symmetric and antisymmetric ν(Mn–O–Mn) fundamentals using the relationship

$$\frac{I_{\text{asym}}}{I_{\text{sym}}} = \tan^2(\theta/2)\left[\frac{(m(\text{O}) + 2m(\text{Mn})\sin^2(\theta/2))}{(m(\text{O}) + 2m(\text{Mn})\cos^2(\theta/2))}\right] \tag{8}$$

where m(O) and m(Mn) are the atomic masses of oxygen and manganese, respectively. For Mn_2O_7, this value will be somewhat inaccurate because of coupling between bridging and terminal ν(Mn–O) vibrations. It is also rendered somewhat inaccurate by the anharmonicity of the vibrations involved.

This last point is emphasized if we rely upon shifts in peak position upon isotopic substitution to calculate bond angles. It is possible to calculate the A–B–A bond angle of a molecule A_2B by isotopic substitution of either A or B. In Figure 6 is shown the IR spectrum arising from the antisymmetric $\nu(MoO_2)$ vibration of matrix-isolated (**9**), ca. 45% enriched in $^{18}O_2$. The isotopic splittings due to the natural abundance of the isotopes of Mo and due to $^{16}O_2$ and $^{18}O_2$ can be seen. It is possible to calculate O–Mo–O bond angles from either isotope splitting assuming that the O–Mo–O group behaves as

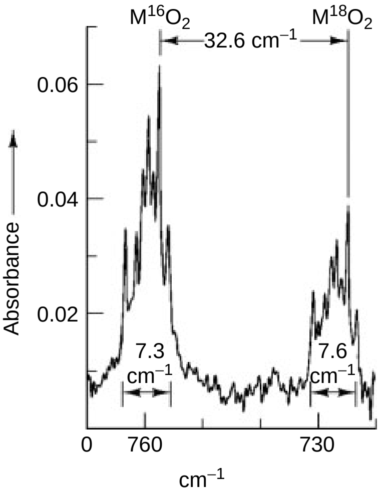

Figure 6 The 780–720 cm^{-1} of the IR absorption spectrum of *trans*-$O_2Mo(CO)_4$. The two bands are assigned to $\nu_{\text{as}}(^{16}\text{O}{=}\text{Mo}{=}^{16}\text{O})$ and $\nu_{\text{as}}(^{16}\text{O}{=}\text{Mo}{=}^{16}\text{O})$. Both clearly exhibit Mo isotope structure. (Reprinted with permission from Ref. 11a © 1984 American Chemical Society)

an isolated harmonic triatomic oscillator. In fact, the observed frequencies are necessarily anharmonic. Thus, the isotopic substitution

$$^{16}\text{OMo}^{16}\text{O} \longrightarrow {}^{18}\text{OMo}^{18}\text{O} \tag{9}$$

gives an upper limit θ_u for the bond angle from

$$\sin\left(\frac{\theta_u}{2}\right) = \left[\frac{m(\text{Mo})\{m(^{16}\text{O}) - m(^{18}\text{O})R_1\}}{2(m(^{16}\text{O}))(m(^{18}\text{O}))(R_1 - 1)}\right]^{1/2} \tag{10}$$

where $m(\mathrm{X})$ is the atomic mass of X and

$$R_1 = \left[\frac{\nu(\mathrm{Mo^{18}O_2})}{\nu(\mathrm{^{16}MoO_2})}\right]^2 \qquad (11)$$

Similarly, the isotopic substitution

$$\mathrm{O^{x}MoO} \longrightarrow \mathrm{O^{y}MoO} \qquad (12)$$

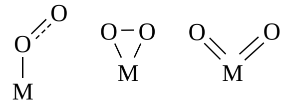
gives a lower limit, θ_1, from

$$\sin\left(\frac{\theta_1}{2}\right) = \left[\frac{(m(^{x}\mathrm{Mo}))(m(^{y}\mathrm{Mo}))(1 - R_2)}{2(m(\mathrm{O}))\{R_2(\mathrm{M}(^{y}\mathrm{Mo})) - m(^{x}\mathrm{Mo})\}}\right]^{1/2} \qquad (13)$$

where

$$R_2 = \left[\frac{\nu(^{y}\mathrm{MoO_2})}{\nu(^{x}\mathrm{MoO_2})}\right]^2 \qquad (14)$$

As well as providing information on bond angles, isotopic substitution experiments may tell us about the mode of coordination of atoms within a molecule. Again the example taken is that of oxo species although, of course, the technique may as well be applied to other chemical entities. For oxo species it is necessary to distinguish between the modes of coordination (**10**), (**11**), and (**12**), where M = metal or other atom. Typically, (**10**) shows ν(O–O) in the region 1000–1200 $\mathrm{cm^{-1}}$, whereas ν(O–O) and ν(M=O) of (**11**) and (**12**), respectively, both occur in the typical range 750–1000 $\mathrm{cm^{-1}}$, at least when M is a transition metal. A clear distinction between (**10**), (**11**), and (**12**) may be made by enrichment of the molecules with ^{18}O. Structure (**10**) is easily distinguished since two IR bands result from ν(O–O) of the mixed $^{16}\mathrm{O}^{18}\mathrm{O}$ isotopomers owing to the possibility of two distinct modes of coordination, that is, M–^{16}O–^{18}O and M–^{18}O–^{16}O. The IR spectra shown in Figure 7 illustrate this point for the molecule cyclopentadiene-*O*-oxide (**14**), formed when (**13**) is subjected to photolysis in a 10% O_2-doped N_2 matrix. To distinguish between (**11**) and (**12**) is again more difficult. In principle, (**12**) should show two ν(M=O) absorptions but (**11**) should show only one ν(O–O) absorption. In practice, often only one ν(M=O) band is seen for (**12**) either because one feature is obscured, or because $\nu_{sym}(\mathrm{MO_2})$ is weak owing to a wide O–M–O bond angle. When generated from a mixture of $^{16}O_2$, $^{16}\mathrm{O}^{18}\mathrm{O}$, and $^{18}O_2$, however, the absorption associated with ν(O–O) of (**11**) takes the form of a single symmetrical triplet; under similar circumstances, (**12**) is expected to display one or two unsymmetrical triplets, derived from the antisymmetric and symmetric MO_2 stretching fundamentals. The unsymmetrical pattern results from strong coupling between the two stretching modes of the ^{16}O=M=^{18}O unit since the reduction in local symmetry allows mixing between the two stretching vibrations



(**10**) (**11**) (**12**)

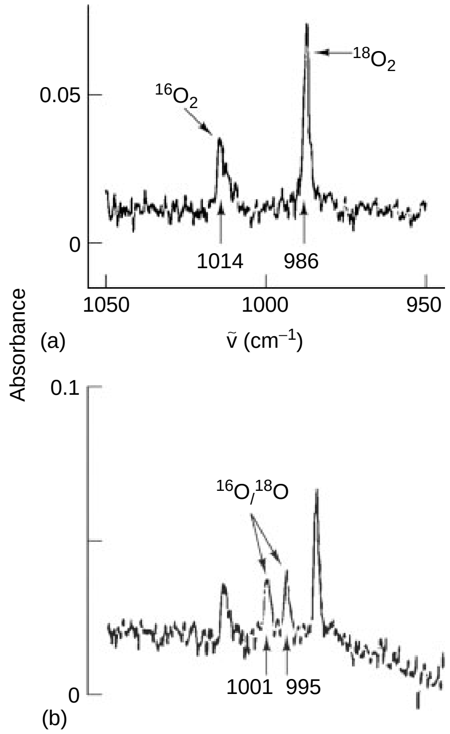


Figure 7 IR spectra recorded after photolysis of diazocyclopentadiene in O_2-doped N_2 matrices: (a) $^{16}O_2$ and $^{18}O_2$ present; (b) $^{16}O_2$, $^{16}\mathrm{O}^{18}\mathrm{O}$ and $^{18}O_2$ present. (**13**) (**14**)

that otherwise (on symmetry grounds) cannot mix. The effect is illustrated schematically in Figure 8.

It is always desirable to back up IR absorption spectroscopy with *Raman* measurements. The different selection rules for the two techniques means that, at least for symmetric species, it is often necessary to have data from both types of measurement to have a full picture of the vibrational spectrum. Raman spectroscopy has been used to study many matrix-isolated species although there are problems regarding intensity and photosensitivity. An excellent review exists on the subject that highlights both the applications and difficulties of the method.[12] A molecule that has been well characterized by both IR and Raman spectroscopy is the matrix-isolated species $\mathrm{Mo(CO)_5(N_2)}$ (**15**).[13] Spectra for (**15**) are illustrated

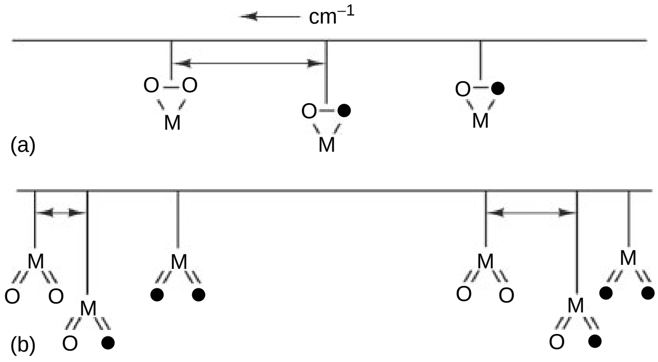

Figure 8 Predicted ^{18}O isotopic splitting patterns in the IR spectra of (a) the ν(O–O) band of a dioxygen complex and (b) the symmetric and antisymmetric ν(M=O) bands of a bent dioxometal complex assuming a scrambled 1:2:1 $^{16}O_2$, $^{16}O^{18}O$, $^{18}O_2$ mixture (O = ^{16}O, • = ^{18}O)

in Figure 9. From the coincidence of the two a_1 ν(CO) modes (assigned to the a_1 symmetry class on the basis of polarization studies on the Raman lines) and the noncoincidence of the other two ν(CO) features, C_{4v} symmetry was assigned to the molecule, implying the structure (**15**) with a linear Mo–N–N unit.

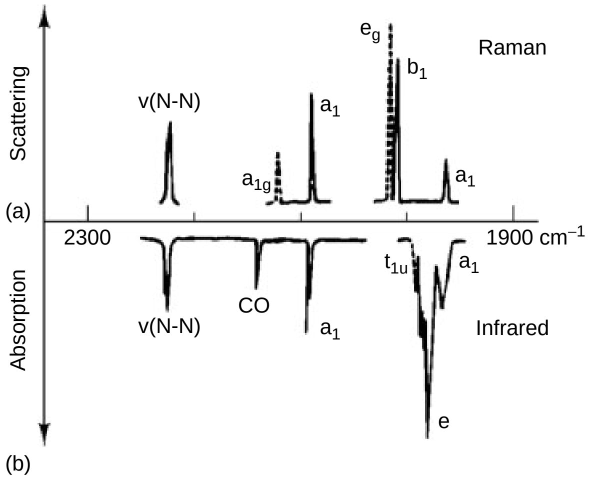

Figure 9 (a) Raman and (b) IR spectra of matrix-isolated $MO(CO)_5(N_2)$. The peaks drawn as dashed lines are due to unreacted $Mo(CO)_6$. (Reprinted with permission from Ref. 13 © 1978 American Chemical Society)

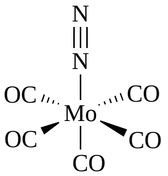


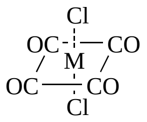
(**15**)

4.5 Electronic Spectroscopy

Electronic spectroscopy (*see Electronic Spectroscopy*), in one form or another, has been the principal method used for the detection of short-lived intermediates. UV−visible absorption was the initial spectroscopic method used with flash photolysis and flow systems, and for each of these methods it remains the most commonly used approach. For species in low-temperature matrices, many varieties of electronic spectroscopy have been used. These include UV−visible absorption and emission, fluorescence, magnetic circular dichroism (MCD) and magnetic linear dichroism, and photoelectron spectroscopy. It is unfortunate, therefore, that in many cases electronic spectroscopy yields little or no structural information. The exceptions are high-resolution spectra, where vibrational or rotational fine structure may be seen.

4.6 Extended X-ray Absorption Fine Structure (EXAFS)

EXAFS (*see Extended X-ray Absorption Fine Structure*) has been used to study a number of matrix-isolated species. EXAFS occurs when an X-ray photon with sufficient energy is absorbed by an atom so that a core electron is ejected. This electron may be represented as an outgoing spherical wave originating at the absorbing atom. If the atom has neighbors, backscattering from them causes interference with the outgoing wave. The outcome is that there are variations in the absorption coefficient that depend on the spatial relationship of the central atom and its neighbors. Thus, by measuring the EXAFS spectrum it is possible to measure bond distances and angles around the central atom. The EXAFS experiment involves measuring the absorption spectrum in the vicinity of the absorption edge for the chosen element. Almost universally, synchrotron radiation is used as the source. EXAFS has been used to study various matrix-isolated metal clusters; the first example of a combined in situ Fourier transform infrared (FTIR) and EXAFS study of a matrix-isolated molecule was reported for dibromomethane, (CH_2Br_2). This work has now been extended to a number of metal carbonyl halide and other molecules.**[14]** In Figure 10 is given the EXAFS spectrum and Fourier transforms for $FeCl_2$ isolated in solid CO; the observed curves are compared with calculated curves for the molecule *trans*-$Fe(CO)_4Cl_2$ (**16**). A very good fit is obtained; thus bond lengths may be calculated: Fe–C, 1.85(3) Å Fe–O, 2.96(4) Å; Fe–Cl, 2.25(3) Å. As with NMR, the allure of this method lies in deriving of bond lengths for matrix-isolated species.



(**16**)

4.7 Mössbauer Spectroscopy

Mössbauer spectroscopy (*see Mössbauer Spectroscopy*) has been used to look at a number of matrix-isolated species. However, the absence of structural information makes it appropriate to combine Mössbauer spectroscopy with other methods. Peden *et al*. report combined IR and Mössbauer spectra for the products of condensing iron vapor with CO: $Fe(CO)_x$ ($x = 1-5$) and $Fe_2(CO)_y$ ($y = 8$ or 9). The Mössbauer spectra also reveal the presence of unreacted iron atoms in the solid CO, which, of course, cannot be seen in IR absorption.

4.8 Quantum Calculations

Most current matrix-isolation studies involve the use of computational calculations to back up experimental results. It is beyond the scope of this chapter, however, to discuss these in any detail. Such calculations, typically using ab initio methods although sometimes adopting the density functional approximation, are used not only to model stable molecules, but also short-lived intermediates and transition states. In this way calculations may provide information about molecules and reactions that is impossible to obtain through experiment alone. In other cases calculations are used to back up, or confirm experimental findings. Typically geometries, energies and vibrational frequencies and intensities are calculated for a species of interest. A number of specific examples are quoted in the following sections of this chapter.

5 PHOTOCHEMISTRY OF TRANSITION METAL CARBONYLS

It is not surprising that transition metal carbonyls rank amongst the most well-studied of photochemical reactants (*see* ***Photochemistry of Transition Metal Complexes: Theory***). They are almost ideal candidates for such work since they have high quantum yields for photochemical reactions (in particular for substitution of carbonyl groups). They also show UV absorptions with large extinction coefficients and are strong IR absorbers and Raman scatterers (especially in the 1600–2200 cm^{-1} region, associated with CO stretching fundamentals), so that electronic and vibrational spectroscopy can readily be applied to monitor reactions of these molecules. Moreover they are generally volatile and readily soluble in nonpolar solvents so that sampling is rarely a problem.

There are very many known photochemical reactions of metal carbonyls; two classic examples are the substitution of a CO group by a donor ligand, for example, a

phosphine:

$$Cr(CO)_6 + PPh_3 \xrightarrow[\text{cyclohexane}]{h\nu} Cr(CO)_5PPh_3 + CO \qquad (15)$$

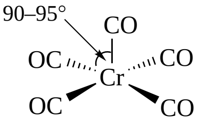
and the deposition of solid $Fe_2(CO)_9$ when solutions of $Fe(CO)_5$ are irradiated:

$$2Fe(CO)_5 \xrightarrow[\text{glacial acetic acid}]{h\nu} Fe_2(CO)_9 + CO \qquad (16)$$

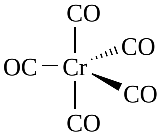
Some of the earliest systematic studies of related reactions were carried out in the early 1960s by Sheline and his coworkers at Florida State University. They studied the replacement of carbonyl groups of metal carbonyls by electron donor and *π-acceptor* molecules; a further aim was to develop an understanding of the mechanism of such reactions. They found that exposure to UV light of a colorless solution of $W(CO)_6$ in *n*-hexane containing acetonitrile resulted in the solution turning bright yellow almost immediately. At the same time, new IR absorptions in the 1700–2200 cm^{-1} region appeared that could be assigned to the molecules $W(CO)_5(MeCN)$, $W(CO)_4(MeCN)_2$, and $W(CO)_3(MeCN)_3$. Not surprisingly, the distribution of these products was affected by the time of photolysis. After 20 s, $W(CO)_5(MeCN)$ was the principal product and only a low yield of $W(CO)_3(MeCN)_3$ was seen. The yield of $W(CO)_3(MeCN)_3$ was increased substantially if the photolysis time was increased to 150 s. Perhaps more interesting is the observation that $W(CO)_6$ is regenerated if the photolyzed solution is allowed to stand unphotolyzed for 180 s. These workers postulated that the 16-electron intermediate $W(CO)_5$ is involved in the reaction. However, other plausible interpretations are possible. Firstly, an associative or a dissociative mechanism could operate. Secondly, if a dissociative mechanism is preferred, it is conceivable that this could proceed via a radical or an ionic pathway. The observations of Sheline *et al.* provided circumstantial evidence in favor of the radical dissociative process. What was needed was firm evidence to establish the presence of the pentacarbonyl intermediate.

5.1 The Search for 'Unsaturated' Metal Carbonyl Molecules

Early experiments to search for the $Cr(CO)_5$ molecule involved flash photolysis of cyclohexane solutions of $Cr(CO)_6$ with UV–visible detection. Problems arose owing to impurities in the solvent interacting with unsaturated intermediates. Although some evidence was obtained for 'naked' $Cr(CO)_5$ it was not possible to confirm the existence of this species nor to distinguish between square pyramidal, C_{4v} (**17**), and trigonal bipyramidal, D_{3h} (**18**), geometries (*see Isomer, Types of*).



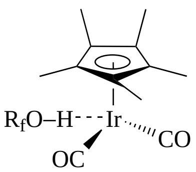
(**17**)



(**18**)

These findings indicate general difficulties in interpreting the results of flash photolysis experiments with UV–visible detection. First, no detailed structural information can be obtained. Second, minute traces of impurity in the solvent interfere strongly with the spectral behavior. It has now become clear that $Cr(CO)_5$ (and other unsaturated carbonyls) are almost always complexed by solvent or matrix molecules or atoms. Even in a neon matrix there is some interaction to produce the species Ne···$Cr(CO)_5$. 'Naked' $Cr(CO)_5$ can be made in the gas phase, and by some rather cunning time-resolved solution experiments. Here, solvated $Cr(CO)_5$ is formed by UV photolysis of $Cr(CO)_6$, then the solvating molecule is removed by visible photolysis. Fast time-resolved spectroscopy allows the decay of the naked $Cr(CO)_5$, as it resolvates, to be monitored. It is clear that this decay is extremely rapid.

The use of tunable IR lasers means that nowadays structural information is more readily derived from flash photolysis experiments, and it is often of much interest to study molecular interactions of metal carbonyls in solution. It is now possible to make an estimate of the strengths of alkane···Cr bonds in species such as $(CO)_5Cr$···X (X = alkane). Even neutral saturated metal carbonyls may show quite strong solvent interactions and such interactions may provide clues to any subsequent photochemical reactions. IR spectra have been obtained that provide strong evidence for intermolecular H-bonding between the 18-electron species $[Cp^*Ir(CO)_2]$ and the sterically crowded fluoroalcohol $(C_3F_7)(CF_3)_2COH$ in *n*-heptane solution (**19**).[15] A similar interaction might explain why O–H activation of MeOH is seen upon UV photolysis of cryogenic liquid xenon solutions of MeOH and $[Cp^*Ir(PMe_3)H_2]$.

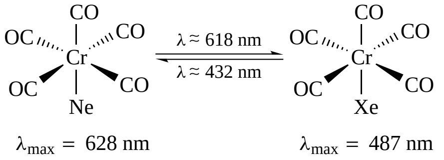


(**19**)

It is still of much interest to consider the early experiments in which molecules such as $Cr(CO)_5$ were studied in hydrocarbon glasses and inert gas matrices, since it is from these experiments that structural data on these species (albeit necessarily in their weakly solvated forms) was derived. IR detection of $M(CO)_5$ (M = Cr, Mo, or W) molecules trapped

in a frozen hydrocarbon glass at 100 K showed three IR active ν(CO) absorptions whose relative intensities are indicative of C_{4v} symmetry (**17**) for the species. The effect of any possible distortion may be minimized by moving to a frozen inert gas matrix. In 1971, Graham, Poliakoff, and Turner published the results of experiments in which they succeeded in producing $M(CO)_5$ molecules by photolysis of $M(CO)_6$ in argon or methane matrices at 20 K. A pattern of IR bands corresponding to C_{4v} (**17**) symmetry for the molecules was again seen. A detailed analysis of the IR spectrum of $Cr(CO)_5$ produced on photolysis of randomly substituted $Cr(^{13}CO)_x(^{12}CO)_{6-x}$ containing ca. 50% ^{13}CO gave an accurate fit to a C_{4v} structure. From intensity data, axial–radial bond angles (α) of 90–95° were calculated.

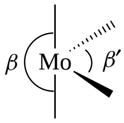
Even in such an inert environment it soon became clear that the $M(CO)_5$ molecules are not completely free from interaction with the host material. On moving from a frozen hydrocarbon glass to a methane matrix the shifts in the position of the IR bands of $Cr(CO)_5$ are relatively modest (4–6 cm^{-1}). By contrast, quite a large shift in the position of the visible band of $Cr(CO)_5$ is seen upon changing the host material. This feature is centered at 489 nm when methane is employed as host, but shifts to 487 nm for xenon, 545 nm for argon, 560 nm for sulfur hexafluoride, and a high value of 624 nm for neon. In a mixed Ne/Xe matrix, two bands are seen, demonstrating that a specific interaction with each noble gas occurs since a generalized solvent effect would lead to a single absorption located somewhere between the positions of the absorptions in the pure matrices. Photochemical experiments show that a reversible photochromic reaction takes place (equation 17). It is presumed that neon has the weakest interaction with the metal carbonyl fragment and therefore that the situation in a neon matrix most closely resembles the gas phase.



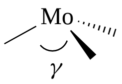
(17)

It is possible to make naked $Cr(CO)_5$ in the gas phase. Pulsed laser excitation at 249 nm of $Cr(CO)_6$ vapor yields $Cr(CO)_5$ and CO. Time-resolved IR spectroscopy reveals that the structure of gaseous $Cr(CO)_5$ is the same as that adopted in a solid matrix, that is, (**17**). Thus, the square pyramidal structure for ground state $Cr(CO)_5$ is confirmed. Photons of wavelength 249 nm are sufficiently energetic to rupture more than one M–C bond. Thus, after only 0.5 µs, the yield of $Cr(CO)_5$ decays and $Cr(CO)_4$ is seen as the principal product. If the wavelength of the exciting radiation is reduced to 193 nm then a high yield of $Cr(CO)_3$ is seen after 0.5 µs. The gaseous molecules $Cr(CO)_4$ and $Cr(CO)_3$ are found to adopt C_{2v} (**20**) and C_{3v} (**21**) symmetries, respectively.

It is rather more difficult to generate high yields of the molecules $M(CO)_4$ and $M(CO)_3$ (M = Cr, Mo, or W) in a



(**20**)



(**21**)

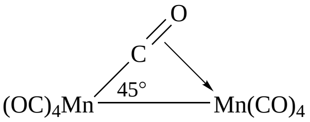
low-temperature matrix since energy transfer is much more efficient than in low-pressure gas-phase systems. Prolonged photolysis is required, but the molecules may be produced and isotopic studies using ^{13}CO show that the structures of these molecules are the same as in the gas phase. For $Mo(CO)_4$, the angles β and β' are calculated as 174° and 107°, respectively; for $Mo(CO)_3$ $\gamma = 105°$.

It is of interest to compare the structure of the d^6 molecule $Mo(CO)_4$ with that of the d^8 species $Fe(CO)_4$ generated by UV photolysis of matrix-isolated $Fe(CO)_5$.$^3Fe(CO)_4$ also adopts C_{2v} symmetry with $\beta = 150°$ and $\beta' = 120°$. A simple consideration of the d orbital splitting pattern for a d^8 species of C_{2v} symmetry suggests the presence of two unpaired electrons; this hypothesis was proved by the experimental observation of a temperature-dependent MCD spectrum for $Fe(CO)_4$ (diamagnetic species do not show any temperature dependence of their MCD signals). Thus, $Fe(CO)_4$ is the first binary transition metal carbonyl shown to have a high-spin electronic ground state. An interesting point about the structures of these unsaturated metal carbonyls is that none of them are much distorted from the structures that would be obtained by selective removal of CO groups from an octahedron. It is possible that an overriding factor in determining these structures is the maximization of overlap between filled ligand orbitals and unfilled metal d orbitals (*see High-spin & Low-spin Compounds* and *Ligand Field Theory*).

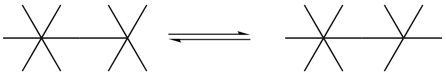
Differences between matrix-isolation and gas-phase photochemistry become more distinct when dinuclear and trinuclear carbonyls are considered. For a simple metal–metal bonded dinuclear carbonyl such as $Mn_2(CO)_{10}$, two primary photochemical steps are possible, namely M–CO dissociation or M–M bond rupture. In solution both processes occur, whereas in rigid media CO loss is seen as the sole discernible primary photolysis step, presumably because $Mn(CO)_5$ radicals readily recombine in the matrix cage. In argon matrices, photolysis of $Mn_2(CO)_{10}$ yields $Mn_2(CO)_9$, a molecule with a semibridging carbonyl group (with ν(CO) at 1764 cm^{-1}) that is shown by polarization studies to lie at about 45° to the Mn–Mn axis (**22**). By contrast, $Re_2(CO)_{10}$ gives rise to two unbridged isomers of $Re_2(CO)_9$ with the CO vacancy in equatorial (**23a**) or axial (**23b**) positions. The two isomers may be interconverted by UV irradiation. In a similar vein, $M_3(CO)_{12}$ (M = Fe or Ru) molecules, when trapped in methylcyclohexane glass at 90 K, show CO loss as the primary photolytic step, although the reaction sequence is complicated by the presence of different isomers of the photoproduct $M_3(CO)_{11}$. By contrast, in hydrocarbon solution, photofragmentation of the cluster takes place. In fluid media, bimolecular reactions

involving large fragments may occur, which are prevented in rigid matrices. An example is provided by the formation of a species $Cr_2(CO)_{10}$ (whose structure remains unknown) upon photolysis of gaseous $Cr(CO)_6$, presumably by a reaction of the type

$$Cr(CO)_6 + Cr(CO)_4 \longrightarrow Cr_2(CO)_{10} \quad (18)$$



(22)

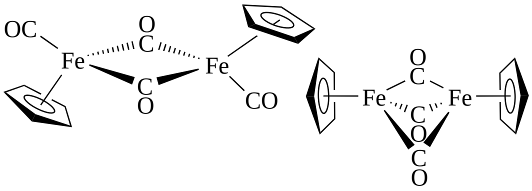


(23a) **(23b)**

The photochemistry of more complex carbonyls that contain ligands other than CO has been studied in some detail. Time-resolved IR spectroscopy has been used to study the photochemistry of the dinuclear carbonyl $[CpFe(CO)_2]_2$ (*see Cyclopentadienyl*) in solution and the results of these experiments have been compared with those obtained from earlier matrix-isolation work.[16]

In a CH_4 matrix at 12 K, (**24**) yields, upon UV photolysis, the CO-bridged dimer (**25**). When (**24**) is subjected to flash photolysis in cyclohexane solution at room temperature, time-resolved IR studies show that both (**25**) and the mononuclear radical $[CpFe(CO)_2]$ are formed within 5 μs. The radical has a half-life of <25 μs while (**25**) has a half-life of 1.5 ms under the experimental conditions. If the cyclohexane solution is doped with the two-electron donor molecule MeCN it is possible to monitor the formation of the substitution product $[Cp_2Fe_2(CO)_3L]$ (L = MeCN) (equation 19).

$$[CpFe(CO)_2]_2 + L \xrightarrow[\text{cyclohexane}]{h\nu} [Cp_2Fe_2(CO)_3L] + CO \quad (19)$$



(24) **(25)**

Kinetic studies, as illustrated by the spectra in Figure 11, leave little doubt that the principal intermediate in the photosubstitution is not the radical but rather the dinuclear species (**25**). This situation is not true, however, for all ligands. When the hydrocarbon solution is doped with the phosphine $P(OMe)_3$ in place of MeCN, a reaction with the radical is seen:

$$[CpFe(CO)_2] + P(OMe)_3 \longrightarrow [CpFe(CO)\{P(OMe)_3\}] + CO \quad (20)$$

The different pathways are reflected by the magnitudes of the bimolecular rate constants at 25 °C: L = MeCN, $k_2 \sim 7.6 \times 10^5\ dm^3\ mol^{-1}\ s^{-1}$; L = $P(OMe)_3$, $k_2 \sim 8.9 \times 10^8\ dm^3\ mol^{-1}\ s^{-1}$. The latter value is only about one order of magnitude slower than the diffusion controlled limit. These studies show the value of time-resolved IR spectroscopy for obtaining kinetic data.

When the photochemistry of carbonyls that also contain ligands other than CO is considered, it is not always the case that loss of CO predominates as the principal reaction pathway. For example, irradiation of $[CpMo(CO)_3Et]$ (M = Mo or W) generates $[CpM(CO)_3H]$ by loss of C_2H_4 (*see Alkene Complexes*). Scheme 1 presents a plausible mechanism for this process, which has been studied in *n*-heptane solution by time-resolved IR spectroscopy and in low-temperature matrices. Two distinct dicarbonyl species (**26**) and (**27**) are seen. In a matrix, (**26**) and (**27**) may be interconverted by photolysis at selected wavelengths. The reaction then proceeds via cis and trans isomers of $[CpM(CO)_2(C_2H_4)H]$. The results suggest that, in this system, β-hydrogen transfer is a facile process; they have important implications for the current interest in *agostic* hydrogen interactions.

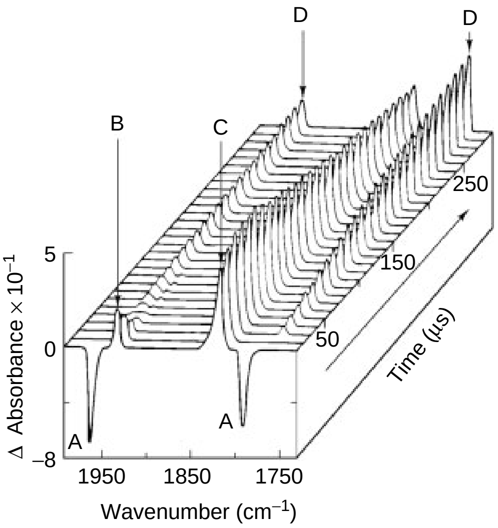


Figure 11 Time-resolved IR spectrum obtained after flash photolysis of $[CpFe(CO)_2]_2$ and MeCN in cyclohexane solution. Two intermediates, B = $CpFe(CO)_2$ and C = $CpFe(\mu\text{-}CO)_3$, are seen. D is the reaction product $Cp_2Fe_2(CO)_3(MeCN)$. Scheme 1 Photochemistry of [CpMEt(CO)$_3$](M = Mo, W)

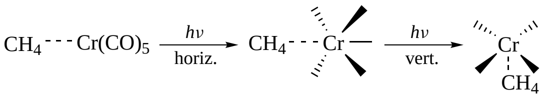
5.2 Reactions of Unsaturated Metal Carbonyls with CO, N$_2$, and H$_2$

Unsaturated metal carbonyls are necessarily prone towards addition reactions. Thus 16-electron species such as M(CO)$_5$ (M = Cr, Mo, or W) and Fe(CO)$_4$ will readily react with two-electron donor ligands. A large number of such reactions are known. Here details of three examples are considered, namely, the addition of CO, N$_2$, and H$_2$ molecules (*see* ***Hydride Complexes of the Transition Metals***).

Sheline's early experiments showed that M(CO)$_6$ molecules could be regenerated when photolyzed solutions of the hexacarbonyl were left to stand. Matrix-isolated M(CO)$_6$ may be obtained from M(CO)$_5$ only by annealing or upon *photolysis* into the visible absorption band of the pentacarbonyl:

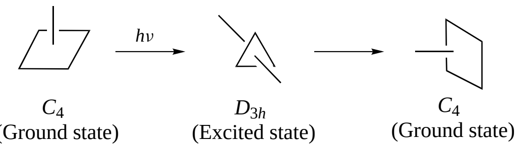
$$\mathrm{M(CO)_5} + \mathrm{CO} \xrightarrow{h\nu\text{(visible) or anneal}} \mathrm{M(CO)_6} \qquad (21)$$

The mechanism of the photochemical reaction has been the subject of some elegant experiments involving polarized light both for photolysis and for spectroscopic measurements.[17] Unpolarized UV photolysis of Cr(CO)$_6$ in pure methane matrices yields randomly oriented Cr(CO)$_5\cdots$CH$_4$ molecules. Polarized visible photolysis leads to specifically oriented Cr(CO)$_5\cdots$CH$_4$ molecules, as evidenced by the development of linear dichroism in the visible absorption band. The direction of the spectral dichroism depends upon the direction of polarization of the irradiating beam (equation 22).



(22)

These experiments show that the matrix holds the Cr(CO)$_5$ fragment rigid at the beginning and end of the photolysis period, but that mobility is possible during irradiation. The most likely explanation is that visible photolysis causes the Cr(CO)$_5$ fragment to be excited from the ground state C_{4v} configuration to a D_{3h} excited state. The excited state can then relax back to a C_{4v} geometry, but reorientation of the molecule may occur (equation 23).



(23)

It is of course possible to propose a mechanism by which an M(CO)$_5$ fragment may take up a free CO molecule on visible photolysis to form M(CO)$_6$. This is via photoreorientation causing the vacant site of M(CO)$_5$ to move around the molecule, such that it may be directed towards any adjacent CO molecule trapped within the matrix cage. In this way a chemical bond will be formed between CO and the M(CO)$_5$ fragment. Alternatively, if the vacant site of the final product is directed towards a methane molecule, Cr(CO)$_5\cdots$CH$_4$ will be formed. This product is, however, still labile to visible photolysis, so reorientation may continue. Thus a reaction is possible with any CO molecule that is adjacent to the M(CO)$_5$ fragment. To backup this hypothesis it would be desirable to observe excited-state Cr(CO)$_5$ directly. Very recent solution experiments have been directed towards this end, but as yet such a species has defied unequivocal identification.

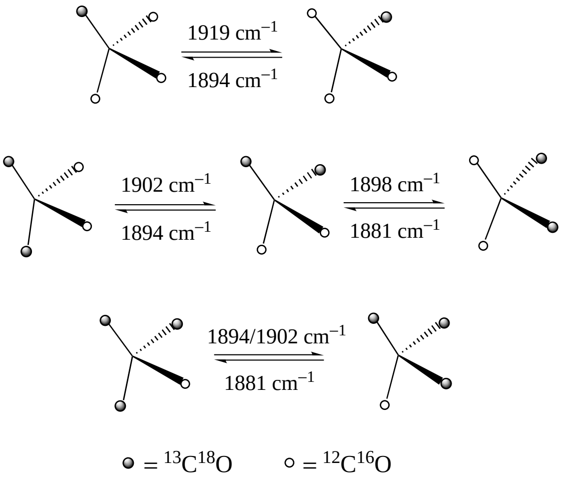
In a similar vein, near-IR photolysis of matrix-isolated Fe(CO)$_4$ promotes a reaction with photoejected CO to regenerate Fe(CO)$_5$:

$$\mathrm{Fe(CO)_4} + \mathrm{CO} \xrightarrow[20\,\mathrm{K}]{h\nu\text{(near IR)}} \mathrm{Fe(CO)_5} \qquad (24)$$

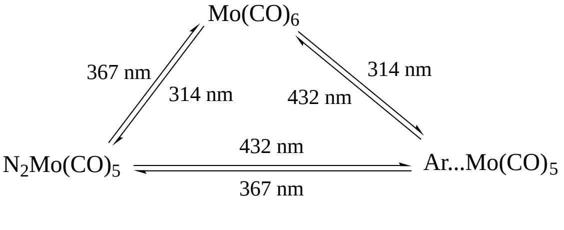
This finding led to an interesting study by Turner, Poliakoff *et al.* on the laser-induced isomerization of Fe(CO)$_4$. A statistical mixture of the different isotopomers of Fe(^{12}C^{16}O)$_{4-x}$(^{13}C^{18}O)$_x$ was formed in an argon matrix at 20 K by UV photolysis of matrix-isolated Fe(CO)$_5$

that had been 40% enriched with $^{13}C^{18}O$. These isotopomers are readily distinguished by their different IR absorption bands in the ν(CO) region. In all, there are seven possible isotopomers of $Fe(^{12}C^{16}O)_{4-x}(^{13}C^{18}O)_x$: two each of $Fe(^{12}C^{16}O)_{4-x}(^{13}C^{18}O)_x$ and three of $Fe(^{12}C^{16}O)_{4-x}(^{13}C^{18}O)_x$. It was found that irradiation of the matrix with the output of a tunable IR laser at a frequency corresponding to one particular isotopomer promoted a selective rearrangement as shown in Scheme 2. These interconversions may clearly be described as pseudorotations but the results show that the permutational mode is not that expected for the normal *Berry Pseudorotation* seen, for example, in the thermal rearrangement of SF_4. Thus the isomerization of $Fe(CO)_4$ was the first reported example of a non-Berry pseudorotation.

Visible photolysis of $Mo(CO)_5$ trapped in matrices containing N_2 results, not only in the regeneration of $Mo(CO)_6$, but also in the formation of a *dinitrogen complex* $Mo(CO)_5(N_2)$ (Scheme 3).[13] This molecule has been characterized by IR and Raman spectroscopy. Studies involving isotopic substitution with $^{15}N_2$, $^{15}N^{14}N$, and ^{13}CO have confirmed that the molecule has C_{4v} symmetry and thus a linear Mo–N–N unit is implied (**15**). Similar reactions are known for $Cr(CO)_5$, $W(CO)_5$, $Fe(CO)_4$, and $Ni(CO)_3$.

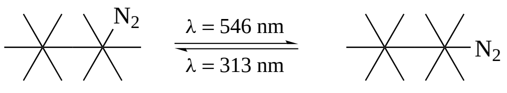


Scheme 2 Selective intramolecular rearrangement of isotopomers of $Fe(CO)_4$ partially enriched in ^{13}CO via a non-Berry pseudorotation



Scheme 3

The photochemical reaction of the binuclear carbonyl $Re_2(CO)_{10}$ with N_2 has been studied by matrix isolation. In an N_2 matrix at 10 K, $Re_2(CO)_{10}$ yields $Re_2(CO)_9$ upon UV photolysis. When the matrix is annealed to 15–20 K the equatorial isomer $Re_2(CO)_9(N_2)$ (**28**) is generated by a bimolecular reaction. Irradiation of the matrix with visible light ($\lambda = 546$ nm) converts (**28**) to the axial isomer (**29**), while (**29**) can be reconverted to (**28**) on UV irradiation at 313 nm.



(**28**) (**29**)

Although providing valuable structural information, such matrix experiments tell us little or nothing about the thermal stability of these dinitrogen complexes nor of the strength of the M–N bond. Experiments have sought to address this problem by looking at similar reactions in low-temperature inert solvents such as liquid xenon. It is shown that the molecule $Cr(CO)_5(N_2)$ survives at temperatures as high as $-35\,°C$. For the related molecule $Ni(CO)_3(N_2)$, kinetic studies of its dissociation have been possible, giving an estimate of about 40 kJ mol^{-1} for the activation enthalpy of the dissociative process:

$$Ni(CO)_3(N_2) \xrightarrow[\text{slow}]{-N_2} Ni(CO)_3 \xrightarrow[\text{fast}]{CO} Ni(CO)_4 \qquad (25)$$

Thus it is possible to estimate the enthalpy of the Ni–N bond (*see Bond Energies*).

The reactions between unsaturated metal carbonyls and dihydrogen have attracted much interest. Sweany discovered that a reversible interconversion between $Fe(CO)_4$ and $Fe(CO)_4H_2$ could be initiated by selective photolysis:

$$Fe(CO)_4 + H_2 \underset{\text{UV-visible}}{\overset{\text{IR}}{\rightleftharpoons}} Fe(CO)_4H_2 \qquad (26)$$

In this case, there is no reason to suppose that hydrogen is coordinated in any way other than the classical dihydride manner (**30**) (*see* ***Hydrides: Solid State Transition Metal Complexes***). However, similar experiments using $Cr(CO)_5$ gave a product $Cr(CO)_5H_2$ for which strong circumstantial evidence pointed towards the nonclassical dihydrogen structure (**31**). Unfortunately, in low-temperature matrices

(**30**) (**31**)

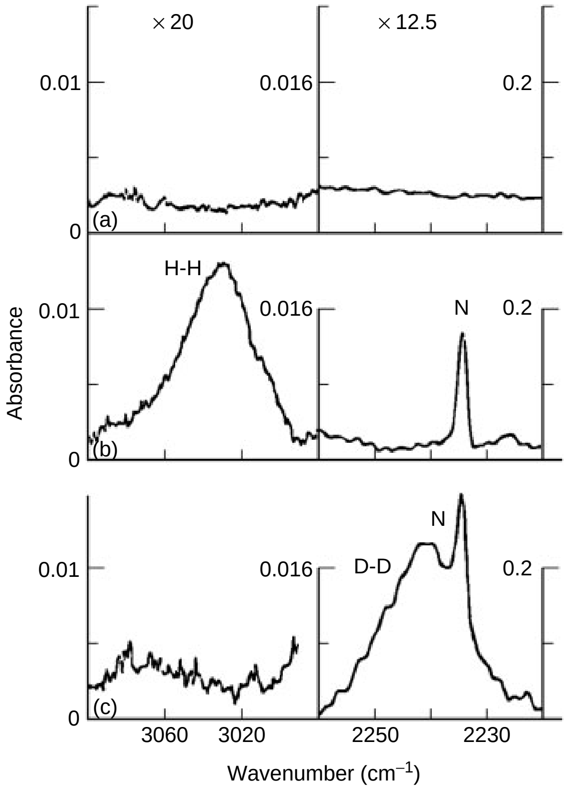


Figure 12 IR spectra of $Cr(CO)_6$ in hydrogen-doped liquid xenon solution: (a) before photolysis; (b) after photolysis in H_2-doped Xe; (c) after photolysis in D_2-doped Xe. N is an impurity band. the ν(H–H) mode was too weak to be observed. This problem was overcome by Poliakoff, Turner and coworkers who repeated the experiment in liquid xenon solution at 200 K.[9] Taking advantage of the long path length (27 mm) of their cell, they were able to obtain the spectra illustrated in Figure 12 in which the ν(H–H) vibration and its counterpart when D_2 replaces H_2 as reactant are clearly visible. Interest in such complexes continues. The Nottingham group have shown that photolysis of $[CpV(CO)_4]$ in liquid xenon solution doped with H_2 generates the nonclassical complex $[CpV(CO)_3(\eta^2\text{-}H_2)]$. By contrast, under similar conditions, $[CpTa(CO)_4]$ yields a classical dihydride $[CpTa(CO)_3(H)_2]$ while $[CpNb(CO)_4]$ gives rise to a temperature-dependent equilibrium between the classical $[CpNb(CO)_3(H)_2]$ and nonclassical $[CpNb(CO)_3(H_2)]$ compounds. This equilibrium has been investigated by the use of time-resolved IR spectroscopy. Thus, we see a smooth trend where dihydrogen coordination is favored at the top of the group and the dihydride at the bottom.

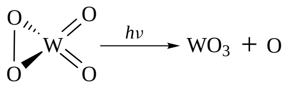
The reactions of $M(CO)_6$ (M = Cr, Mo or W), $(\eta^6\text{-}C_6H_3Me_3)M(CO)_3$ (M = Cr or Mo) and $W(CO)_5CS$ with H_2 and N_2 in polyethylene matrices have been investigated.[17] A high pressure (5000 lb in^{-2}) and low-temperature (30 K) cell was utilized to carry out these reactions, an approach that allows some of the advantages of 'traditional' matrix isolation to be combined with some of the advantages of low-temperature solution work. UV photolysis of $M(CO)_6$ gives: under N_2, $M(CO)_5N_2$ and on prolonged photolysis $M(CO)_{6-x}(N_2)_x$ ($x = 2-4$); under H_2, $M(CO)_5(\eta^2\text{-}H_2)$, and *cis*-$M(CO)_4(\eta^2\text{-}H_2)_2$ – the disubstituted products being previously unknown for W or Mo. One of the interesting features of this experimental arrangement is that the construction of the cell allows gases to be exchanged during a single experiment. Thus, thermal exchange between coordinated N_2 and H_2 ligands in $M(CO)_5L$ compounds may be studied. It was found that the order of reactivity follows the sequence Mo > Cr > W. UV irradiation of $(\eta^6\text{-}C_6H_3Me_3)M(CO)_3$ (M = Cr or Mo) and $W(CO)_5CS$ also leads to hitherto uncharacterized N_2 and H_2 complexes.

5.3 Photochemical Reactions of Metal Carbonyls with Dioxygen

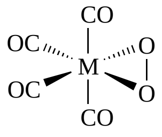
UV irradiation of matrices containing $M(CO)_6$ molecules (M = Cr, Mo, or W) and O_2 leads to the formation of oxocarbonyl species with fewer than five coordinated carbonyl groups that also contain, in one form or another, coordinated oxygen. Apparently the most stable oxocarbonyl molecule to be produced by photooxidation (*see Oxo Complex* and ***Dioxygen & Related Ligands***) of matrix-isolated $Cr(CO)_6$ is chromyl carbonyl (**8**).[18] The IR spectra of this species show clearly that the O–O bond has been cleaved. The C–Cr–C (from intensity measurements) and O–Cr–O (from ^{16}O–^{18}O isotopic shifts) bond angles are estimated at approximately 118° and 129°, respectively. This molecule attracts interest because it was the first example of a stable chromium(IV) carbonyl compound (*see Oxidation Number*), and yet it appears to be one of the most stable intermediates to be formed during photooxidation of $Cr(CO)_6$. The high energies of the ν(CO) vibrations (2125 and 2063 cm^{-1}) reflect the minimal capacity of the metal center to engage in back donation to the π-antibonding (*see Back Bonding*) orbitals of the CO groups.

The discovery of chromyl carbonyl prompted a search for analogs of the other group 16 metals, namely molybdenum and tungsten. However, it was soon found that the photooxidation of $Mo(CO)_6$ and $W(CO)_6$ proceeds in a somewhat different manner. Here the molecules $O_2M(CO)_2$ (M = Mo or W) are seen in only low yield and the most abundant oxocarbonyl species seen are the previously unknown complexes *trans*-dioxotetracarbonylmolybdenum and *trans*-dioxotetracarbonyltungsten (**9**).[11] These species were characterized by IR and Raman spectroscopy, including isotopic substitution with ^{13}CO and ^{18}O. Crucial evidence for the *trans* O=Mo=O formulation came from the observed splitting of the $\nu_{as}(MoO_2)$ IR absorption arising from the natural abundance of the different isotopes of molybdenum (see Figure 6).

For each of the group 16 hexacarbonyls, it is apparent that common to each reaction is an intermediate $(\eta^2\text{-}O_2)M(CO)_4$ (**32**). Upon UV photolysis the O–O bond is cleaved and CO groups are lost from the metal center yielding, upon prolonged photolysis, binary metal oxide molecules. Thus, $Cr(CO)_6$ yields as the final oxidation product CrO_2, while $Mo(CO)_6$ forms a mixture of MoO_2 and MoO_3. The formation of binary tungsten oxides from $W(CO)_6$ is somewhat more complex. The final product is WO_3 but this appears to be formed not from free WO_2, but rather from the molecule $(\eta^2\text{-}O_2)WO_2$ by loss of an O atom:

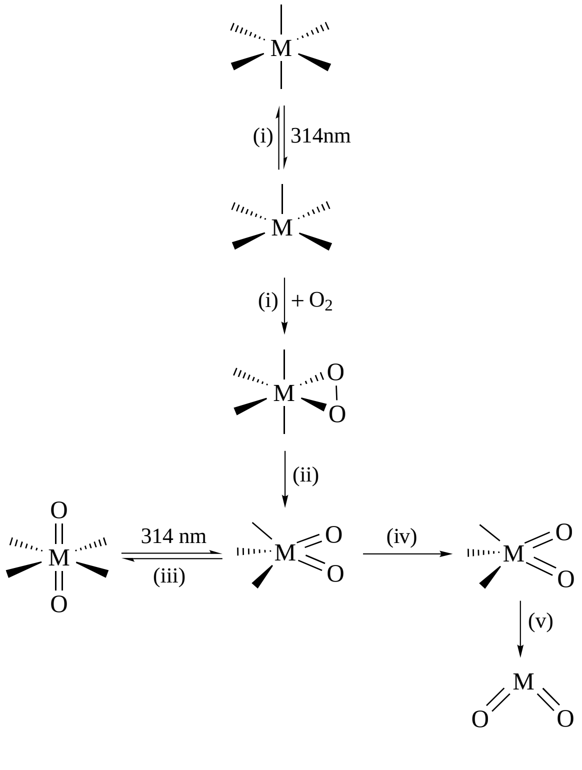


(27)



(**32**)

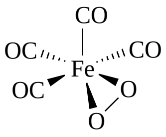
On the basis of these matrix-isolation experiments, a more-or-less complete mechanism for the photooxidation of the binary carbonyls $M(CO)_6$ (M = Cr, Mo, or W) in Ar matrices containing O_2 at 20 K can be proposed (Scheme 4): (i) Cr, 544 nm, Mo 403 nm, W, 435 nm; (ii) Cr, W 367 nm, Mo 314 nm; (iii) Mo and W only, Mo 403 nm or anneal at 35 K, W anneal at 35 K; (iv) Cr 314 nm or anneal at 35 K; Mo, W 314 nm; (v) Cr and Mo only.



Scheme 4

One distinctive feature of these photochemical reactions is the clear photoselectivity displayed. Thus, by using different wavelengths of light it is possible to build up the concentrations of individual species at the expense of others. For example, a high yield of the peroxo complex $(\eta^2\text{-}O_2)M(CO)_4$ (where M = Mo or W) is generated upon visible (blue or green) photolysis, while near-UV photolysis promotes rupture of the O–O bond and loss of CO to form the dioxo species $O_2M(CO)_3$.

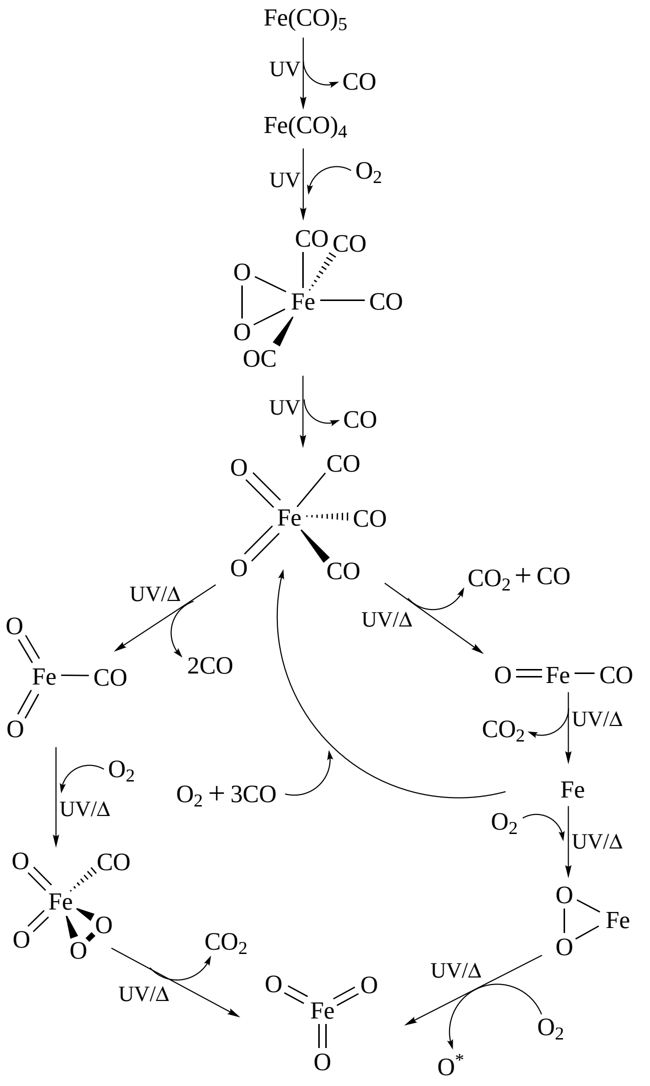
Iron pentacarbonyl ($Fe(CO)_5$) may be photooxidized in a similar manner. Although no fewer than five distinct iron carbonyl intermediates are seen, there is no sign of any photoselectivity in this reaction sequence.[18] It is possible, however, to build up reasonable concentrations, at least of the early intermediates, by carefully controlling the time of photolysis. Hence, it appears that the first oxidation product is $(\eta^2\text{-}O_2)Fe(CO)_4$, where the O_2 ligand occupies a basal site in a square pyramidal framework (**33**).



(**33**)

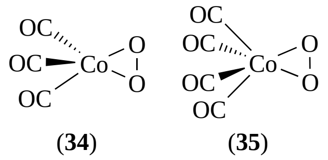
Photolysis then proceeds by rupture of the O–O bond and loss of CO to generate $O_2Fe(CO)_3$. Later oxocarbonyl intermediates are difficult to characterize since they are invariably formed only in meagre quantities. However, the nature of the final molecular binary oxide products does appear to have been resolved. They are the peroxo iron(II) species $(\eta^2\text{-}O_2)Fe$ and the planar (or near planar) iron(VI) oxide FeO_3. Taken together the results point to the reaction scheme shown in Scheme 5 for the matrix photooxidation of $Fe(CO)_5$ in Ar or CH_4 matrices containing O_2 at 20 K.

Attention turned to the dinuclear carbonyls $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, and $Co_2(CO)_8$. Regarding mechanistic information, the study of $Re_2(CO)_{10}$ has been the most fruitful. Here two distinct oxocarbonyl species, which appear to contain only one rhenium atom each, are formed. The final product of the reaction is the O-bridged oxide Re_2O_7. In a similar vein, $Mn_2(CO)_{10}$ yields Mn_2O_7 upon matrix photooxidation, although there is no hint of any intermediate in this process, no matter what steps are taken to produce such species. The photooxidation of $Co_2(CO)_8$ is likely to follow a pathway even more complex than that of $Mn_2(CO)_{10}$ or $Re_2(CO)_{10}$. In this case not only is there competition between M–C and M–M bond rupture as the primary photochemical step, but there is also the complication of photoisomerism of the molecule.



Scheme 5

Three isomers of $Co_2(CO)_8$, one with CO bridges, have been identified in low-temperature matrices and these readily interconvert upon UV–visible photolysis. In the event, two mononuclear peroxocobalt carbonyls, $(\eta^2\text{-}O_2)Co(CO)_3$ (**34**) and $(\eta^2\text{-}O_2)Co(CO)_4$ (**35**), are formed; they have been identified by comparison of their IR spectra with those of the same products formed by cocondensation of Co atoms with mixtures of CO and O_2.



(**34**) (**35**)

6 MAIN GROUP MOLECULES IN HIGH-TEMPERATURE VAPORS

6.1 Background

Many chemical molecules that are not stable under normal conditions at room temperature are found in high-temperature vapors. These include gaseous molecular forms of compounds such as metal oxides or chlorides that are normally encountered as solids at room temperature. Other species found in high-temperature vapors have unusual valencies and coordination numbers. Examples are the molecules OPCl and O_2PCl, which contain unusual two-coordinate trivalent and three-coordinate pentavalent phosphorus atoms, respectively. It is of interest to study such species to extend our knowledge of the structure and bonding of small molecules to new regions of the periodic table. Moreover, many such species are proposed chemical reaction intermediates.

Some methods of characterization of high-temperature molecules rely on direct flow-system vapor-phase measurements, for example, mass spectrometric and electron diffraction studies. Matrix isolation also plays a significant role in that vapor species may be trapped by rapid quenching. The most unambiguous results have perhaps been drawn from a combination of the two approaches.

6.2 Group 13

Monovalent compounds of the higher members of group 13 tend not to be stable. However, such species have been proposed as reaction intermediates (*see* ***Aluminum: Inorganic Chemistry*** and ***Boron Hydrides***). Thus, the reaction, discovered by Alfred Stock, in which B_2Cl_4 may be produced by the zinc discharge reduction of BCl_3, is believed to proceed via the intermediacy of BCl, which *inserts* into a B–Cl bond of a second BCl_3 molecule:

$$Zn^* + BCl_3 \xrightarrow{\text{discharge}} ZnCl_2 + [BCl] \quad (28)$$

$$[BCl] + BCl_3 \longrightarrow B_2Cl_4 \quad (29)$$

Similarly, higher boron subhalides (e.g. the pale-yellow tetrahedral molecule B_4Cl_4, the yellow–orange B_9Cl_9, and the red B_9Br_9) may be built up in discharge reactions of BCl_3 or BBr_3, presumably again via BCl or BBr molecules, although the exact reaction mechanisms remain obscure. Monovalent molecules akin to BCl are stable in high-temperature vapors; they may be studied by gas-phase or matrix-isolation methods. Particularly well-studied are the aluminum monohalides.

These molecules can be generated in a variety of chemical systems. Thus, AlCl is formed when Al vapor, at about 1000 K, is allowed to react with $AlCl_3$ vapor, at about 350 K,[19] while AlBr may be generated in a number of ways, for example,

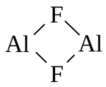
$$2Al(g) + MgBr_2(g) \xrightarrow{1500\,K} 2AlBr(g) + Mg(g) \quad (30)$$

$$2Al(v) + Br_2(g) \xrightarrow{1250\,K} 2AlBr(g) \quad (31)$$

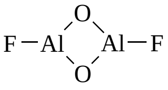
Aluminum monofluoride is formed by the reaction of Al vapor with HF at 1100 K. All of these molecules have been studied in both the gas-phase and in low-temperature matrices. It is found that the neon matrix gives IR spectra that most closely resemble those obtained from the gas phase.

These monohalide molecules are prone to aggregation in matrices; thus cyclic dimers such as (**36**) are formed. Two possible routes available to monovalent Al molecules to achieve the more stable trivalent state are addition of a two-electron donor, or insertion into a two-electron bond. Unsurprisingly, therefore, AlF reacts with O atoms in a matrix to form the linear molecule OAlF, a product that is itself prone to dimerization, forming (**37**). The structures of (**38**) and (**37**) have been investigated by isotopic substitution experiments involving ^{18}O and also by theoretical calculations. The structure of (**38**) is similar to that adopted by the stable solid $(SAlCl)_2$ (**39**), which is formed when $AlCl_3$ and Al_2S_3 are heated together at around 600 K:

$$2AlCl_3 + 2Al_2S_3 \xrightarrow{600\,K} 3(SAlCl)_2 \tag{32}$$

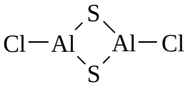


(**36**)



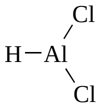
(**37**)

(**38**)



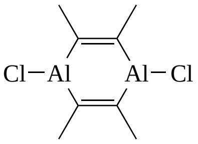
(**39**)

An example of an insertion reaction of an aluminium monohalide (cf. the insertion reactions of BCl mentioned earlier) is provided by the formation of planar $HAlCl_2$ (**40**) from AlCl and HCl in a low-temperature matrix. Similarly, GaCl will insert into HCl or H_2 to form the matrix-isolated chlorogallanes $HGaCl_2$ and H_2GaCl, respectively.

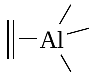


(**40**)

Aluminum monochloride may be generated in sufficient quantities to be used on a preparative scale. Cocondensation of AlCl vapor and dimethylacetylene at 77 K leads, upon warming the mixture to room temperature,[20] to the formation of an air- and moisture-sensitive product. This product shows an Al:Cl ratio of 1:1 while mass spectrometry suggests a molecular formula of $Al_4Cl_4C_{16}H_{24}$. A room-temperature single crystal X-ray diffraction study reveals the nature of the product. It consists of two dimeric 1,4-dialumina-2,5-cyclohexadiene rings (**41**) joined by a π-interaction between the Al atoms of one ring and the C=C bonds of the other (**42**). The C=C bonds are somewhat longer (136.7 pm) than an uncoordinated C=C bond, while the mean Al–C distance of 235.4 pm is approximately 10% greater than the Pt–C distance in the well-known alkene complex *Zeise's Salt*, $K[Pt(C_2H_4)Cl_3]$. The product is of interest as it might well be akin to intermediates in reactions of organoaluminum compounds; perhaps even in polymerization reactions catalyzed by Ziegler–Natta catalysts.



(**41**)



(**42**)

Interest in the reactions of monovalent aluminium compounds in low-temperature matrices has continued. Monomeric AlCl reacts, upon photoactivation, with acetylene in an argon matrix via insertion to give the acetylide species Cl(H)AlCCH.[21] IR spectroscopy with isotopic substitution was used to identify the product. This work provides an example of the use of quantum chemical calculations in probing the structure of unstable matrix-isolated compounds. Since the early 1990s almost all experimental matrix-isolation studies have been backed up by quantum calculations. These are used to predict structures of reactive species and to calculate minimum energies for these structures. Calculations may also be used to predict the IR spectrum of a particular species such that observed and calculated spectra may be compared. The work quoted here[21] is one example taken from many, but the principles of using experiment and calculation together are demonstrated. The energies of the acetylide product and of an alternative cyclic species are calculated, as are IR spectra for the species. As may be seen from Figure 13, there is an excellent match between the observed and calculated spectra. The work also illustrates the point that calculations do not replace experimental findings. It is still necessary to carry out isotopic substitution experiments and to compare observed and calculated IR spectra for the various isotopomers of the proposed product. This approach has been extended to the more complex reaction between photoactivated AlCl and 2-butyne; here two products are seen that are believed to be the insertion product $Cl(H)AlCH_2CCCH_3$ and the cyclic aluminacyclopropene isomer.[21] In a similar vein, AlF reacts with O_2 in an argon matrix to give peroxo and bis-superoxo complexes of aluminium, that is, $FAlO_2$ and $FAlO_4$.[22] The IR spectra shown in Figure 14 illustrate very nicely the importance of isotopic substitution in investigating systems such as this. It may be seen that when prepared from a mixture of $^{16}O_2$ and $^{18}O_2$ $FAlO_2$ shows a doublet of bands in the ν(O–O) region. This same product, however, gives a *triplet* of bands when a *scrambled* mixture of $^{16}O_2$, $^{16}O^{18}O$, and $^{18}O_2$ are used. $FAlO_4$ gives a triplet with unscrambled $^{16}O_2$ and $^{18}O_2$ – showing the

presence of two O_2 molecules. Once again Density functional theory (DFT) calculation back up the experimental studies (Figure 15).

In this area of chemistry, the use of *laser ablation* to generate metal atoms that may be cocondensed with a wide range of reagents has been particularly useful. Laser ablation often allows monomeric species to be produced when traditional thermal methods for generating metal vapors lead to dimers or oligomers. In this way, the aluminium carbonyls $Al(CO)_2$ and $Al_2(CO)_2$ – a cyclic molecule that shows some degree of aromaticity – have been prepared.[23] Recent developments in refrigeration techniques have allowed matrix temperatures of 3.5 K to be attained, which, in turn, has allowed pure hydrogen matrices to be deposited. The combination of utilizing laser ablation to generate metal atoms and depositing pure hydrogen as the matrix material has led to the development of new areas of metal hydride chemistry. When laser-ablated aluminium atoms are cocondensed with H_2 at 3.5 K and the mixture is subjected to ultraviolet irradiation and annealing to 6.5 K the product is the elusive molecule Al_2H_6.[24] Under normal conditions the only known aluminium hydride is the polymer $(AlH_3)_n$. A combination of IR spectroscopy and quantum chemical calculations show that this molecule is isostructural with diborane, B_2H_6. This study may be contrasted with a study of gallium hydrides utilizing more traditional methods of evaporation of gallium vapor from a resistively heated cell and cocondensation of the vapor with ca. 1% H_2-doped Ar.[25] In this case, the cyclic molecule $Ga(\mu\text{-}H)_2Ga$ is formed.

Laser-ablated aluminium, gallium, indium, or thallium atoms all react with HCN in excess argon.[26] Here both cyanide and isocyanide products viz MCN and MNC are seen (M = Al, Ga, In or Tl). No H-containing products are seen. These findings contrast with the results of experiments where laser-ablated group 2 atoms are cocondensed with HCN-doped argon.[27] Beryllium atoms give rise to HBeCN and HBeNC alongside BeCN and BeNC. Magnesium, calcium, strontium, and barium yield neither any H-containing products nor any cyanides. Only the isocyanides MNC (M = Mg, Ca, Sr or Ba) are formed. Why should the group 2 and 13 atoms behave so differently here? It appears that two mechanisms operate, namely insertion into the C–H bond or attack at the N atom. Calculations suggest that only Be and Al will insert into the C–H bond. With beryllium the H-containing product is seen, but rearrangement to the isocyanide also occurs. For aluminium direct insertion into C–H gives AlCN by loss of an H atom. All of the heavier atoms react by attack at the N atom to yield the isocyanides MNC. When M is a group 2 atom this product is stable, but when M is a group 13 atom the isocyanide rearranges to the more stable cyanide.

6.3 Group 14

Isoelectronic with monovalent group 13 molecules are divalent molecules of group 14 elements (*see* ***Germanium: Inorganic Chemistry***; ***Silicon: Inorganic Chemistry*** and ***Silicon: Organosilicon Chemistry***). The most populous class of these species are the silylenes, divalent compounds of silicon. It is not appropriate here to provide a detailed review of silicon chemistry since such material is more expertly and comprehensively covered elsewhere. However, it is pertinent to this discussion to make some mention of silylene chemistry.[28]

Silylenes are often generated by pyrolysis. Indeed, the simplest silylene of all, SiH_2, may be formed by pyrolysis of SiH_4. The presence of SiH_2 as an intermediate in this reaction, which yields ultimately Si_2H_6 and H_2, was first suggested over 30 years ago by Purnell and Walsh as a result of their kinetic studies:

$$SiH_4 \xrightarrow{\Delta} [SiH_2] + H_2 \quad (33)$$

$$[SiH_2] + SiH_4 \longrightarrow Si_2H_6 \quad (34)$$

the disilane Si_2H_6 being formed by an insertion reaction into the Si–H bond of SiH_4. As for isoelectronic group 13 molecules such as BCl and AlCl, it is not surprising to find that silylenes are prone towards insertion.

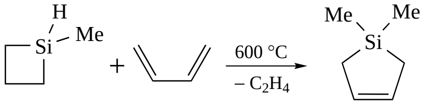
Silylene, SiH_2, was originally studied by electronic spectroscopy in the gas phase. Dubois *et al.*,[29] obtained its spectrum in 1968 and from it were able to estimate values for the bending vibrations of the second electronically excited ($^1A_1$) and ground ($^1B_1$) states of ~860 and ~1004 cm^{-1}, respectively. A rotational analysis of the fine structure of these bands afforded bond angles of 92° and 123° and r(Si–H) bond lengths of 1.516 and 1.487 Å for the $^1A_1$ and $^1B_1$ states of silylene. IR detection of silylene awaited the formation of the molecule in a low-temperature matrix. Good yields of this species were obtained by Fredin *et al.*, who cocondensed Si atoms with H_2. A spontaneous insertion reaction then yields SiH_2:

$$Si + H_2 \longrightarrow SiH_2 \quad (35)$$

They obtained a value of 994.8 cm^{-1} for the wavenumber of the bending mode, in reasonable agreement with the gas-phase value.

Dimethylsilylene, Me_2Si, long postulated as a reaction intermediate, was first observed directly in 1979; it was formed photochemically. It is now known to be generated also in high-temperature vapors, for example, pyrolysis of

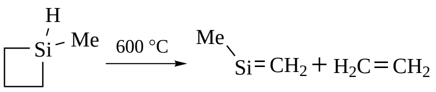
1-methylsilacyclobutane (**43**) in a tenfold excess of butadiene at 1000 K yields 1,1-dimethylsilacyclopent-3-ene (**44**) as a major product (equation 36).



(36)

(**43**) (**44**)

The favored reaction mechanism is that which yields methylsilene and ethylene upon pyrolysis (equation 37).

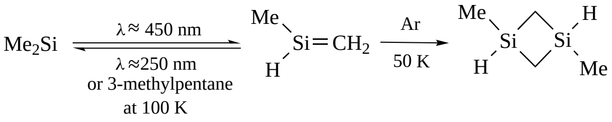


(37)

and the methylsilene rapidly isomerizes to dimethylsilylene (equation 38), which then adds to butadiene to yield the product (**44**).

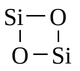
$$MeSi{=}CH_2 \xrightarrow{\Delta} Me_2Si \quad (38)$$

The isomerization of methylsilene and dimethylsilylene is now a well-known reaction in low-temperature matrices. It is a photochromic process that may be reversed upon irradiation of the matrix at selected wavelengths. Warming to temperatures as low as 100 K promotes the formation of the more thermally stable silylene (equation 39).

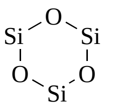


(39)

Thermochemical calculations show that the principal vapor species in the silicon/oxygen system is the monoxide SiO. This is the most stable molecule to contain a Si–O multiple bond. In 1969, Anderson and Ogden reported the results of matrix-isolation experiments in which the vapor over heated silica, SiO_2, (at 2000 K) or overheated silica/silicon mixtures (at 1600 K) was cocondensed with excess Ar or N_2. These results show that alongside the monomer, SiO, the dimer Si_2O_2 (**45**) and trimer Si_3O_3 (**46**) are also trapped in the matrix.



(**45**)



(**46**)

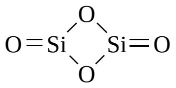
A point to be resolved is the extent to which the abundances of the matrix-isolated species reflect the composition of the high-temperature vapor. Mass spectrometric studies indicate that Si_2O_2 but not Si_3O_3 is present in the vapor. Thus it is presumed that Si_3O_3 is formed during the freezing of the matrix. A reinvestigation of this system has shown that if the temperature of the heated SiO_2 is raised above 1500 K, then the monomer is the most abundant gaseous species; at relatively high concentration, however, dimerization proceeds readily within the matrix. Normal coordinate analysis of the observed frequencies of the IR absorptions and ab initio self consistent field (SCF) calculations have been carried out for Si_2O_2 and are consistent with the cyclic planar structure (**45**).

Several reactions of matrix-isolated SiO are known. Irradiation of an argon matrix containing SiO and Cl_2 leads, via an insertion reaction, to the product $OSiCl_2$, the silicon analog of phosgene:

$$SiO + Cl_2 \xrightarrow[\text{Ar, 20 K}]{h\nu} O{=}SiCl_2 \quad (40)$$

The IR spectrum of this molecule shows it to be planar with a force constant indicating an Si=O double bond, which is, however, somewhat weaker than the corresponding C=O double bond in phosgene itself.

Molecular SiO_2 is prepared by reacting matrix-isolated SiO with O atoms. Thus codeposition of SiO molecules with microwave-excited O_2 and excess argon yields a species that shows a prominent IR band at 1416.5 cm^{-1}.[30] Isotopic substitution experiments allow this feature to be assigned to the asymmetric stretch of a linear SiO_2 molecule. Force constant calculations show that the Si=O bonds of SiO_2 are rather weaker than the C=O bonds of CO_2. Similarly, matrix-isolated Si_2O_2 will react with O_2 to yield (**47**), the dimer of SiO_2, whose structure has been determined by isotopic substitution with ^{18}O, and the natural abundance of ^{28}Si, ^{29}Si, and ^{30}Si isotopes.



(**47**)

Silicon monosulfide, SiS, is formed if CS_2 gas is passed over silicon heated to 1270 K. Its matrix chemistry shows a strong resemblance to that of SiO. Thus, it reacts with Cl_2 to yield $SSiCl_2$ and with O atoms to form OSiS, the silicon analog of carbonyl sulfide. The latter molecule is of interest since it is shown to contain both Si=O and Si=S double bonds, while both experimental observations and ab initio calculations confirm the double bond nature of the Si=S linkage in $SSiCl_2$.

In 1992, Andrews and his coworkers[31] attempted to characterize small high-temperature molecules in the germanium/oxygen/sulfur system. In this system, only the monooxide, GeO, and the monosulfide, GeS, are well-known, both having been studied in the gas phase by a variety of methods including electronic absorption and emission,

microwave absorption, and IR emission spectroscopy. They have also been observed in low-temperature matrices, while GeO_2 has been detected only in matrices. Andrews' approach has been to pass vapor-phase reagents through a microwave discharge. The systems studied are: (i) germane + sulfur; (ii) germanium + sulfur; (iii) germanium + oxygen + sulfur. The species present in each system are characterized by their behavior upon annealing the matrix and by isotopic substitution experiments. Thus, the new molecules SGeS and SGeO are seen. Like GeO_2, these are both linear; force constant calculations indicate some multiple bonding between Ge and S atoms although, as expected, such bonding is weak. Another molecule to show Ge=S multiple bonding is $Me_2Ge{=}S$. Michl *et al.* reported the first matrix-isolation study of this molecule, formed either by pyrolysis of the trimer $(Me_2GeS)_3$ or by the interaction of S atoms with dimethylgermylene (Me_2Ge). The vibration of most significance is the Ge=S stretch, which occurs at 604.5 cm^{-1}. It is attributable to a highly polar true double bond, since single bond Ge–S stretching vibrations typically occur around 410 cm^{-1}.

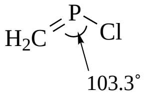
As in group 13 chemistry, laser ablation of metal sources has recently been used to allow new areas of group 14 chemistry to be explored. Again the use of dihydrogen matrices gives a route to group 14 metal hydrides. When laser-ablated silicon atoms are cocondensed with H_2-doped neon or argon a wide range of hydrides are formed, namely the monomeric species $SiH_{1,2,3,4}$ and the dimers $Si_2H_{2,4,6}$.[32] In pure deuterium matrices the major product is SiD_4 with smaller amounts of SiD_3, Si_2D_6 and Si_2D_4, but no SiD or SiD_2 was seen. Laser-ablated germanium atoms give, in H_2-doped neon or argon matrices, all four monomeric hydrides ($GeH_{1,2,3,4}$). Likewise all four monomeric germanium deuterides are seen in solid pure D_2. This suggests that the activation barrier for further reactions of GeD and GeD_2 might be higher than for the corresponding reactions of SiD and SiD_2.[33] Laser-ablated silicon and germanium atoms also react with ammonia to form 1:1 complexes that exhibit an interesting photochemistry.[34] Upon irradiation at $\lambda = 290$ nm, the insertion product $HSiNH_2$ is formed, while photolysis in the region 250–280 nm destroys $HSiNH_2$ and produces $SiNH_2$. Experiments utilizing thermally generated silicon atoms from a graphite cell heated to 1450–1650 °C have also been performed.[35] When Si atoms, formed in this way, are cocondensed with Me_2O or MeOH and the mixture is photolyzed a wide range of products are formed. These include the silylene MeOSiMe and the silanones $Me_2Si{=}O$ and $Me(H)Si{=}O$. The direct observation of silanones in detectable quantities under these conditions suggests that such reactions may be useful as a new route for the generation of these transient species.

6.4 Group 15

Small phosphorus (*see* ***Phosphorus: Inorganic Chemistry*** and ***Phosphorus–Nitrogen Compounds***) molecules with unusual valencies and coordination numbers are found in high-temperature vapors. An example is the phosphaethylene $CH_2{=}PCl$. This species has been prepared by pyrolysis of methyl dichlorophosphite (equation 41)

$$MeOPCl_2 \xrightarrow{\Delta} H_2C{=}PCl + HOCl \qquad (41)$$

and has been studied in the gas phase by microwave spectroscopy. It is thus shown to have a C=P distance close to 165.5 pm, a P–Cl distance close to 206.0 pm, and a C–P–Cl bond angle of 103.3° (**48**).



(**48**)

Isoelectronic with $CH_2{=}PCl$ is OPCl. This molecule has been prepared by two separate routes:

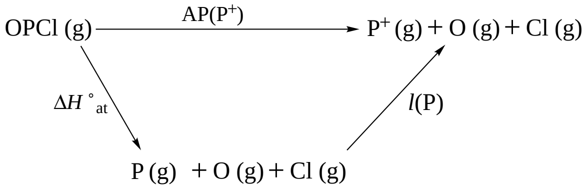
$$POCl_3(g) + Ag(s) \xrightarrow{1100\,K} OPCl(g) + 2AgCl(s) \qquad (42)$$

$$PCl_3(g) + H_2O(g) \xrightarrow{700\,K} OPCl(g) + 2HCl(g) \qquad (43)$$

It has been studied by IR spectroscopy (when trapped in a low-temperature matrix) and by mass spectrometric studies on the vapor. Isotopic studies ($^{35}Cl/^{37}Cl$ and $^{16}O/^{18}O$) allow the O–P–Cl bond angle to be calculated from the IR spectra at ca. 105° (i.e. close to the bond angle of CH_2PCl). From the observed appearance potential (20.9 eV) of P^+ [$AP(P^+)$] in the mass spectrum of OPCl, it is possible to estimate the enthalpy of atomization of $OPCl_{(g)}$ via the Born–Haber cycle (Scheme 6). Hence, since the standard enthalpies of formation of $P_{(g)}$, $O_{(g)}$, and $Cl_{(g)}$ are all known, the standard enthalpy of formation of $OPCl_{(g)}$ [$\Delta H^\circ_{f298}(OPCl)$] may be estimated as -250.7 kJ mol^{-1}.

A reaction similar to that with $OPCl_3$ occurs between $OPFX_2$ vapor (X = Cl or Br) and silver to produce OPF, a molecule that is isoelectronic with SiF_2 and SO_2. IR studies of Ar matrices and mass spectrometric studies of the vapor indicate that the O–P–F bond angle = 109 ± 5° and $\Delta H^\circ_{f298}(OPF_{(g)}) = -404.4$ kJ mol^{-1}.

Even more uncommon than molecules containing trivalent two-coordinate phosphorus are those that contain pentavalent



Scheme 6

three-coordinate phosphorus. The molecule O_2PCl may be prepared cleanly by UV irradiation of an Ar matrix containing OPCl and O_3:

$$OPCl + O_3 \xrightarrow[\text{Ar matrix}]{h\nu} O_2PCl + O_2 \quad (44)$$

The formation of O_2PCl from OPCl is illustrated by the spectra shown in Figure 16. IR spectra show O_2PCl to be a planar molecule (**49**) with a relatively wide O–P–O bond angle (~135°) and an unusually strong P–Cl bond (with a stretching force constant of $370\,N\,m^{-1}$). These observations may be rationalized by ab initio calculations.

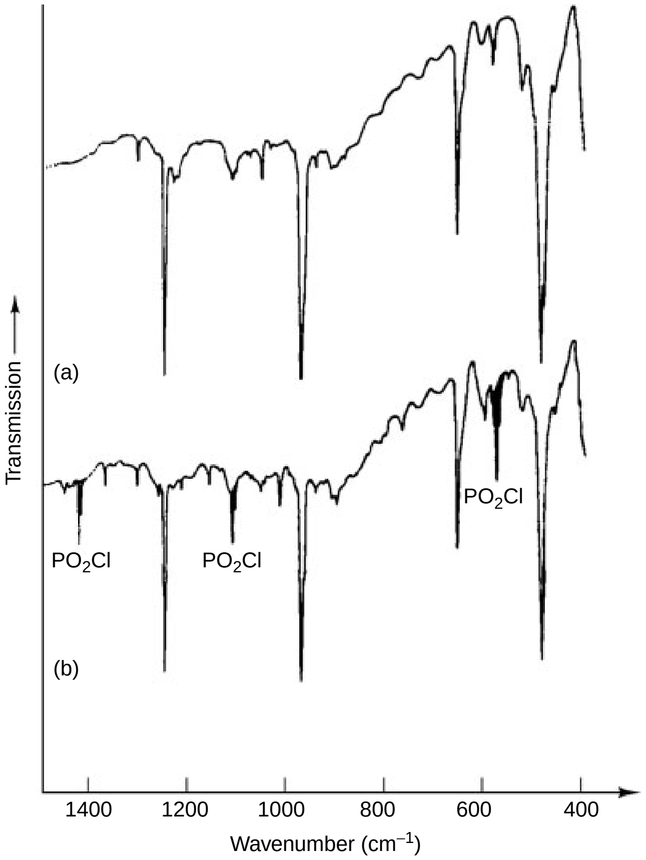


Figure 16 (a) IR spectrum of OPCl (derived from the reaction of $OPCl_3$ with Ag) cocondensed with $^{18}O_3$ in an argon matrix at ca. 15 K; (b) IR spectrum of the sample following UV irradiation for 15 min, showing the formation of the photoproduct O_2PCl. (Reprinted with permission from Ahlrichs *et al.*, *J. Am. Chem. Soc.*, 1986, 108, 3596. © 1986 American Chemical Society)

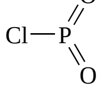


(**49**)

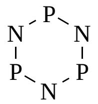
Several analogs of OPCl, produced in high-temperature vapors, have likewise been the subjects of matrix-isolation experiments. For example, SPCl can be made by the high-temperature reaction of $SPCl_3$ with Ag. It has an SPCl bond angle of about 110°. Preparation of OAsCl presents a more difficult challenge since the obvious precursor, $OAsCl_3$, does not survive long, even at normal temperatures. However, OAsCl can be generated if a gaseous $AsCl_3/O_2$ mixture is passed over silver heated to about 1350 K. Less successful have been attempts to study OSbCl. Although a reaction occurs between $SbCl_3$, O_2, and Ag at about 1350 K, Sb_4O_6 is a ubiquitous product alongside OSbCl, and IR absorptions of the binary oxide mask those of the ternary species.

The phosphorus nitride radical PN, isoelectronic with SiO, has recently been detected in interstellar space. It is readily prepared in high-temperature vapors either by heating solid P_3N_5 to 1100 K or by dehalogenation of cyclic $(NPCl_2)_3$ with Ag:

$$P_3N_5(s) \xrightarrow{1100\,K} 3PN(g) + N_2(g) \quad (45)$$

$$(NPCl_2)_3(g) + 6Ag(l) \xrightarrow{1300\,K} 3PN(g) + 6AgCl(g) \quad (46)$$

When the vapor containing PN is cocondensed with excess krypton at 10 K the PN monomer and P_3N_3 trimer are seen, but there is no hint of the dimer P_2N_2. The monomer is readily converted into the trimer, as illustrated by the spectra shown in Figure 17, if the matrix is annealed to 35 K. Isotopic substitution with ^{15}N and ab initio SCF calculations show that P_3N_3 has a planar cyclic structure (**50**).



(**50**)

The formation of P_3N_3 from P_2 and N_2 molecules is shown to be an endothermic process, while the formation of P_3N_3 from three molecules of PN is found to be strongly favored. PN reacts with silver atoms in hydrocarbon glasses at 77 K. The product, as determined by ESR spectroscopy, is AgPN. Local density functional calculations suggest that Ag bonds exclusively to the P nucleus of PN in a bent geometry with an Ag–P–N bond angle close to 97.4°. An interaction is also found between copper(I) chloride and PN molecules in solid argon. Here the interaction appears to be between the Cu and N atoms and the product is a linear species ClCuNP.[36]

Various routes have been used to generate matrix-isolated phosphorus oxide radicals, for example, PO_2 and PO_3. These are: (i) codeposition of phosphine with O atoms from a microwave discharge source; (ii) the matrix reaction of P_2 (generated by heating GaP) and O_3; (iii) laser ablation of P_4O_{10}; (iv) laser ablation of red P in a stream of O_2. Both

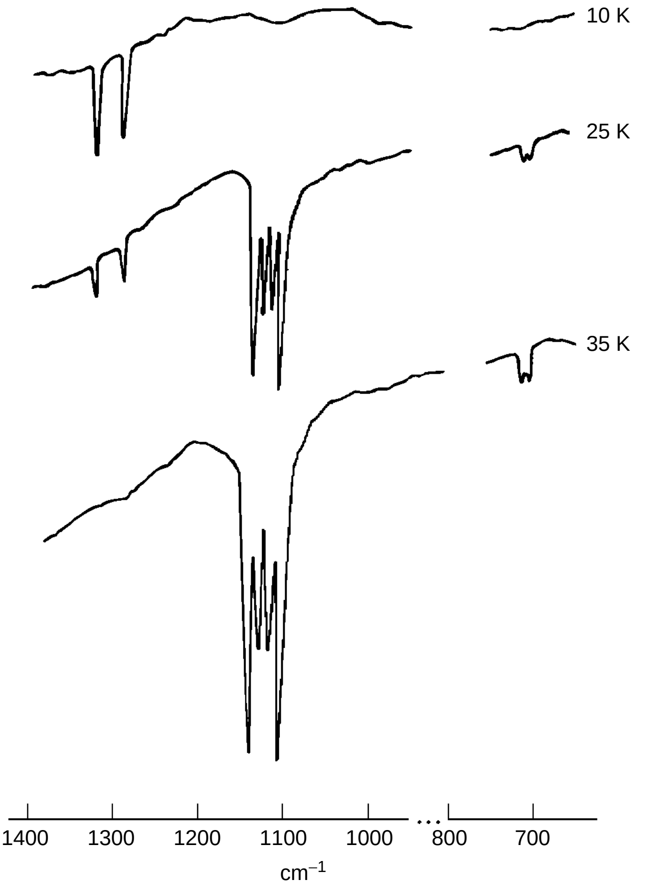


Figure 17 IR spectra of the 14N/15N isotopomers of PN and P_3N_3 (formed from PN upon annealing the matrix to 25–35 K) in a krypton matrix. (Reprinted from Ref. 36a © 1977, with permission from Elsevier)

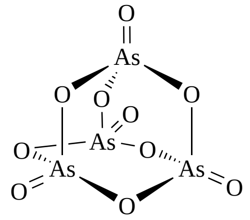
PO_2 and PO_3 are seen in all four systems; these are highly reactive species so it is not surprising to see P_2O_5 also, formed by reaction of PO_2 with PO_3 upon diffusion. The reaction of the high-temperature molecule P_2 with O_3 yields the new molecule P_2O alongside cyclic P_4O_2, while the reaction of PH_3 with O generates also the H-containing species HPO, HOPO, H_2PO, and HPOH. The nature of the products formed by the laser ablation of P_4O_{10} depends upon the nature of the solid material used. The hexagonal form, the commercially available variety, gives mainly molecular P_4O_{10} with some P_2O_5 and PO_2. By contrast, the polymeric orthorhombic form yields little molecular P_4O_{10} but much higher quantities of PO, PO_2, P_2O, and P_2O_5. A similar distribution of products is obtained if red phosphorus is laser-ablated in a stream of O_2.

The phosphorus sulfides PS, P_2S, and PS_2 have been made by allowing P_4 and S_8 vapors to react in an Ar discharge.[37] Isotopic substitution studies show that P_2S is linear like P_2O and N_2O, while PS_2 is bent like PO_2 and NO_2. The species in the vapor above heated P_4S_{10} have been the focus of some controversy. It has been claimed that P_4S_{10} sublimes undissociated. However, matrix-isolation experiments reveal that the molecule P_4S_9 is also present in the vapor even at temperatures as low as 450 K. Some P_2S_5 is also formed upon vaporization of P_4O_{10}. By contrast, volatilization of pure P_4S_9 solid at 450 K yields no vapor-phase P_4S_9; rather, P_4S_7 and P_4S_{10} are generated by disproportionation.

The vapor species formed upon heating arsenic(V) oxide in vacuo include the four decomposition products As_4O_n ($n = 6$ to 9) as well as As_4O_{10} (**51**), which has been characterized by its IR spectrum.

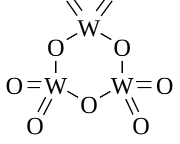


(**51**)

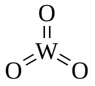
6.5 Group 16: Oxides and Oxy Salts

Several routes exist to molecular metal oxides. These include reactions of metal atoms with oxygen or photolysis of a suitable precursor, for example, a metal carbonyl in the presence of O_2 (see Section 5.3). Both of these methods lend themselves particularly well to trapping and detection by matrix isolation. A third means of generating molecular metal oxides is to heat a solid oxide sample, thus producing molecules in the vapor. The resulting gaseous species can then be studied either directly in the gas phase, or, following freezing with excess inert gas, in a matrix. A wide range of matrix-isolated metal monoxide molecules have been made in this way.

Higher oxides may also be formed. When WO_3 is heated to 1250–1700 K, the vapor contains a number of species of which the principal one appears to be the trimer W_3O_9. Gas electron diffraction studies suggest that the most likely structure of this species is one containing a six-membered ring (**52**). Mass spectrometry confirms the presence of W_3O_9 in the vapor and suggests also that the dimer W_2O_6 and tetramer W_4O_{12} are present. In order to make monomeric WO_3, a different technique must be employed. This is sputtering of a W electrode in a mixture of O_2 and an inert gas followed by rapid freezing of the products. IR experiments employing isotopic substitution show that WO_3 has planar D_{3h} symmetry (**53**).



(**52**)



(**53**)

Dimanganese heptoxide, Mn_2O_7, is a volatile liquid and readily sublimes undissociated. The heavier congener, Re_2O_7,

is less volatile and only vaporizes upon heating to about 400 K. It appears to sublime without dissociation, though an unidentified IR band ubiquitously appears in the spectrum of the matrix-isolated compound. This band has been variously attributed to: (i) aggregates of Re_2O_7; (ii) ReO_3 formed by loss of O_2 from Re_2O_7 and dissociation upon heating; (iii) $HReO_4$ formed by reaction of Re_2O_7 with traces of moisture. A definitive solution to this problem is not yet forthcoming, and the situation is complicated by the known rather complex behavior of rhenium oxides at high temperature. Upon volatilization at ca. 750 K, ReO_3 generates Re_2O_7 via the disproportionation reaction

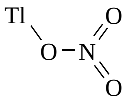
$$3ReO_3(s) \xrightarrow{\Delta} ReO_2(s) + Re_2O_7(g) \qquad (47)$$

which generates Re_2O_7 in the gas phase while leaving a residue of solid, involatile ReO_2. What mass spectrometric and matrix-isolation studies have so far failed to confirm is whether or not the Re_2O_7 is accompanied by ReO_3 in the vapor. Again the situation is complicated by the presence of $HReO_4$ whenever any traces of water are found.

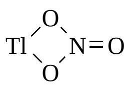
Many structural studies have been made on the species present in the vapors above oxysalts such as alkali metal nitrates, chlorates, perrhenates, and so on. In part, the interest in such work lies in determining the mode of coordination of the metal atom to the oxyanion in the monomeric vapor species. Both gas electron diffraction and matrix isolation have been employed to seek an answer to this question.

Three plausible structures may be envisaged (**54–56**) for a simple monomeric metal nitrate such as $TlNO_3$. Electron diffraction studies indicate that the bidentate structure (**55**) is preferred, a mode of ligation that is also adopted by $MReO_4$ and $MClO_4$ (M = Li, K, Cs, or Tl). Such structures may readily be determined by IR spectroscopy involving isotopic substitution with ^{18}O. In Figure 18 are illustrated IR spectra for $CsReO_4$, 50% enriched in ^{18}O,[38] assuming bidentate coordination. Other metal oxysalts showing bidentate coordination are metal phosphates (MPO_3) and phosphites (MPO_2) and their arsenic analogs (**57, 58**). Metal sulfates and their selenium analogs also tend to show bidentate coordination. Molecular thallium sulfate has been prepared in situ in low-temperature matrices by cocondensing Tl_2O vapor with SO_2 and excess Ar:

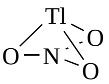
$$Tl_2O + SO_2 \xrightarrow[\text{excess Ar}]{\text{cocondense}} Tl_2SO_3 \qquad (48)$$



(**54**)



(**55**)



(**56**)

Alkali metal sulfates or selenates are generated in the gas phase by heating the appropriate solid material. Both

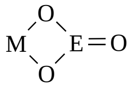
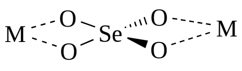
(**57**)



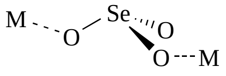
(**58**)

E = P or As

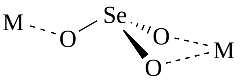
adopt a bis-bidentate D_{2d} structure (**59**). For the molecular metal selenites,[39] it appears that the selenite anion has an unsymmetrical structure. As shown in Figure 19, the best fit between observed and calculated IR spectra is found for O–Se–O bond angles of 101, 115, and 115°. This finding suggests the possibility of monodentate (**60**) or a combination of mono- and bidentate (**61**) coordination of the cation to the central selenite pyramid.



(**59**)



(**60**)



(**61**)

In contrast to the above molecules, cesium chlorate, $CsClO_3$, provides a rare example of tridentate coordination of a metal cation to an oxyanion (**62**).

(**62**)

Devlin has reported some interesting results regarding the solvation of $LiNO_3$ molecules in a low-temperature matrix.[40] In a pure Ar matrix, $LiNO_3$ adopts structure (**55**) and the degenerate ν_3 mode of the trigonal nitrate ion is split into two components separated by 262 cm^{-1}. However, if $LiNO_3$ is cocondensed with Ar-containing Lewis bases such as water or Tetrahydrofuran (THF) then the Lewis base molecules coordinate to the lithium ion. The splitting of ν_3 thus decreases in regular steps corresponding to an increase in coordination number of the Li ion. In Figure 20 are illustrated the IR spectra of $LiNO_3$ in Ar matrices doped with concentrations of THF ranging from 1 to 25%. One remarkable feature of these experiments is that the coordination number of the Li ion reaches a higher value in the matrix than it does in solution!

6.6 Group 17: Halides

Simple alkali metal halide molecules, for example NaCl and KCl, are found in the vapors above heated samples of the solid compounds. These vapor species have been studied by IR spectroscopy of gases and matrices, and by gas electron diffraction. The studies show that planar rhombic dimers are also present.

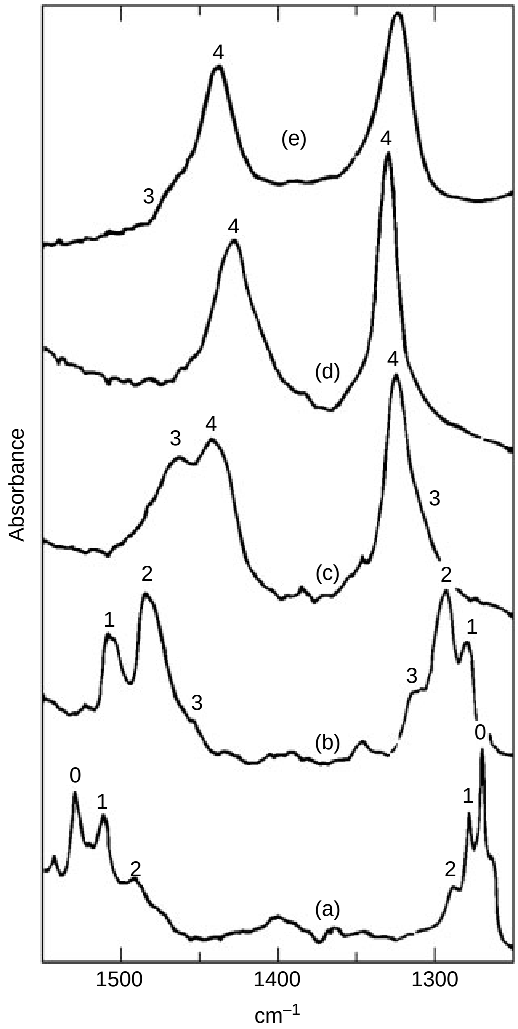

Figure 20 IR spectra of $LiNO_3$ in (a) 1% THF-doped solid argon; (b) 7% THF-doped solid argon; (c) 25% THF-doped solid argon; (d) pure solid THF (all at 25 K); (e) pure THF solution at 298 K. The numbers refer to n in $LiNO_3{\cdot}(THF)_n$. (Reproduced by permission of American Institute of Physics from Ritzhaupt *et al.*, *J. Chem. Phys.*, 1985, **82**, 1167)

There has, over the years, been some controversy regarding the structure adopted by the dihalide molecules MCl_2 (M = Ca, Cr, Mn, Fe, Co, Ni, and Zn). One school of thought has it that these molecules are linear, a view supported by the results of gas electron diffraction, and molecular beam deflection studies. In N_2 matrices, however, $CoCl_2$ and $NiCl_2$ are strongly bent, probably owing to interactions with the N_2 host, and even in Ar matrices there is evidence that $FeCl_2$, $CoCl_2$, and $NiCl_2$ are all slightly bent with bond angles around 160°. Those who follow the results of matrix-isolation spectroscopy will be reminded of the controversy that once attended the structure of molecular $AlCl_3$. Gas electron diffraction supported the expected planar geometry. Matrix-isolation studies were in conflict, one group preferring a pyramidal shape while another, that of Beattie and Ogden, a

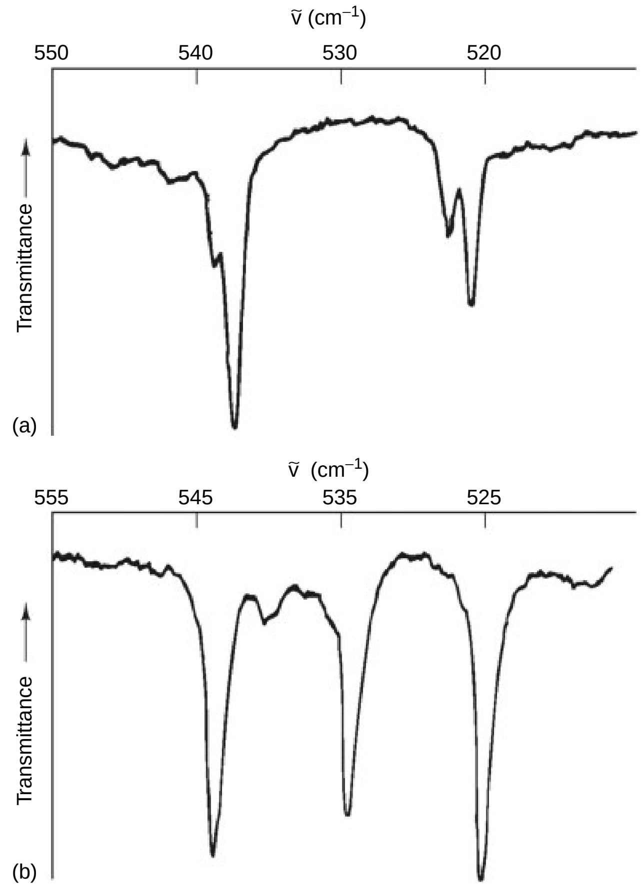

Figure 21 IR spectra of $CsUF_6$: (a) in an argon matrix; (b) in a nitrogen matrix (both at 14 K). (Reproduced by permission of The Royal Society of Chemistry from Arthers *et al.*, *J. Chem. Soc., Dalton Trans.*, 1984, 711)

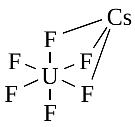
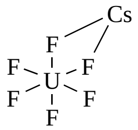
planar molecule. The discrepancy was finally resolved when it was realized that the nonplanarity of $AlCl_3$ in some matrices results from weak complex formation.

It is clear that interactions between guest molecules and the matrix host can, in certain instances, cause significant structural perturbations to the guest species. An exemplary case is provided by $CsUF_6$. The spectra of this molecule (Figure 21) look quite different in argon or nitrogen matrices. This difference appears to result from a change in coordination of the Cs^+ cation to the UF_6^- anion upon moving from one matrix to the other. In argon the interaction is tridentate (**63**), in nitrogen it is bidentate (**64**). Thus, the overall molecular symmetry is lowered from C_{3v} to C_{2v} upon moving from argon to nitrogen matrices.



(**63**)



(**64**)

It is appropriate to end with the caveat that it is a weakness shared by many of these studies of high-temperature salt molecules that the IR characterization of the species does not extend to motions of the cation. Hence the location of the cation, or cations, has to be inferred circumstantially from the perturbation experienced by the anion. The basis of the argument does make the results vulnerable to misinterpretation, and there is no doubt that the surest results relate to molecules whose identities can be vouched for independently, for example by gas electron diffraction studies.

6.7 Group 18

One of the most interesting developments in the study of main group chemistry by matrix-isolation spectroscopy over the past few years has been the great expansion of the chemistry of the rare gases. Although the following work does not involve generation of reactive species in high-temperature vapors, it is included here because of its importance in the current understanding of rare gas chemistry. Much of this work has been done in the laboratories of Räsänen and his coworkers at Helsinki, Finland. In 1995 it was shown that irradiation of HI in a xenon matrix led to the formation of the species HXeI. This had charge transfer characteristics $[(HXe)^+I^-]$ and was identified by its strong H–Xe stretching vibration.[41] The list of such molecules has grown over the years and now includes krypton and argon species, for example, HKrCl and HArF and those with a wide range of electronegative components, for example, HXeOH, HXeSH, HXeH, HXeCN, HxeNC, and HXeNCO. It has been shown that these neutral rare gas compounds form from the neutral fragments $H + Y + Rg$ where H and Y fragments are produced by photolysis of the HY precursor and Rg is the rare gas. The intrinsic stability of the molecules is of great interest and it has been shown, for example, that HXeBr and HXeCl are stable in neon matrices, indicating intrinsic stability rather than a stability that depends upon the presence of a Xe (or Kr) matrix host. These molecules will form weak, but stable complexes in matrices. Thus HXeOH gives the complexes HXeOH-H_2O and HXeOH-$(H_2O)_2$ in H_2O-doped argon matrices while HArF, HKrF and HKrCl all form N_2 complexes in N_2-doped matrices. The yields of HRgY molecules are increased by annealing the matrix as the mobility of the H atoms formed by photodissociation of HY is increased. In this way the kinetics of the formation of HKrCl and DKrCl by annealing of krypton matrices containing H (or D) and Cl atoms (formed themselves by photodissociation of HCl or DCl) may be used as a measure of the mobility of H and D atoms in low-temperature matrices. Not surprisingly the D atoms are shown to migrate at a slower rate than H atoms under these conditions.

It must be remembered that there is an enormous amount of current research involving the chemistry of reactive intermediates. In this short review, it has been possible only to describe selected areas of work. It is hoped, however,

that this will illustrate the principles of how such research is carried out and how the results of these studies have importance for a wide range of chemical and other scientific applications. The interdisciplinary nature of this research should also be noted. Work by spectroscopists – using a range of techniques – synthetic chemists, theoreticians, and kineticists is all brought together. The most successful findings in this area usually require input from those with a range of specialized interests.

1 INTRODUCTION

Silicon is the most abundant (≈27.7%) electropositive element in the Earth's crust and second only to oxygen in overall abundance, the two elements together accounting for approximately four out of every five atoms on the surface of the Earth. Elemental silicon does not seem to occur naturally but it is usually combined with oxygen to form the very wide variety of silicates (*see Silica* and ***Zeolites***) that make up many of the world's rocks. Silicon is not found to any appreciable extent in the atmosphere, and only relatively small amounts are found in the hydrosphere, although organisms such as diatoms and some plants are able to extract silicon in the form of silica or silicic acid from aqueous solutions and use solid deposits of silica as skeletal or protective material. For example, hydrated silica, $SiO_2{\cdot}nH_2O$, is used by a number of organisms for protection and strength, for example, in plant leaves and the teeth of limpets. For general reviews on silicon in biology, see References 1–3 and Section 1.2 below.

Despite the ubiquitous nature of silicate materials and humankind's historical use of them, elemental silicon was not isolated until the nineteenth century when Berzelius used potassium to reduce potassium hexafluorosilicate (equation 1). (For a review of the history of the discovery of the element and its occurrence, see Gmelin.[4])

$$K_2SiF_6 + 4K \longrightarrow Si + 6KF \qquad (1)$$

The mid-nineteenth century also saw the preparation of simple, volatile, covalent compounds such as $(EtO)_4Si$, $SiCl_4$, and SiH_4 and the first organometallic silicon compound (Et_4Si) by Friedel and Crafts in 1863. Considerable growth in non-silicate silicon chemistry occurred in the first part of the twentieth century with Stock and Kipping working on silanes (Si–H containing compounds) and organosilicon compounds, respectively. This work then set the foundation for the enormous growth that silicon chemistry has seen since the 1940s, particularly in the fields of polymers containing silicon in their backbone, and organosilicon compounds that have been studied to see how their chemistry compares with that of carbon compounds. This article will deal only with the inorganic compounds of silicon and excludes all compounds containing a silicon to carbon bond (such organosilicon compounds may be found in the article ***Silicon: Organosilicon Chemistry***) except for silicon carbide and simple silyl cyanides in which the carbon may be viewed as 'inorganic'. Compounds that cannot be isolated under normal conditions and which are fleeting intermediates will be mentioned briefly but not discussed in detail. As in other areas of chemistry, computational work on silicon compounds has grown rapidly in recent years; an excellent comparative review of the theoretical aspects of Si, Ge, Sn, and Pb compounds can be found in Reference 5.

1.1 Elemental Silicon and its Production

The production of high purity silicon has become increasingly important during the last three decades as its semiconductor properties have been utilized in an enormous variety of electronic devices.[6] The early work on the chemical and physical properties of silicon and its simple inorganic compounds has been discussed in detail.[7] Large-scale production of silicon is achieved by reduction of quartz, SiO_2, with carbon at approximately 1700 °C (equation 2), that is, well above the melting point of silicon.

$$SiO_2 + 2C \xrightarrow{1700\,^{\circ}C} Si + 2CO \qquad (2)$$

The silicon prepared by this route is known as metallurgical grade or ferrosilicon and contains varying amounts of iron which is derived from impurities in the silica used and by addition of iron to the reduction process. Leaching impurities from the ferrosilicon affords higher purity silicon (ca. 98.5%), containing Fe, Al, Ca, and O as main impurities, which can be used for chemical purposes such as the direct synthesis of organochlorosilanes (*see* ***Silicon: Organosilicon Chemistry***).

The preparation of high purity silicon for use in the electronics industry has been achieved using several methods relying on the formation, purification by distillation, and reduction of volatile silicon compounds such as SiF_4, $SiHCl_3$, and SiH_4 (for preparations of these compounds, see below). Scheme 1 outlines the basic features of the process to prepare single-crystal silicon using $HSiCl_3$ as the volatile silane, the low boiling point of which enables distillation to give a much higher purity starting material than in the SiO_2 reduction where physical separation of impurities is difficult.[6]

A second method of Si preparation involves the thermal decomposition of Na_2SiF_6 to give SiF_4, which is then reduced by sodium to give a mixture of NaF and Si. The sodium salts are then removed by aqueous acid leaching to give a high quality powder of Si.[8] A more recent and widely used method involves the thermal decomposition of SiH_4 (which can be obtained in higher purity than $SiHCl_3$ from redistribution reactions, Scheme 2) to give high purity polycrystalline rods.[9]

The high purity silicon prepared by the methods above is either polycrystalline or in the form of a microcrystalline powder. Two methods are used to prepare large, dislocation-free single-crystal silicon: the Czochralski method and the zone-refining or float zone method. The equipment used in the Czochralski method is shown in Figure 1. The graphite crucible is filled with polycrystalline pieces which are then melted. A seed crystal is dipped into the melt and then slowly withdrawn such that the silicon slowly crystallizes as it is removed from the hot zone. Both the graphite crucible and the pulling seed are rotated, often counter to each other, so that resistivity and oxygen content can be made uniform. Single crystals of 30-cm diameter and more than 1 m in length can be prepared in this way, but it is difficult to keep the large volume of molten silicon free from contamination by the silica container and from impurities in the inert gas blanket for the long periods of time required.[6]

The zone-refining method is shown in Figure 2. In this method, only a small band of the polycrystalline silicon rod is melted at any one time and the molten zone is moved along the length of the rod, and impurities dissolve preferentially in the molten phase and so are drawn to the end of the rod. Again, single-crystal silicon crystallizes on a seed crystal, and single-crystal growth continues as the melt zone is moved. This method also allows large single crystals to be prepared. Contamination is more easily controlled as only a small fraction of the silicon is molten at any one time and the liquid zone is not in contact with any solid container. The float zone method can be applied more than once to a silicon rod to increase purity. Table 1 gives a summary of some of the more important data associated with elemental silicon and the silicon atom.

The chemistry that can be carried out at a silicon surface has become more significant in recent years as the dimensions

^{29}Si	28.976495	4.67%
^{30}Si	29.973770	3.10%

of electronic devices based on crystalline silicon have become ever smaller. In addition to older methods such as doping, etching, and deposition of films to modify Si surfaces, newer studies have shown that reactions involving, for example, unsaturated species such as dienes, alkynes, and aromatic compounds can also occur and lead to Si–C bond formation. (These studies have been reviewed; see References 11 and 12). The reaction of elemental silicon, usually alloyed with copper, is the basis of the 'Direct Process' used for the preparation of simple alkylchlorosilanes (for a review see Reference 13).

The etching of silicon in the form, for example, of a wafer can be achieved in many ways and leads to a material known as 'porous silicon'. Etching can be achieved chemically, photochemically, or electrochemically using electrolytes usually comprising solutions of concentrated aqueous HF containing various additives. The size of the pores produced in the silicon can be varied from about 1×10^{-9} to 1×10^{-5} m, depending on the conditions used. The nature of the pores can also be varied greatly to include, for example, pores that are spongelike or cylindrical. The interest in porous silicon arises from its light-emitting properties such as photoluminescence and chemiluminescence and from its physical properties such as its high surface area (hundreds of square meters per cubic centimeter). If HF etching is used to prepare the porous silicon then the surface of the silicon is terminated by Si–H bonds and these can be used to carry out further chemistry at the surface such as oxidation to give Si–OH groups or hydrosilylation to give pendent organic groups. Such surface modification means that the materials may be used for bio- and chemical-sensing, new materials supports, and for mass spectrometry applications. The many methods of preparation and the potential uses of porous silicon have been reviewed.[14–17]

1.2 Silicon in Biology

Silica dissolves from the mineral environment into water to become bioavailable as silicic acid, $Si(OH)_4$, and can reach a concentration of up to 2 mM at near neutral pH. At higher concentrations, oligomerization takes place followed by the formation of colloidal particles of hydrated silica, $SiO_2.\times H_2O$. Silicic acid in water is used by organisms such as diatoms and radiolaria to build up complicated exoskeletons of hydrated silica and plants can take in silicic acid to build up silica materials that can strengthen stems and leaves or make protective spikes (*see* ***Biomineralization***). Thus, terrestrial plants can, at an average composition of 0.15% Si, contain more silicon than magnesium or phosphorus. Clearly, animals eating vegetation may consume large amounts of silicon in their normal diet. The effects of silicon in diet and silicon deficiency have been the subjects of several studies that have been reviewed.[18] It seems that although the silicon in higher animals plays neither a significant structural role nor participates in Si–C bond formation, it is useful in its interaction with toxic metals such as aluminum where it can affect the metal's bioavailability, distribution, and excretion. The bio-manipulation of silicic acid and its polycondensation into silica has been shown to

involve several classes of proteins that have been named ‘frustulins’ (isolated from cell walls of diatoms), ‘silaffins’ (found occluded within biosilica) and ‘silicateins’ (also found occluded in silica needles). The mechanisms used by these biological controllers of silica production are of significant interest as they may be used to produce synthetic silica with high surface area and/or well-defined porosity.[19] Numerous reviews of the various aspects of biological silicon chemistry in plants, concerning, for example, silicon deposition in higher plants, the effects of silicon on plant growth and crop yield, and silicon resources for agriculture can be found in Reference 20.

2 ONE-COORDINATE COMPOUNDS

Compounds containing silicon bonded to only one other atom are unstable and are usually only generated and observed as reactive intermediates of short half-life. Silicon compounds subjected to flash photolysis or electrical discharges in the gas phase produce short-lived species SiX (X = H, F, Cl, Br, I, C, Si, etc.), the band structure of which have been studied in detail.[21] The structures, electronic configurations, and so on of SiX (X = H, F, Cl, Br, I, N, O, etc.) have also been the subject of MNDO (modified neglect of diatomic overlap) and other calculations.[22,23]

Silicon monoxide, SiO, is formed in a wide range of reactions such as those between SiO_2 and Si, SiO_2 and Mg, SiO_2 and CO, and $SiCl_4$ and O_2, at high temperatures. The reaction between Si and SiO_2 (equation 3) in an oxygen-free atmosphere may be troublesome in the high-temperature postoxidation annealing process used during the fabrication of semiconductor devices. However, the reaction is inhibited if O_2 is present (which presumably oxidizes SiO back to SiO_2 as it is formed) during the annealing process.[24] When quartz, SiO_2, is heated to sufficiently high temperatures for vaporization to occur, the predominant species in the gas phase is found to be SiO. Commercially SiO has been produced as a dark brown cokelike mass on a substrate from the reaction of Si with SiO_2 at 1250 to 1400 °C (for a review on the production, properties, and applications of SiO, see Reference 25). As a fine brown powder, freshly prepared SiO is pyrophoric and readily oxidizes to give SiO_2. Rapid cooling on to a cold surface, or condensation into an inert gas mixture, enables SiO to be isolated and studied spectroscopically. Thus condensation of an Ar/SiO mixture on to a cold copper surface allows IR spectroscopic identification of SiO, $(SiO)_2$, and $(SiO)_3$ with characteristic IR absorbances at 1226, 803 and 768, and 972 cm^{-1} respectively. The IR data suggest that $(SiO)_2$ has a cyclic structure.[26] Monomeric SiO can react in a matrix with metals, for example, reaction with Pd gives PdSiO the bonding in which is thought to be similar to the corresponding carbonyl, PdCO. The reactions of SiO in noble gas matrices have been reviewed.[27]

$$Si^{+\bullet} + HX \rightleftharpoons [SiHX]^{+\bullet *} \longrightarrow SiX^{+} + H^{\bullet}$$

$$X = Cl, OH, SH, NH_2$$

Scheme 3

$$Si + SiO_2 \longrightarrow 2SiO \quad (3)$$

Silicon monosulfide, SiS, is formed in the high-temperature reaction between silicon and sulfur, or between SiO_2 and metal sulfides such as FeS or ZnS. It is also formed on passing H_2S over Si at 1500 K and it can be trapped in an argon matrix and analyzed by IR spectroscopy, showing a band at 739 cm^{-1} for SiS. The monosulfide reacts in the matrix with co-condensed COS to give linear SiS_2, which absorbs at about 900 cm^{-1}.[28]

There is continuing interest in the gas-phase reactions of silicon cations because of the increasing use of chemical vapor deposition in the semiconductor industry and the interest in the preparation of three-coordinate silicon cations in condensed phases. Atomic silicon cations, $Si^{+\bullet}$, react with a wide range of inorganic and organic species in the gas phase to give more complicated species that can be investigated by ion cyclotron resonance, flow tube techniques, or ion-trap techniques. Some simple examples of these reactions are shown in Scheme 3. Initially a long-lived intermediate form, it then breaks down to give the silicon-containing cation and H•. These and other reactions of $Si^{+\bullet}$ have been reviewed.[29]

Metal silicides such as NaSi, KSi, and $CaSi_2$ that appear from their empirical formulas to contain single-coordinate Si are, in fact, complicated three-dimensional solids. Metal silicides have found increasingly numerous applications in the semiconductor industry, in thermoelectric devices, and in structural applications. They may be prepared in numerous ways, for example, by depositing a layer of metal onto Si and then heating, by coevaporation of a metal and Si, or by chemical vapor deposition using a mixture of SiH_4, H_2, and a volatile metal complex. Metal silicides exhibit a wide variety of structures including isolated Si^{4-} ions such as in Mg_2Si, tetrahedral $Si_4{}^{4-}$ ions as in KSi, layers as in $CaSi_2$, and three-dimensional networks as in $SrSi_2$. These are beyond the scope of this review, but have been reviewed elsewhere.[30–33]

3 TWO-COORDINATE COMPOUNDS

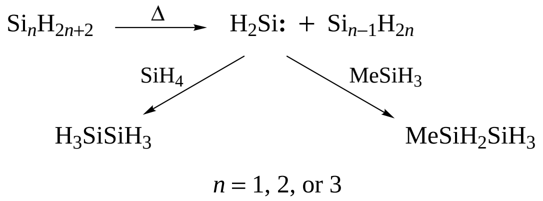
Two-coordinate X_2Si: species are called silylenes (by analogy with carbenes) and are best described as reactive intermediates which may be trapped and observed spectroscopically at low temperatures in an inert matrix, but most of which have short lifetimes under normal conditions. The structures and electronic configurations of X_2Si: (X = H, F,

Cl, Br, O, etc.) have been calculated by MNDO and other more sophisticated theoretical methods.[22,23,34,35] Experimental values for the X–Si–X angle in X_2Si: species have been found to be 92.5, 100.76, 102.8, and 102.7° respectively for X = H, F, Cl, and Br. This suggests that repulsions between the X groups as well as electronic effects may play an important part in determining the structure of silylenes.[36]

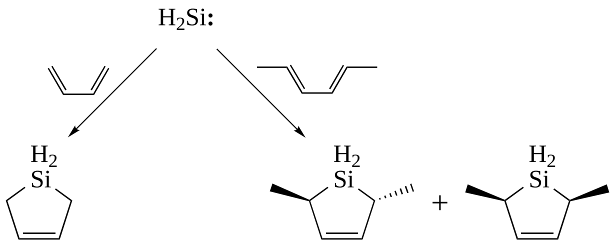
The simplest silylene H_2Si: is formed by the pyrolysis of SiH_4 and the higher perhydrosilanes and it undergoes two typical types of reaction: insertion and addition. Silylene readily inserts into Si–H bonds (Scheme 4) both in perhydro- and alkylsilanes (organosilanes such as Et_3SiH are often used as chemical traps for R_2Si: species).[37]

Silylene also undergoes nonstereospecific addition to a variety of conjugated dienes (Scheme 5).[37]

Difluorosilylene is much more stable than other simple silylenes, having a half-life at room temperature of about two minutes, much longer than that of difluorocarbene (ca. 1 s), but much shorter than that of GeF_2 which is a stable



Scheme 4

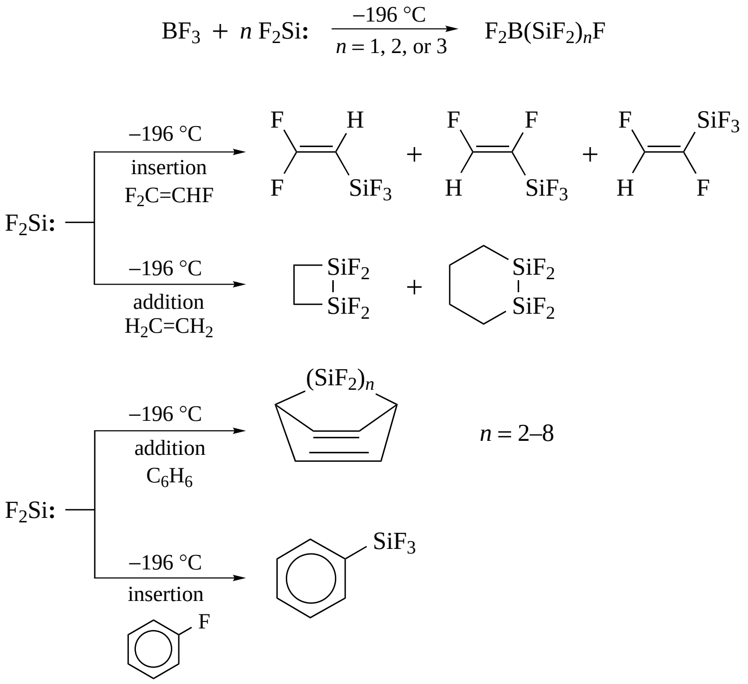


Scheme 5

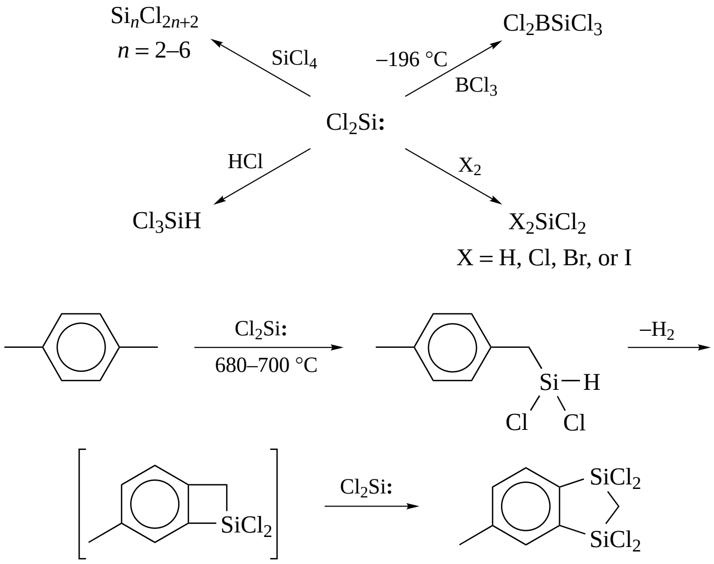
solid. This has meant that much of the chemistry of F_2Si: has been investigated in the condensed rather than the gas phase. The silylene is readily prepared at high temperature, and in the absence of trapping agents forms oligo- and polyperfluorosilanes (equation 4).[37]

$$n\text{Si} + n\text{SiF}_4 \xrightarrow{1200\,^\circ\text{C}} 2n\text{F}_2\text{Si:} \xrightarrow{-196\,^\circ\text{C}} \text{Si}_n\text{F}_{2n+2} + \text{polymers} \quad (4)$$

As in the case of H_2Si:, difluorosilylene undergoes both insertion and addition reactions (Scheme 6), although in this case there is often more than one SiF_2 unit in the product, which is perhaps not surprising in view of the formation of Si_nF_{2n+2} species on condensation. Insertion reactions occur readily with fluoroalkenes, but addition occurs with other alkenes. This is presumably due to the high strength of the Si–F bond formed in the insertion which drives the reaction.[37]



Scheme 6



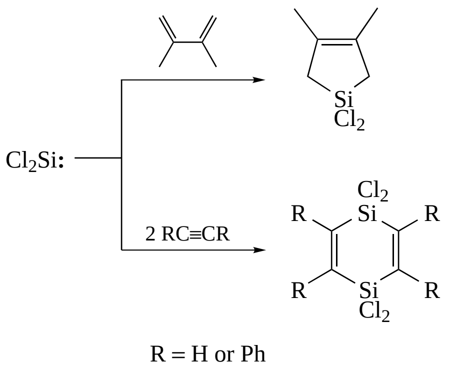
Scheme 7

Dichlorosilylene may be prepared by pyrolysis of perchloropolysilanes and again undergoes both insertion and addition reactions. The insertion into a wide variety of bonds, including C–H bonds, has been studied (Scheme 7). At the elevated temperatures used in these reactions, elimination of H_2 and cyclization may also occur and, if the ring formed is strained, a further Cl_2Si: insertion may occur.[37]

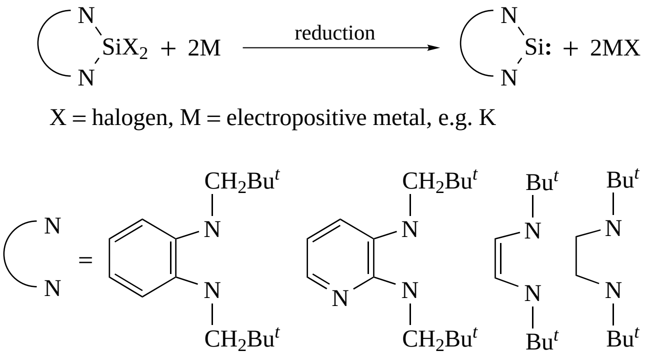
As in the case of F_2Si:, addition of Cl_2Si: to alkenes occurs readily (Scheme 8), but the products rarely contain Si–Si bonds even if more than one Si atom is present in the product, due to dimerization.[37,38]

The flash photolysis of H_3SiX (X = Cl, Br or I) gives rise to HXSi:, the structures of which have been investigated by emission and absorption spectra. Like the X_2Si: species they have a singlet ground state with a relatively small angle at silicon.[30] Photolysis of H_3SiN_3 at 193 nm in an argon matrix at 10 K leads to the formation of HSi≡N that can be characterized by IR and UV spectroscopy at low temperature but which decomposes rapidly as it is warmed.[39] The co-condensation of SiO and O_2 in an argon matrix gives isolated, linear SiO_2 molecules (quite unlike the extended array of four-coordinate silicon atoms in SiO_2 in the form of quartz) having a characteristic IR band at 1400 cm^{-1}.[40,41] The mixed chalcogen species, SiOS may also be trapped from the reaction between SiS and O atoms.[42]

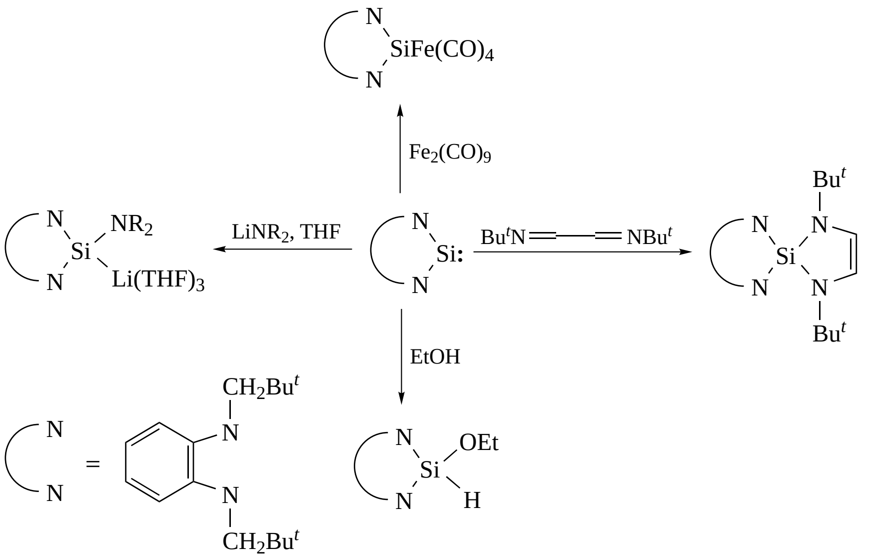
Although the chemistry of silylenes was for many years restricted to that of reactive species where the two substituents at Si were small, since the mid 1990s the realization that steric protection of the silylene center could enable stable silylenes to be isolated under normal laboratory conditions has led to a blossoming of new chemistry. Nitrogen substituted silylenes can be prepared by reduction of halosilane precursors as shown in Scheme 9. Reagents such as potassium in THF, potassium-graphite and finely divided magnesium can be used to effect the reduction and fluoro-, chloro-, or bromosilanes may be used as precursors. Although thermally stable, these



Scheme 8



Scheme 9



Scheme 10

silylenes are reactive towards a wide range of compounds and typically undergo reactions that involve nucleophilic addition to an unsaturated organic compound, insertion into polar bonds such as O–H, C–X (X = Cl, Br or I), or N–M (M = Li, Na or K), and reactions with transition metal centers. Examples of these reactions are shown in Scheme 10. The chemistry of these and related silylenes has been the subject of many publications, these have been reviewed recently.[43–46]

4 THREE-COORDINATE COMPOUNDS

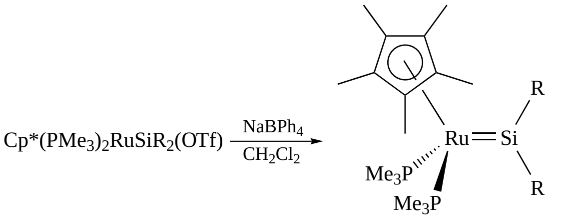
The structural details of three-coordinate silicon compounds have, as their one- and two-coordinate analogs discussed above, mainly been obtained at either very high- or low temperatures or using very rapid spectroscopic techniques. This is due to their high reactivity and short half-lives, in turn due to the reluctance of silicon to form multiple bonds as, unlike carbon, it is usually much more thermodynamically advantageous to form two single bonds rather than one double bond to silicon. Early work on three-coordinate silicon compounds has been reviewed.[30] The structures of unsaturated Si–H containing compounds such as $H_2Si{=}SiH_2$ and other low-coordinate species such as silylenes have been the subject of much theoretical investigation. The calculated structures of these fascinating compounds and comparisons with experimentally derived data for them are available.[47]

Trivalent inorganic silicon cations are extremely rare in solution (but common in the gas phase[48]) and their existence has remained a matter of some dispute.[49–51] Many calculations on the structures and the stability of R_3Si^+, $R_3Si\bullet$, and R_3Si^- species have been carried out and are reviewed.[34,51] Silyl radicals, $R_3Si\bullet$, and silyl anions, R_3Si^-, may be prepared, although the radicals tend to have a short half-life. The inorganic radicals $R_3Si\bullet$ (R = H, F or Cl) are known, although organic-substituted silyl radicals are much more common and are used for radical reductions in organic chemistry. The radicals are usually prepared by UV photolysis of R_3Si–H compounds either alone or in the presence of radical initiators such as *t*-BuOOBu-*t*, and may be observed spectroscopically in inert gas matrices at low temperatures.[30]

An X-ray investigation of $MSiH_3$ (M = K, Rb, or Cs; for their preparation, see Section 5.1.3) shows that the compounds crystallize in the sodium chloride face-centered cubic lattice. This differs from the NiAs structure of KCH_3 and gives an effective ionic radius for SiH_3^- of about 2.26 Å.[52] The most widely studied of the compounds is $KSiH_3$, which also has an orthorhombic β-form[53] (see Section 5.1.3 for details of its reactions). The formation and use of the Cl_3Si^- ion by treatment of Cl_3SiH with tertiary amines or from $BrSiCl_3$ is discussed more fully in Section 5.2.3 Three-coordinate $SiOX_2$ (X = F or Cl) are formed in an argon matrix from the photolysis of SiO and X_2[41,54] while $SiOCl_2$ can be isolated in a matrix from the combustion of $SiCl_4$ with O_2.[55]

Stable compounds containing simple three-coordinate silicon atoms other than the alkali metal salts were not isolated until a range of transition metal silylene complexes were prepared. However, instead of having simple structures of the type $R_2Si = ML_n$, that is, analogous to their carbon analogs, the silicon atom is usually further coordinated by a donor ligand such as HMPA or THF. Some donor-free complexes have, however, been prepared in solution.

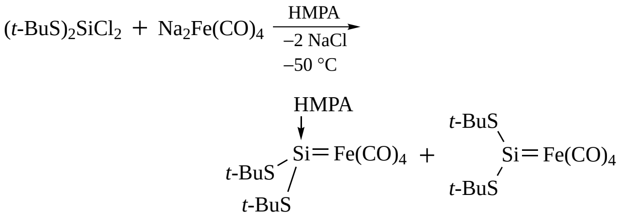
Displacement of a good leaving group from silicon in a noncoordinating solvent (equation 5) allows solvent-free complexes (**1**) to be prepared when the substituents on silicon are bound via sulfur. As would be expected by analogy with carbene complexes, the ^{29}Si NMR chemical shift for these complexes is at very low field (264.4 and 268.7 ppm, respectively, for R = S-*p*-tolyl and SEt, respectively) and they also react readily with donor molecules such as MeCN to give four-coordinate, donor stabilized silylene species.[56,57] (See Section 6 below for further details of transition metal silyl complexes.)



(5)

(**1**) R = S-*p*-tolyl or SEt

The salt elimination method (equation 6) may also be used to prepare silylene complexes and, again if sulfur ligands are present, a donor-free complex may be formed as shown, although it is only the minor product along with the donor stabilized complex (**2**) which it readily forms in the presence of excess HMPA. The donor-free complex is only stable below −30 °C and decomposes above this temperature to give $HFe_3(CO)_{11}^-$ and the polysilane $[(t\text{-BuS})_2Si]_n$.[58]



(**2**)

(6)

5 FOUR-COORDINATE COMPOUNDS

The chemistry of silicon is largely that of four-coordinate compounds although, as seen in Section 7, higher coordination is readily achieved and many stable compounds containing five- and six-coordinate silicon are known. Silicon forms unusually strong bonds to the electronegative elements such as the halogens, oxygen, and nitrogen; Table 2 shows typical bond energies in some representative four-coordinate compounds. The bonds to the halogens and to oxygen are even stronger than their carbon analogs, but, as will be seen in the following section, compounds containing such bonds are also usually much more reactive than their carbon analogs.

Table 2 Average covalent bond strengths and lengths in silicon compounds[59,60]

	Bond strength (kJ mol^{-1})	Bond length (Å)
Si–H	326	1.48
Si–F	582	1.55
Si–Cl	391	2.02
Si–C	301	1.87
Si–Si	226	2.32
Si–O	452	1.51

5.1 Perhydrosilanes

Although the chemistry of carbon, the near neighbor of silicon in the periodic table, is greatly dominated by the vast array of compounds containing C–H bonds, there are far fewer comparable silicon species. Generally speaking, the simple alkanes are rather unreactive and, even in more complicated compounds containing other functional groups, the C–H bonds are likely, along with C–C bonds, to be the least reactive in the molecule. Compounds containing Si–H bonds do not occur naturally and this is due to the high reactivity of the Si–H bond toward a wide variety of reagents. The Si–O bond is very strong and its formation is often the overriding factor in many reactions, and many of the compounds described in Section 6, including the hydrides, react with water or dilute aqueous acid or base to give Si–O containing products. Why then is the chemistry of silanes so different from that of alkanes? An important difference between carbon and silicon is their electronegativity, 2.5 and 1.8 (on the Pauling scale), respectively. The rather greater electropositive character of silicon means that in contrast to carbon, in which the C–H bond is polarized $C^{\delta-}$–$H^{\delta+}$, the Si–H bond is polarized in the opposite manner $Si^{\delta+}$–$H^{\delta-}$. This, combined with the relatively high ionic character of the Si–H bond, and the fact that it is about 90 kJ mol^{-1} weaker than the C–H bond, means that Si–H compounds are much more reactive than their carbon analogs. The Si–H bond also has greater ionic character than the C–H bond. The availability of d-orbitals on silicon means that five- or six-coordinate intermediates or transition states are readily accessible, and the larger size of silicon also means that incoming reagents have more space in which to attack than in comparable carbon compounds. The chemical and physical properties of hydrosilanes are discussed in detail elsewhere.[61,62]

5.1.1 *Preparation of Silicon Hydrides*

Several methods are available for the preparation of compounds containing Si–H bonds. Historically, the silicon hydrides $H(SiH_2)_nH$ (n = 1, 2, 3, etc.) were prepared by reaction of various metal silicides (such as those of Mg, Al, and Fe) with hydrochloric or phosphoric acid (equation 7).[63] For example, Mg_2Si addition to dilute phosphoric acid affords H_4Si, H_3SiSiH_3, $H_3SiSiH_2SiH_3$, Si_4H_{10}, and Si_5H_{12} (together

$$R_nSiX_{4-n} + (4-n)\,MH \xrightarrow{\text{ethereal solvent}} R_nSiH_{4-n} + (4-n)\,MX$$

R = alkyl, aryl, H, etc.; X = any halogen; MH = LiH, $LiAlH_4$, etc.; n = 0–3; solvent usually = THF, Et_2O, or $(MeOCH_2CH_2)_2O$

$$2Cl_3SiSiCl_3 + 3LiAlH_4 \longrightarrow 2H_3SiSiH_3 + 3LiCl + 3AlCl_3$$

Scheme 11

with higher silanes) in an approximate ratio 8:6:3:2:1 but with only a 25% overall conversion of silicide to silane silicon. The yields from this type of reaction are low because of the hydrolysis of the Si–H bonds in the products by the aqueous environment. Better yields are obtained by treatment of Mg_2Si with NH_4Br in liquid ammonia (for the detailed preparation of silane from NH_4Br and Mg_2Si, see Brauer[64]) or with $H_2NNH_2{\cdot}2HCl$ in hydrazine. More recent analysis of the products from this type of reaction show that silanes containing up to nine silicon atoms are formed.[65]

$$Mg_2Si + \frac{H_2O}{H^+} \longrightarrow SiH_4 + Mg(OH)_2 \qquad (7)$$

These methods are no longer used because the separation of the mixtures formed leads to low yields of the individual silanes. A far more general method, and one that can conveniently be carried out on a laboratory scale, is the reduction of halosilanes using reagents such as $LiAlH_4$ or LiH (Scheme 11). Unfortunately, polyhalides cannot be partially reduced in this way, that is, $SiCl_4$ cannot be reduced to H_2SiCl_2. Silyl deuterides, Si_nD_{2n+2}, can be prepared in similar ways to the hydrides, that is, by D_2O/DCl decomposition of Mg_2Si or by reduction of halides with $LiAlD_4$.

Disilane, H_6Si_2, has also been produced cleanly by CO_2 laser irradiation of monosilane SiH_4[66] and a detailed procedure for the preparation of disilane, trisilane, and higher silanes by passage of an electric discharge through SiH_4 has also been reported.[67] Physical data for some silanes are given in Table 3 and, as would be expected by analogy with the alkanes, the small silanes are volatile gases and the larger ones are liquids with boiling points that increase as the molecular weight increases. Further properties of the higher silanes (NMR and Raman spectra, viscosity, and surface tension) are available,[68–70] and the physical and thermodynamic properties of SiH_4 have been reviewed.[71] There are also reviews of the manufacture and applications of SiH_4[62,72] and of the methods associated with analysis and purification of SiH_4.[62,73]

Table 3 Physical properties of perhydrosilanes[74]

	Mp (°C)	Bp (°C)	Density (g cm^{-3})
SiH_4	−185	−112	1.44 g L^{-1} (gas)
H_3SiSiH_3	−132.5	−14.5	0.685 at −25 °C
$H_3SiSiH_2SiH_3$	−117.4	52.9	0.739 at 20 °C

$(H_3Si)_3SiH$	−99.4	101.7	0.793 at 20 °C
$H_3Si(SiH_2)_3SiH_3$	−72.8	153.2	0.795 or 0.827, both at 20 °C
$(H_3Si)_2SiHSiH_2SiH_3$	−109.8	146.2	0.820 at 20 °C
$(H_3Si)_4Si$	−57.8	134.3	0.815 at 20 °C
$H_3Si(SiH_2)_4SiH_3$	−44.7	193.6	0.827 at 20 °C
$(H_3Si)_2SiHSiH_2SiH_2SiH_3$	−78.4	185.2	0.840 at 20 °C
$(H_3SiSiH_2)_2SiHSiH_3$	−69	179.5	0.843 at 20 °C

5.1.2 Structure of Perhydrosilanes

The structure of H_4Si and D_4Si has been investigated in the gas phase. Tetrahedral geometry is found as expected and the bond lengths are 1.49 and 1.47 Å, respectively, for the H and D compounds.[75] The structure of H_3SiSiH_3 has been determined by electron diffraction in the gas phase and shows an Si–Si bond length of 2.331 Å (which is slightly shorter than that found in elemental Si and in Si_2Me_6), an Si–H bond length of 1.492 Å, and an H–Si–Si angle of 101.3°.[76] Calculations on the structure of SiH_4 and related silanes are discussed in References 35 and 77.

5.1.3 Reactions of Perhydrosilanes

The perhydrosilanes are toxic and spontaneously flammable in air and form explosive mixtures with oxygen. The mechanism of SiH_4/O_2 explosions has been investigated, and the products from such reactions depend greatly on the initial composition of the mixture. For mixtures $>$70% O_2, the products are SiO_2 and H_2O, but for mixtures $>$70% SiH_4, the products are SiO_x (SiO deposited may be a mixture of SiO_2 and Si), Si, and H_2.[78] Extreme caution should, therefore, be exercised in their handling. Accidental release of silane into the atmosphere may lead to fire or explosion hazards, and spontaneous ignition of a SiH_4/N_2 mixture in air may occur above about 2.5 volume % SiH_4. (The problems associated with handling silane have been addressed.[79]) As has been stated above, highly pure silane undergoes thermal decomposition at about 570–670 °C to give highly pure silicon, and SiH_4 has therefore become an important gas used in the manufacture of integrated circuits and photovoltaic cells. There has been considerable discussion about the mechanisms of the plasma or thermal chemical vapor deposition of Si from SiH_4. Much work has suggested that the silyl radical $SiH_3{\cdot}$ is the dominant species responsible for deposition, but more recent work suggests that silylene, H_2Si:, is the most important species which, together with disilane (which is formed by insertion reaction as shown below), when adsorbed on to a surface, breaks down to give silicon.[80,81] The mechanism of deposition may also involve the adsorption of H_2Si: on to a surface and then insertion of further H_2Si: units into the Si–H bonds of the absorbed species; further insertions and loss of H_2 lead to the buildup of material containing Si–Si bonds (Scheme 12).[82] The use of SiH_4 and chlorosilanes for the deposition of Si has been discussed[83] and the reactions of SiH_4 to form transition metal complexes are described in Section 6.1. The ionization and

$$SiH_4\,(g) \xrightarrow{heat} H_2\,(g) + H_2Si{:}\,(g) \longrightarrow H_2Si{:}\,(ads)$$

$$H_2Si{:}\,(ads) \xrightarrow{2H_2Si:} (H_3Si)_2Si{:}\,(ads) \xrightarrow{H_2Si:} etc.$$

Scheme 12

ensuing fragmentation of SiH_4 gives $SiH_x^{+\bullet}$ (where x = 1, 2, or 3) that can undergo hydride exchange reactions or clustering with neutral SiH_4. Reactions of these ions with inorganic and organic compounds have been reviewed.[29]

As stated above, the most obvious reaction of silanes is their oxidation by, for example, oxygen, water, and alcohols (in great contrast to the analogous alkanes). From this it follows that silanes are good reducing agents and organosilicon compounds (which are much easier to handle than the perhydro compounds) such as Et_3SiH have been used extensively to carry out reductions in organic chemistry. (For reductions in organic chemistry using $(EtO)_3SiH$, see Fieser.[84]) Although silanes do not appear to react with pure water or slightly acidic water under normal conditions, in slightly basic solution rapid and complete hydrolysis occurs with the evolution of hydrogen. The hydrolytic cleavage of a Si–Si bond also affords H_2, and this method can therefore be used to ascertain the number of Si–H and Si–Si bonds present in a molecule by measuring the volume of hydrogen evolved (Scheme 13).

Silane reacts with methanol to give the alkoxysilanes $(MeO)_nSiH_{4-n}$ ($n = 2, 3, 4$) and with higher alcohols in the presence of base to give tetraalkoxysilanes (equation 8).[85] This type of reaction is, however, rarely carried out as the alkoxysilanes produced are more conveniently prepared from alcohols and $SiCl_4$ (which is more readily available than SiH_4 and much more easily handled). Similarly, silyl esters, $Si(OCOR)_4$, are also usually prepared from polyhalogenosilanes rather than from silane and a carboxylic acid.

$$SiH_4 + 4ROH \xrightarrow{RO^-} Si(OR)_4 + 4H_2 \qquad (8)$$

$$R = Et,\ n\text{-}Pr,\ n\text{-}Bu,\ etc.$$

Silane reacts with alkali metals (Na, K, Rb, and Cs) over a period of between about a week for Cs, and two or three months for Na, to give H_3SiM species (see Section 4 for a description of their structures) in the ether solvents $MeOCH_2CH_2OMe$ or $(MeOCH_2CH_2)_2O$ by two different pathways depending on the stoichiometry of the reagents (Scheme 14).[86,87]

$$SiH_4 + 2KOH \xrightarrow{H_2O} K_2SiO_3 + 4H_2$$

$$+ PhGeBr_3 \longrightarrow PhGe(SiH_3)_3$$

$$M = Si,\ Ge,\ or\ Sn$$

Scheme 15

The most well known of the alkali metal derivatives is $KSiH_3$, which acts as a nucleophile in a wide range of displacement reactions, for example, with HCl to give SiH_4 and KCl, with MeCl to give H_3SiCH_3,[88] and with $PhCH_2Cl$ to give $PhCH_2SiH_3$,[89] or as a reducing agent, for example, reducing CO_2 to CO.[90] Silylpotassium reacts with various other halides to give silyl substituted products and a range of such reactions are depicted in Scheme 15.[91,92]

The reactions between $KSiH_3$ and perhydrosilanes (equation 9) afford various other silylpotassium reagents, which have also been used to prepare other functional oligosilanes in a manner similar to that shown in Scheme 15.[93,94]

$$H_3SiK + (H_3Si)_nSiH_{4-n} \xrightarrow{MeOCH_2CH_2OMe} (H_3Si)_nSiKH_{4-n-1} \qquad (9)$$

$$n = 1, 2, \text{or } 3$$

5.2 Silicon Halohydridosilanes, H_nSiX_{4-n} ($n = 1$–3, X = Halogen), etc.

These compounds are highly reactive like the perhydrosilanes and must be handled with care because of their ready hydrolysis in the atmosphere to give the corrosive and toxic hydrogen halides, HX (X = F, Cl, Br, or I). Again, this high reactivity is in great contrast to the relative inertness of common halohydroalkanes such as CH_2Cl_2 and $CHCl_3$. Of all the halohydrosilanes, trichlorosilane is by far the most important and the most widely studied because of its industrial uses, for example, in the preparation of high purity silicon as discussed earlier in Section 1.1 and in the preparation of organosilanes via the ***Hydrosilation Catalysis*** reaction.

5.2.1 Preparation of Halohydrosilanes

Trichlorosilane is produced and used on a large industrial scale and it is usually prepared from the reaction of Si with HCl at about 300 °C, which can also give H_2SiCl_2.[95] The

preparation of $SiHBr_3$ and SiH_2Br_2 can be achieved in a similar manner from Si and HBr.[96] At 360 °C and above, Si reacts with HBr to give $SiHBr_3$ and $SiBr_4$ in varying proportions depending on the temperature, a higher temperature giving a greater proportion of $SiBr_4$.[97] Silicon tetrachloride can also be reduced with hydrogen to give $SiHCl_3$ (equation 10).[98]

$$SiCl_4 + H_2 \xrightarrow{525-650\,^{\circ}C} SiHCl_3 + HCl \qquad (10)$$

The monohalo- and the dihalosilanes H_3SiX and H_2SiX_2 (X = Cl, Br or I) may be prepared by the reaction between silane and one or two equivalents of HX respectively, catalyzed by the corresponding aluminum halide (equation 11).

$$H_4Si + nHX \xrightarrow{AlX_3} H_{4-n}SiX_n + nH_2 \qquad (11)$$
$$n = 1 \text{ or } 2$$

The fluorosilane H_3SiF cannot be prepared in this way but is readily available by halogen exchange reactions from, for example, the reaction between SbF_3 and H_3SiCl. The other fluorohydrosilanes H_2SiF_2 and $HSiF_3$ are similarly prepared by treatment of the corresponding chloro or bromo compound with a metal fluoride, for example, heating $SiHCl_3$ with TiF_4 at 100 to 200 °C affords $SiHF_3$.[99]

The iodosilane H_2SiI_2 can be prepared by cleavage of the Si–Ph bonds in Ph_2SiH_2 with HI[100] or more conveniently by treating $PhSiH_3$ with I_2 (Scheme 16).[101] (Cleavage of $PhSiH_3$ with HBr or HI similarly gives H_3SiBr or H_3SiI.[102,103])

Aryl groups such as Ph, *p*-tolyl, and α-naphthyl are all readily cleaved from silicon by HX/AlX_3 to give a variety of halohydrodisilanes (Scheme 17).[104] Similarly, an extensive range of halotrisilanes including most of the possible isomers of Si_3X_7H, $Si_3X_6H_2$, $Si_3X_5H_3$ (X = Cl, Br or I), $Si_3I_4H_4$, $Si_3I_3H_5$, and $Si_3I_2H_6$, can be prepared by cleavage of the Si-aryl bonds of corresponding arylsilanes using HX. Detailed NMR spectroscopic studies of these compounds have been carried out.[105]

Compounds containing Si–H bonds generally react readily with halogens; SiH_4 with Cl_2 or Br_2 gives explosive reactions

$$PhSiH_3 + I_2 \xrightarrow[\text{ethyl acetate}]{-78\,^{\circ}C} PhSiH_2I + HI \longrightarrow H_2SiI_2 + C_6H_6$$

Scheme 16

$$\left.\begin{array}{r} PhH_2SiSiH_2Ph \\ Ph_2HSiSiHPh_2 \\ Ph_3SiSiH_3 \end{array}\right] \xrightarrow[HX]{AlX_3} \begin{array}{l} XH_2SiSiH_2X \\ X_2HSiSiHX_2 \\ X_3SiSiH_3 \end{array}$$
$$X = \text{Br or I}$$

Scheme 17

but the vigor of these reactions is ameliorated at low temperature, and H_3SiBr and SiH_2Br_2 may be isolated from such reactions (equation 12).[106,107]

$$SiH_4 + 2Br_2 \xrightarrow{-80\,^{\circ}C} SiH_2Br_2 + 2HBr \qquad (12)$$

The reaction of hydrogen halides with disilane gives halodisilanes but these, apart from IH_2SiSiH_3, tend to disproportionate. Reactions of the higher silanes with halogens also afford halohydrosilanes but such reactions are often accompanied by Si–Si bond cleavage; for example, the reaction of disilane with iodine gives not only H_3SiSiH_2I, $H_3SiSiHI_2$, and $H_2ISiSiIH_2$ but also SiH_2I_2 and $SiHI_3$ in significant yield.[108] For further details and discussion of this type of preparation, see MacDiarmid.[109,110] The triiodide can also usefully be prepared using the high reactivity of the Si–N bond, as shown in Scheme 18.[109,110]

The physical properties of some halohydrosilanes are shown in Table 4 and, as in the case of the perhydrosilanes, the compounds containing a small number of the lighter halogens

$$SiHCl_3 + 6H_2NPh \longrightarrow SiH(NHPh)_3 + 3PhNH_3Cl$$
$$\downarrow 6HI$$
$$SiHI_3 + 3PhNH_3I$$

are gases at room temperature and pressure while the others are liquids.

5.2.2 *Structure of Halohydrosilanes*

The molecular structures of several halohydrosilanes are known, and some of the structural parameters for them are shown in Table 5.

The structures of H_3SiF and H_3SiI in the solid state show clear intermolecular interactions. The molecules form chains (Figure 3), with both Si···F and Si···I distances being less than the sum of the respective van der Waals radii.[120]

5.2.3 *Reactions of Halohydrosilanes*

The halohydrosilanes disproportionate on heating as shown in Scheme 2 and react rapidly with protic reagents such as water, alcohols, and amines to give compounds containing Si–O and Si–N bonds, respectively. In the hydrolysis of such species the halogen is removed first (as HX) giving a hydroxysilane, for example, H_3SiOH, which then undergoes condensation to give a siloxane, for example, $H_3SiOSiH_3$, and finally the Si–H groups are hydrolyzed. Careful hydrolysis of Cl_3SiH affords a mixture of oligomeric silsesquioxanes of

Table 5 Structural data for halohydrosilanes

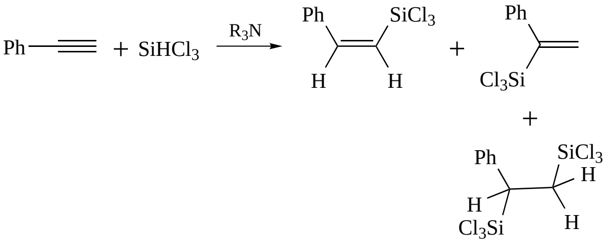
Scheme 19

general formula $(HSiO_{1.5})_n$ ($n = 4–7$),[121] the structures of which are described in Section 5.5.1.

One of the most widely studied of the reactions of trichlorosilane is its interaction with tertiary amines in acetonitrile to give appreciable concentrations of Cl_3Si^- in solution, as shown in Scheme 19.[122]

The silyl anion, Cl_3Si^-, has been widely studied and reacts with a variety of compounds. The Cl_3SiH/R_3N system allows additions to multiple bonds (insertion into the Si–H bond, equation 13) and the formation of organosilicon compounds via the hydrosilation reaction.[122]



(13)

The trichlorosilyl anion also reacts with organic halides in several ways, the simplest of which involves substitution of the halide by an $SiCl_3$ group (Scheme 20).[122]

Unfortunately, organic halides with three or more chlorines on the same carbon undergo more complicated reactions with Cl_3Si^- and tend to give $SiCl_4$ as the main silicon-containing product.[122] With carbonyl compounds a so-called 'reductive silylation' occurs, in which the carbonyl oxygen is lost from the organic compound and is substituted by a Cl_3Si group and an H (Scheme 21).

In the reaction of Cl_3Si^- with acid chlorides, two trichlorosilyl groups are introduced (equation 14); this probably proceeds via a two-step mechanism. The first step involves reductive silylation and loss of the carbonyl group; the second involves a halide displacement as above. These trichlorosilyl compounds may be further treated with Grignard

$$p\text{-}ClC_6H_4CH_2Cl + SiHCl_3 \xrightarrow{n\text{-}Pr_3N} p\text{-}ClC_6H_4CH_2SiCl_3$$

or lithium reagents to give tetraorganosilanes.[122]

$$MeCOCl + SiHCl_3 \xrightarrow[n\text{-}Pr_3N]{MeCN} MeCH(SiCl_3)_2 \qquad (14)$$

The strength of the Si–O (and the Si–S) bond and the stability of the Cl_3Si^- anion also allow the reduction of P^V to P^{III} compounds, S^{IV} to S^{II} compounds, and amine oxides to amines with either $Cl_3SiSiCl_3$ (or in some cases $SiHCl_3/R_3N$) in benzene or chloroform solution under mild conditions (Schemes 22 and 23).[123–126] The silicon-containing products are $SiCl_4$, $Cl_3SiXSiCl_3$ (X = O or S), and $(XSiCl_2)_n$ (X = O or S).

This type of reaction proceeds by a radical mechanism and the product distribution is very dependent on the R groups. Primary acetates give very predominantly ethers, secondary acetates give mixtures, and tertiary acetates give alkane as the exclusive product (Scheme 23).[127–129]

5.3 Tetrahalosilanes

The perhalosilanes X_4Si (X = F, Cl, Br, or I), the higher perhalosilanes, and compounds containing mixtures of halogens are all reactive compounds (as would be expected from the chemistry of the halohydrosilanes described above in Section 5.2.3) that hydrolyze readily to give HX in the atmosphere; they therefore require care in handling, preferably under a blanket of inert gas. The chloride Cl_4Si is by far the most widely used of these compounds and is available on a large scale.

5.3.1 Preparations of Perhalosilanes

The silicon tetrahalides SiX_4 may all be obtained by direct combination of the elements (equation 15). Silicon inflames in fluorine at room temperature to give SiF_4, but heating is required to bring about reactions with the other halogens; iodine vapor passed over silicon above 600 °C gives SiI_4. More conveniently, on a laboratory scale, cleavage of Si-aryl bonds may be used for synthesis, for example, reaction of $PhSiH_3$ with Br_2 affords $PhSiBr_3$, which when treated with $HBr/AlBr_3$ in benzene gives a near quantitative yield of $SiBr_4$.[130] A mixture of Cl_2 and Br_2 over Si at 700 °C affords the mixed halosilanes $SiCl_nBr_{4-n}$ (n = 1–3),[110] as do the pyridine catalyzed redistribution reactions between $SiCl_4$ and $SiBr_4$.[131]

$$Si + 2X_2 \longrightarrow SiX_4 \quad X = F, Cl, Br, or I \qquad (15)$$

Mixed tetrahalosilanes may be prepared by halogenation of a hydrohalosilane and by reaction of a tetrahalosilane with HX (Scheme 24). For example, $SiICl_3$ is formed from I_2 and $HSiCl_3$ and this subsequently reacts with the HI produced in the reaction to give SiI_2Cl_2.[132]

Redistribution reactions also readily occur, for example, mixtures of $SiCl_4$ and SiI_4 in the presence of pyridine afford

$$SiHCl_3 + I_2 \xrightarrow[\text{sealed bomb}]{250\,°C} SiICl_3 + HI \longrightarrow SiI_2Cl_2 + HCl$$

Scheme 24

statistical mixtures of $SiCl_nI_{4-n}$ ($n = 0$–4) under reflux at 61 °C.[133] Tetrafluorosilane reacts with $MgCl_2$ and $AlCl_3$ to give $SiCl_4$ and the mixed SiF_nCl_{4-n} ($n = 1$–3).[134] $HSiI_3$ undergoes halogen exchange reactions with, for example, $SiFBr_3$ to give $SiFBr_2I$, $SiFBr_2I$, $SiFBrI_2$, and $SiFI_3$.[135]

Hexafluorodisilane may be prepared by halogen exchange reactions of Si_2Cl_6 or Si_2Br_6 with a variety of metal fluorides but better yields (70–80%) may be obtained from the reaction between $(MeO)_3SiSi(OMe)_3$ and BF_3 in a sealed bomb at room temperature (equation 16).[136]

$$(MeO)_3SiSi(OMe)_3 + 6BF_3 \longrightarrow F_3SiSiF_3 + 6BF_2OMe \qquad (16)$$

The reaction of Si with SiF_4 at 1150 °C and low pressure gives $(SiF_2)_n$ polymer which, if heated under vacuum at 200 to 350 °C, breaks down to give perfluorosilanes Si_nF_{2n+2} where n is from 1 to 14 or more. The polymer is also broken down by aqueous HF to give silanes Si_nH_{2n+2} ($n = 1$–6).[137] The cleavage of Si_2F_6 with Br_2 affords SiF_3Br and SiF_2Br_2, while the fluorination of $SiBr_4$ with SbF_3 affords all three of the mixed halides.[138] Reaction of $[(MeO)_3Si]_2Si(OMe)_2$ with BF_3 in a sealed tube also gives $(F_3Si)_2SiF_2$ in a manner similar to equation (16).[139] Silicon tetraiodide when treated with silver powder at 208 °C gives I_3SiSiI_3.[140] The reaction between Si_2Cl_6 and Me_3N gives perchlorooligosilanes (equation 17), the exact product isolated, such as Si_5Cl_{12} and Si_6Cl_{14}, being dependent on the stoichiometry of the reagents used, and whether the volatile $SiCl_4$ formed as a coproduct is removed continuously from the reaction mixture.[141]

$$5Si_2Cl_6 + 0.1\%Me_3N \longrightarrow 4SiCl_4 + Si_6Cl_{14} \qquad (17)$$

This type of synthesis has clear advantages over the direct combination of elements method which gives complicated mixtures that need to be separated.[141] The higher perchlorosilanes $Cl_3Si(SiCl_2)_nSiCl_3$ ($n = 1$–6) can be prepared in low yield, along with $SiCl_4$, by passing chlorine over a mixture of $CaSi_2$ and $FeSi_2$ at 120 to 150 °C.[142] Perhalogenated silanes may also readily be made by cleavage of phenyl groups by HX/AlX_3, (X = Cl, Br or I) from either cyclic or acyclic perphenyl compounds (Scheme 25). The preparations and reactions of hydro- and halosilanes containing Si–Si bonds are discussed in more detail by Hengge.[143]

Straight chain perhalooligosilanes may also be prepared from the cyclic phenyl compounds by cleaving the ring first

$$(SiPh_2)_n + 2nHX \xrightarrow[n = 4\text{–}6]{AlX_3} (SiX_2)_n + 2nC_6H_6$$

$$Si_nPh_{2n+2} + 2n{+}2\ HCl \xrightarrow[n = 2,\ 5,\ \text{or}\ 6]{AlX_3} Si_nCl_{2n+2} + 2n{+}2C_6H_6$$

Scheme 25

with halogen and subsequently cleaving the Si–Ph bonds with HX/AlX_3 (equation 18).[144–146]

$$(SiPh_2)_n + X_2 \longrightarrow X(SiPh_2)_nX \xrightarrow{HX/AlX_3} X(SiX_2)_nX + 2nC_6H_6$$
$$X = \text{Br or I};\ n = 4 \text{ or } 5 \qquad (18)$$

The *neo*-pentasilane $(Cl_3Si)_4Si$ is formed along with $SiCl_4$, Si_2Cl_6, Si_3Cl_8, and Si_4Cl_{10} on mercury sensitized photolysis of Cl_3SiH[147] or by base-catalyzed disproportionation of Si_2Cl_6 or Si_3Cl_8 (Scheme 26).[141,148]

Ligand redistribution reactions occur when Si_2Cl_6 and Si_2Br_6 are heated together at 100 °C in a sealed tube, to give all of the mixed halodisilanes $Si_2Cl_nBr_{6-n}$ ($n = 1$–5). Unfortunately, the compounds cannot be separated by vacuum distillation because of further redistribution reactions. The mixed halide, $Br_3SiSiCl_3$, can be obtained pure by cleaving the Ph groups from $Cl_3SiSiPh_3$ using $HBr/AlBr_3$.[149] Reaction of $BrSiCl_3$ with the very hindered aryllithium reagent 2,4,6-*t*-$Bu_3C_6H_2Li$ at −78 °C leads to lithium/halogen exchange and formation of $LiSiCl_3$, which has a surprisingly long half-life at room temperature in THF/Et_2O of about 62 h. Little seems to have been done with $LiSiCl_3$, which could be a valuable reagent for the introduction of Cl_3Si groups.[150]

The tetrasilanes (**3**) react with *t*-Bu_2Hg to give the corresponding silylmercury derivatives, which break down on photolysis to give octasilanes (Scheme 27).[151]

5.3.2 *Reactions of Perhalosilanes*

Silicon halides (especially the readily available chlorides) are probably the most synthetically useful and versatile monomeric inorganic silicon compounds. They may readily be reduced to hydrides, hydrolyzed to silanols (and subsequently to siloxanes), treated with other protic species such as alcohols, carboxylic acids, amines, and thiols to give Si–OR, Si–OC(O)R, Si–NR_2, and Si–SR species respectively, used to make silyl pseudohalogen derivatives by treatment with silver or alkali metal salts, for example, treated with sodium

derivatives of Group 15 elements to give Si–N, Si–P, or Si–As containing compounds, and form a wide range of adducts with amines, phosphines, and so on. They are also one of the main starting materials used for the formation of organosilicon compounds by using, for example, Grignard or organolithium compounds (*see* ***Silicon: Organosilicon Chemistry***). The reduction of silicon halides to give silicon hydrides is discussed in Section 5.1.1 and the reactions of halosilanes to give compounds containing Si–O and Si–N bonds are found in Sections 5.5.1 and 5.6.1.

All of the SiX_4 tetrahalides except the fluoride hydrolyze rapidly to give hydrated silica; the fluoride also undergoes partial hydrolysis but also forms the hexafluorosilicate ion (equation 19).

$$2SiF_4 + 2H_2O \xrightarrow{H_2O} SiO_2{\cdot}nH_2O + SiF_6^{2-} + 4H^+ + 2F^- \quad (19)$$

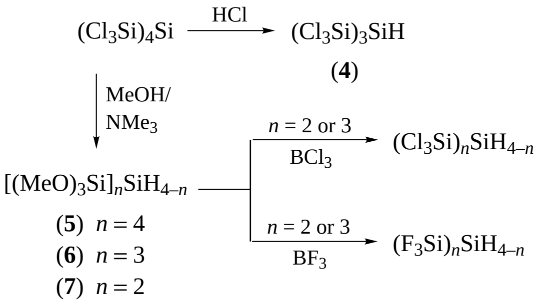
Careful hydrolysis of $SiCl_4$ at −78 °C affords $(Cl_3Si)_2O$ and higher chlorinated siloxanes, $Cl_3Si(OSiCl_2)_nOSiCl_3$ (n = 1−5), as high boiling liquids.[152] These are formed by initial formation of Cl_3SiOH which rapidly condenses to give the disiloxane $(Cl_3Si)_2O$ which may react further with Cl_3SiOH to give the higher siloxanes. $(Cl_3Si)_2O$ may also be prepared by the reaction of $SiCl_4$ with O_2 at 960 to 990 °C.[153] The cyclic dimer $(Cl_2SiO)_2$ is not formed, unlike the S analog. The passage of a mixture of Br_2 and O_2 over Si at 700 °C affords bromosiloxanes such as $(Br_3Si)_2O$ and $(Br_2SiO)_4$; they are also formed on treatment of $SiBr_4$ with O_2 at 670 to 695 °C.[154] Reaction of $SiCl_4$ with H_2S at 900 to 950 °C affords Cl_3SiSH which can be distilled (unlike its oxygen analog Cl_3SiOH) at 95 °C at atmospheric pressure. The pure thiol does undergo condensation at high temperature to give $(Cl_3Si)_2S$, the cyclic compound $(Cl_2SiS)_2$, and $(SiCl_2S)_n$ polymer.[155] The reaction between $SiCl_4$ and AgS at 230 to 250 °C also affords $(Cl_3Si)_2S$.[156] The reaction between $SiCl_4$ and NEt_4SH affords $NEt_4[SiSCl_3]$, which contains four-coordinate near-tetrahedral $SiCl_3S$ units.[157]

The higher chlorosilanes, like $SiCl_4$, all hydrolyze readily and react with protic species; for example, $(Cl_3Si)_2SiCl_2$ reacts with $MeOH/Et_3N$ to give $[(MeO)_3Si]_2Si(OMe)_2$ and with Me_2NH to give $[(Me_2N)_3Si]_2Si(NMe_2)_2$.[158] The *neo*-pentasilane $(Cl_3Si)_4Si$ reacts with HCl to give the tetrasilane (**4**) and with MeOH to give (**5**) or (**6**) and (**7**) depending on the reaction conditions (Scheme 28). Compounds (**6**) and (**7**) react with BCl_3 or BF_3 to afford the corresponding halosilanes.[159–161]

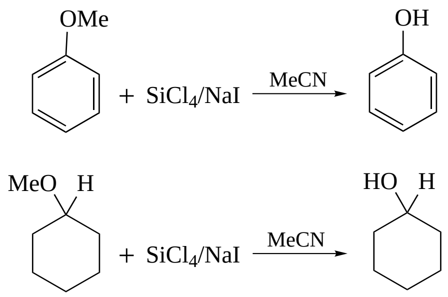
The formation of the strong Si–O bond and an insoluble product (silica) occurs in the reaction between $SiCl_4$ and amines and acids to give amides (equation 20).[162]

$$2RCO_2H + 2R'NH_2 + SiCl_4 \longrightarrow 2RCONHR' + (SiO_2)_n + 4HCl$$
$$RR' = \text{MePh, PhPh, etc.} \quad (20)$$

The reaction of $SiCl_4$ with NaI in acetonitrile gives Cl_3SiI (Scheme 29), which is used in situ to cleave ethers to give (after hydrolysis of the initially formed silyl ether) alcohols and phenols.[163]

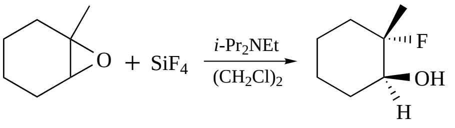


Scheme 28



Scheme 29

Silicon tetrafluoride reacts with epoxides in the presence of a tertiary amine to give fluorohydrins by a mechanism that probably involves five- or six-coordinate silicon species (equation 21).[164] The ionization of SiF_4 by electron impact affords $SiF_x^{+\bullet}$ (where x = 1, 2, or 3), which can form clusters with neutral SiF_4 and react with a range of small inorganic molecules.[29,165]



(21)

5.3.3 *Structures of Perhalosilanes*

The simple tetrahalides SiX_4 are tetrahedral, and bond lengths increase as the halogen gets larger. Some structural details for perhalosilanes are given in Table 6.

5.4 Silyl Pseudohalides

As might be expected, the silyl pseudohalides have chemical properties similar to the silyl halides although the structures of the pseudohalides have been studied in more detail and have been shown to be both interesting and novel.

Table 6 Structural data for tetrahalosilanes

Compound		Si–X (Å)	Method[a]

[a]E = electron diffraction; M = microwave; X = X-ray diffraction.
[b]For a discussion of the crystallization of SiI_4 see Kihara.[172]

5.4.1 Silyl Isocyanates and Isothiocyanates

Silyl isocyanates can readily be prepared by treatment of chlorosilanes (bromo- or iodosilanes would also work but are less readily available) with metal cyanates. With simple halosilanes the product is always the isocyanate isomer although in the case of highly sterically hindered organosilanes, normal cyanates (which thermally isomerize to isocyanates) may be formed using silver cyanate.[173] Thus $Si(NCO)_4$ is formed from the reaction between $SiCl_4$ and KOCN in liquid SO_2, AgOCN in C_6H_6, or $Pb(OCN)_2$ in C_6H_6.[174,175] Similarly, $Si(NCS)_4$ is formed in the reaction between $SiCl_4$ and a variety of thiocyanate salts (equation 22).[176] The Si–N bonds in $(H_3Si)_3N$ are cleaved by HOCN and HSCN to give H_3SiNCO and H_3SiNCS, respectively, providing a route to these compounds that does not involve metal salts.[177]

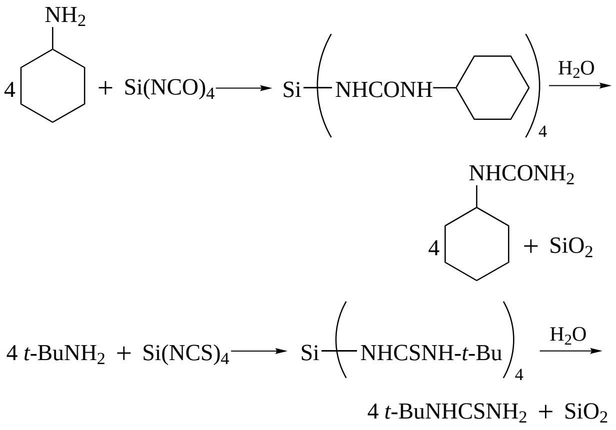
$$SiCl_4 + NH_4SCN \xrightarrow{C_6H_6} Si(NCS)_4 + 4NH_4Cl \qquad (22)$$

Treatment of $HSiCl_3$ with silver or potassium salts also gives $Si(NCE)_4$ (E = O or S) together with the expected $HSi(NCE)_3$ species, which are prepared in greater yield from $HSiI_3$ and the silver salts.[178] As in the case of the perhalo compounds, the pseudohalides also undergo redistribution reactions (Scheme 30).[179]

$$4SiHCl_3 + 3Si(NCO)_4 \xrightarrow[100\ °C]{4\ days} HSiCl_n(NCO)_{3-n} + H_2SiCl_2 + H_2SiCl(NCO), etc.$$
$$n = 0\text{–}3$$

$$SiCl_4 + Si(NCO)_4 \xrightarrow{600\ °C} SiCl_n(NCO)_{4-n}$$
$$n = 0\text{–}4$$

Scheme 30



Scheme 31

The structures of the silyl species H_3SiX (X = NCO, NCS, N_3) have been examined in detail in electron diffraction and microwave spectroscopic studies. The microwave spectra of H_3SiNCO and H_3SiNCS suggest that the Si–N=C=O and Si–N=C=S linkages are linear, but electron diffraction studies show molecules that are bent at N. These data combined suggest that the ground state is linear but that the molecules are readily deformed, and in the gas phase at room temperature they spend most of their time bent.[120] In the solid state, the Si–N=C angle is 158° but this bent geometry appears to be due to weak but well-defined intermolecular Si···N interactions.[120] The structures of a range of silyl pseudohalides H_3SiR (R = N_3, NCO and NCS) have also been calculated, the results comparing well with those from experimental determinations (where these have been carried out) of the structures.[180–182] The linear (or near linear) arrangement in the silyl-isocyanate and -isothiocyanate has been attributed to p_π–d_π bonding involving the 3d orbitals of the silicon. The molecular structure of F_3SiNCO (prepared by passing F_3SiBr over AgOCN) in the gas phase also shows a bent Si–N=C angle of 160.7°.[183] The mixed halides/pseudohalides $SiCl_n(NCO)_{4-n}$ ($n = 1$–3) (prepared by heating a mixture of $SiCl_4$ and $Si(NCO)_4$) also have bent Si–N=C groups of 138, 136, and 145° for $n = 3$, 2, and 1, respectively.[184] The related disilyl species H_3Si–N=C=N–SiH_3 has a near linear Si–N=C=N–Si linkage, rather than the cyanamide structure $(H_3Si)_2NCN$.[185]

Isocyanates and isothiocyanates both react with water in a manner similar to the halosilanes to give hydrated silica. They also react with primary and secondary amines to give silylamines which, on hydrolysis, afford *N*-mono- and *N*,*N*-disubstituted ureas and thioureas (Scheme 31), which is a useful synthesis of these compounds.[186]

5.4.2 Silyl Cyanides and Isocyanides

The structure of H_3SiCN (prepared from H_3SiBr + AgCN) has been studied in detail. The gas-phase structure shows an

H–Si–C angle of 108.6° and in the solid phase 100.4° while the Si–C–N angle is linear and there are short intermolecular Si···N distances, indicating a donor–acceptor interaction which gives an almost linear chain formation that is not seen in the carbon analog, CH_3CN.[120,187]

Although the OCN and SCN groups are normally iso when attached to silicon, the CN group is usually attached via the carbon. However, the reaction between F_3SiBr or F_3SiI and AgCN affords both F_3SiCN and the silyl isocyanide F_3SiNC.[188] The reaction of the sterically hindered chlorosilane $(t\text{-BuO})_3SiCl$ with tetraethylammonium cyanide (equation 23) also affords a mixture of both the normal cyanide and the isocyanide, containing amounts of up to 6.5% of the latter. At 25 °C the equilibrium mixture contains 1.1% of the isocyanide isomer, apparently the only system that contains an appreciable amount of an isocyanide. The IR stretching frequencies for the C≡N and N≡C compounds are 2198 and 2103 cm^{-1}, respectively.[189]

$$(t\text{-BuO})_3SiCl + [Et_4N][CN] \xrightarrow{\text{MeCN}} (t\text{-BuO})_3SiCN + (t\text{-BuO})_3SiNC \quad (23)$$

5.4.3 *Silyl Azides*

The azide derivatives of silicon are generally more stable than organic azides although they may detonate on heating and should be handled with care. Silyl azides may be prepared by several routes (Scheme 32), the most important being hydrazoic acid cleavage of an Si–N bond and (in a manner similar to the other silyl pseudohalogens) by treatment of a silyl chloride with a metal azide.[190] In H_3SiN_3 the Si–N–N angle is about 127°.[191,192]

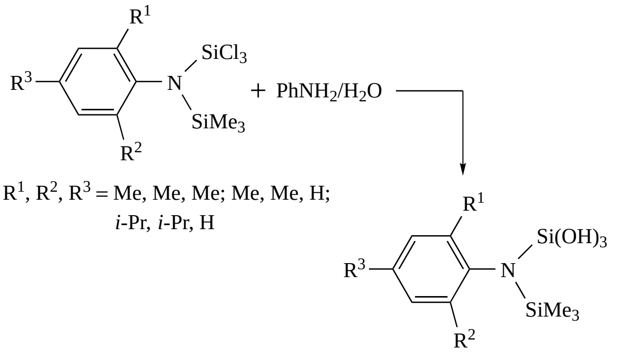
5.5 Silicon–oxygen Compounds

Although a significant fraction of the Earth's crust comprises material containing SiO_4 structural units arranged in three-dimensional arrays, the uses of discrete monomeric $Si(OR)_4$ species have only been widely studied since about the 1950s. Along with the chlorosilanes, the alkoxysilanes and siloxanes are very useful and widely available compounds that are produced in large quantities.

5.5.1 *Silanols and Siloxanes and Their Sulfur, Selenium, and Tellurium Analogs*

The propensity of silicon and oxygen to form materials in which the Si and O atoms alternate to form a polymer causes practical problems when preparations of small molecules containing the SiOH group are undertaken. Thus H_3SiOH, $H_2Si(OH)_2$, $HSi(OH)_3$, and H_3SiSiH_2OH have not been isolated in a pure form. The products obtained in attempted preparations of such species are invariably siloxanes owing to the condensation reaction that takes place very readily between two or more silanol molecules (Scheme 33). Hydrolysis of an $SiCl_3$ group attached to a transition metal may however lead to a stable $Si(OH)_3$ group (see Section 7 concerning transition metal complexes); also a wide variety of organosilanols $R_nSi(OH)_{4-n}$ ($n = 1–3$; R = alkyl or aryl) are known where the steric effect of the R groups tends to hinder condensation reactions.[193]

The use of large, nitrogen-centered substituents at a silanetriol center does allow the isolation and characterization of stable silanetriols as shown in equation (24). These compounds can be used to prepare transition metal siloxide complexes (Scheme 34), still containing potentially moisture-sensitive Si–N bonds that may be precursors to metal-containing ceramics; for reviews of these compounds, see References 193–195.



(24)

The wide range of silicon compounds that are readily hydrolyzed means that the siloxane $H_3SiOSiH_3$ is formed (probably via H_3SiOH) in numerous reactions (Scheme 35).[196]

Similarly, hydrolysis of halodisilanes tends to give siloxane rather than silanol products (Scheme 36).[196]

The compounds $(HSiO_{1.5})_n$ with $n = 4–7$ may, however, be isolated from the careful hydrolysis of Cl_3SiH. Figure 4 shows their polyhedral nature, which also suggests their other name of 'spherosiloxanes'.[121,197] The octasiloxane $(HSiO_{1.5})_8$ may be fully chlorinated to give $(ClSiO_{1.5})_8$, from which the methoxy derivative $(MeOSiO_{1.5})_8$ may be prepared by

$$(H_3Si)_3N + 4HN_3 \xrightarrow{n\text{-Bu}_2O} 3H_3SiN_3 + NH_4N_3$$
$$SiCl_4 + 4MN_3 \longrightarrow Si(N_3)_4 + 4MX$$

treatment with MeONO.[198] For the case of $n = 14$ two isomers, one of D_{3h} and one of C_{2v} symmetry, have been structurally characterized (Figure 5).[199] Larger silicates are treated elsewhere; reviews of the chemistry, preparation, and structures of the oligosilsesquioxanes are available.[200–202]

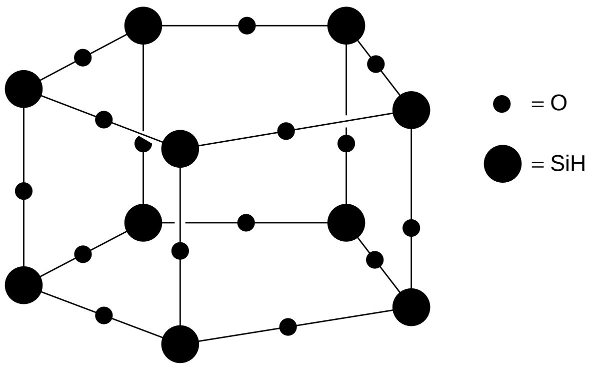

Figure 4 D_{5h} isomer of $(HSiO1.5)n$ for $n = 5$

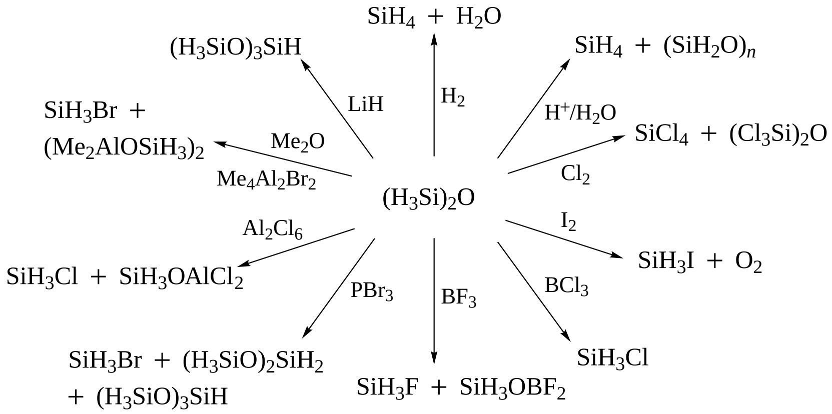
The reactions of $(H_3Si)_2O$ fall into two general classes: those that proceed with Si–O bond cleavage, usually promoted by Lewis acids, and those that lead to condensation reactions, usually promoted by Lewis bases. Typical reactions are shown in Scheme 37.[196]

The preparation of the perchlorosiloxanes $Cl_3Si(OSiCl_2)_n$-$SiCl_3$ ($n = 0-5$) has been discussed above in the halosilanes section. The highly reactive Cl_3SiOH may, however, be generated by photochemical oxidation of $SiHCl_3$ by O_2 or O_3 at low temperature in either an argon matrix or



Scheme 37

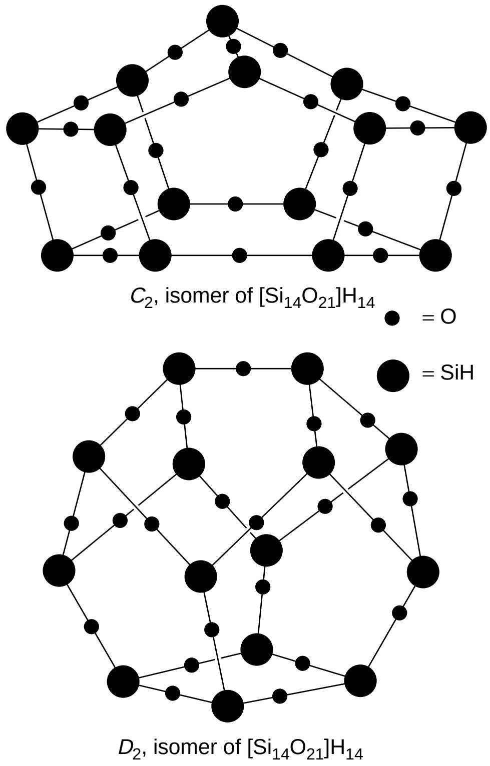


Figure 5 Structures of large spherosiloxanes

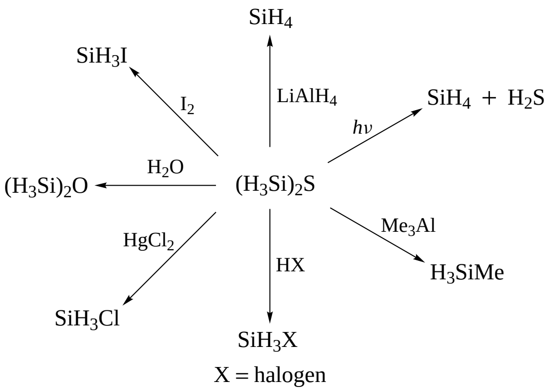
in $SiCl_4$. The compound cannot be isolated but is stable in dilute solution for several days.[203,204] Hydrolysis of H_3SiBr affords $H_3SiOSiH_3$, while reaction between H_3SiI and HgS, $Li[Al(SeH)_4]$ or Ag_2Se, and Li_2Te affords $(H_3Si)_2E$ (E = S, Se, and Te), respectively.[205–207] The lower disilyl chalcogenides hydrolyze to give $(H_3Si)_2O$ as shown, for example, in equation (25).[208]

$$(H_3Si)_2Se + H_2O \longrightarrow (H_3Si)_2O + H_2Se \qquad (25)$$

The reaction between Cl_3SiH or Cl_2SiH_2 and sulfur affords thiols such as Cl_3SiSH.[209,210] Disilyl sulfide undergoes a variety of reactions as shown in Scheme 38.[196]

The Si–O–Si angle in $(H_3Si)_2O$ in the solid phase is unusually wide at 144.1° (144° in the gas phase) for an sp^2 hybridized atom, but this is similar to other siloxanes, and again has been proposed to reflect p_π–d_π bonding between Si and O.[196] As in the simple silyl halides, there are close nonbonded intermolecular interactions in the siloxane with an Si···O distance of 3.05 Å and an O–Si–O angle close to 180°, giving a chain structure.[120] The bond shortening and wide Si–O–Si angles in siloxanes have been attributed to p_π–d_π interaction but molecular orbital calculations have suggested that these structural features are, in fact, the product of the unusually high ionic character of the Si–O bond, and that p_π–d_π bonding is of relatively little importance.[211] A useful discussion of the contributions of the bonding possibilities (p_π–d_π, Si–C σ^* interactions with Si–X bonds, and ionic factors) proposed for Si–X bonds (X = electronegative element) can be found in Reference 212. The solid-state structures of $(H_3Si)_2S$ and $(H_3Si)_2Se$ show angles at the chalcogen of 98.4 and 95.7°, respectively. As



Scheme 38

for the oxygen analog, there are distinct though weaker intermolecular Si···S (or Se) interactions. However, in the siloxane case only, one silicon from each molecule is involved in intermolecular interactions, while in the S and Se analogs, both silicons show nonbonded interactions with the chalcogen giving all silicons five-coordination and the S and Se atoms tetrahedral coordination.[213]

The reaction of $(H_3Si)_2O$ with BX_3 (X = F or Cl) affords H_3SiOBX_2. These compounds together with other X_3SiOBX_2 species (X = H, F, or Cl) have had their structures calculated by MNDO methods. The compounds split into two types, one in which the Si–O–B angle is in the range from 140 to 152° (for X_3SiOBH_2 (X = H, F or Cl) and H_3SiOBF_2) and the second in which the Si–O–B angle is 180° ($X_3SiOBCl_2$ (X = H, F or Cl) and F_3SiOBF_2).[214]

Silanethiols are much more stable towards condensation reactions than their oxygen counterparts and may be isolated from insertion reactions of Si–H containing compounds with S at high temperature or by high-temperature reactions with H_2S (Scheme 39).[209,210]

The disilyl chalcogenides $(H_3Si)_2E$ (E = S, Se, Te) may be prepared from Li_2E and H_3SiBr. In the presence of H_2E an equilibrium is set up with H_3SiEH species (Scheme 40).[215]

$$X_3Si{-}H + S \xrightarrow{85\text{–}350\,^\circ C} X_3SiSH$$

$$Cl_3Si{-}H + S \xrightarrow{690\,^\circ C} Cl_3SiSH + H_2$$

$$Cl_2SiH_2 + S \xrightarrow{190\,^\circ C} HCl_2SiSH + Cl_3SiSH, \text{etc.}$$

E = S, Se, or Te

Scheme 40

5.5.2 Siloxene

Siloxene is the name given to several materials that are prepared by the action of aqueous hydrochloric acid on calcium silicide, $CaSi_2$. Two main types of siloxene are available, the so-called 'Wohler' and 'Kautsky' materials named after the chemists who carried out the original preparations. The siloxenes are prepared as shown in equations (26) and (27), and the structures, that have been the subject of much discussion, are now thought to be as shown in Figure 6. The preparations are carried out in the dark and under argon as the siloxenes are both photosensitive and can be oxidized, the Wohler material being a bright yellow, layered material and the Kautsky material being grayish-green. The effects of the reaction conditions on rate of formation of siloxene have been investigated in detail.[216] The recent interest in siloxene has arisen because it exhibits a strong yellow-green photoluminescence, unlike crystalline silicon which does not emit visible light because of its small indirect bandgap. The presence of siloxene contamination in porous silicon has also been suggested to account for the strong visible photoluminescence from porous silicon. A large number of studies on the electronic and optical properties of siloxene have been published; see References 217–220 and references therein.

$$3CaSi_2 + 6HCl + x\,H_2O \xrightarrow{0\,^\circ C,\ 3\,h} Si_6H_{6-x}(OH)x + 3CaCl_2 + x\,H_2 \quad (26)$$

$$3CaSi_2 + 6HCl + x\,H_2O \xrightarrow{EtOH,\ 0\,^\circ C,\ 6\,h} Si_6H_6O_{2x/2} + 3CaCl_2 + x\,H_2 \quad (27)$$

5.5.3 Silicon Chalcogenides: SiS_2, $SiSe_2$, and $SiTe_2$

The disulfide, SiS_2, and the diselenide and $SiSe_2$, are isostructural in the crystalline phase and have the form of chains of edge-sharing distorted SiS_4 or $SiSe_4$ tetrahedra with Si–S and Si–Se bond lengths of 2.133 and 2.275 Å, respectively.[221] The structure of glassy $SiSe_2$ has been investigated by solid-state ^{29}Si NMR spectroscopy, which suggests that three Si environments are present (analogous to SiS_2) that differ in the number of edge-sharing tetrahedra involving each Si; these are shown in Figure 7.[222–224] Unlike SiO_2, SiS_2, $SiSe_2$, and $SiTe_2$ hydrolyze rapidly in air.[111]

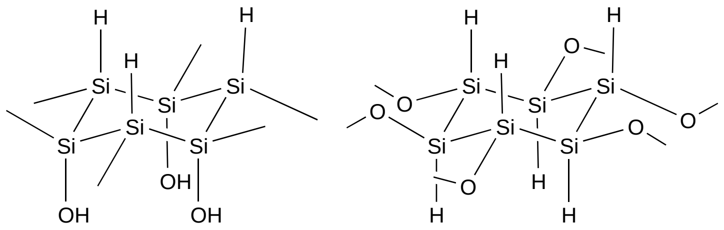

Figure 6 Structures of siloxene materials

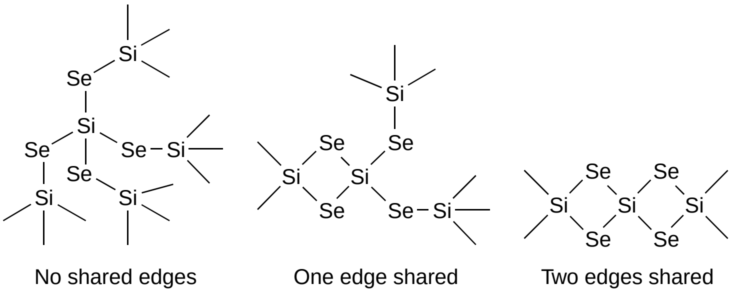

Figure 7 Silicon environments in glassy $SiSe_2$

5.5.4 *Silyl Alkoxides, Phenoxides, and Their Sulfur Analogs*

Simple $(RO)_4Si$ compounds may readily be prepared by the reaction between a chlorosilane and an alcohol (or phenol) (Scheme 41). A problem in this type of reaction is that the HCl formed may cause unwanted side reactions. This may be minimized by blowing dry N_2 gas through the reaction mixture or heating the reaction so that HCl is driven off as it is formed, or a tertiary amine such as pyridine may be added to the reaction, which forms an amine hydrochloride salt that precipitates to remove the HCl.[225] Silicon alkoxides may also be made by reaction of a silicon halide and an alkali metal alkoxide (Scheme 41).[226]

The reaction between $Pb(SR)_2$ (R = Me, Et, or Ph) and $SiCl_4$ affords $Si(SR)_4$. If a deficiency of lead salt is used, partially substituted species such as $Cl_nSi(SEt)_{4-n}$ ($n = 1-3$) may be obtained which may subsequently be reduced by $LiAlH_4$ to give $H_nSi(SEt)_{4-n}$ compounds.[227]

A further method for the preparation of alkyl silicates involves using mineral silicates that contain discrete silicate anions such as SiO_4^{4-} in γ-Ca_2SiO_4 or $Si_2O_7^{6-}$ in $Ca_2ZnSi_2O_7$ (hardystonite) rather than polymeric silicate networks. The anions are protonated and then treated with alcohol to form alkoxysilanes (Scheme 42). This method removes the energy intensive formation of elemental Si (see Section 2) but unfortunately does not give particularly good yields. Alkoxysilanes $(RO)_3SiH$ and $(RO)_4Si$ (R = Me, Et, n-Pr) are also formed in low yield from the direct reaction between Si/Cu alloy and ROH at 260–300 °C.[228]

An unfortunate side reaction in the conversion of $SiCl_4$ to $Si(OR)_4$ is that between the liberated HCl and the alcohol

$$SiHCl_3 + 3ROH \xrightarrow{\text{pyridine}} HSi(OR)_3 + 3py{\bullet}HCl$$

$$SiBr_4 + 3NaO\text{-}t\text{-}Bu \xrightarrow{70\,°C} BrSi(O\text{-}t\text{-}Bu)_3 \xrightarrow[\text{NaO-}t\text{-Bu}]{220\,°C} Si(O\text{-}t\text{-}Bu)_4 + NaBr$$

Scheme 41

$$SiO_4^{4-} + 4H^+ + x\,ROH \longrightarrow Si(OH)_4{\bullet}x ROH \xrightarrow{4ROH} Si(OR)_4 + 4H_2O + x\,ROH$$

Scheme 42

to give an alkyl chloride. This is particularly pronounced in the case of MeOH and higher alcohols such as isopropyl and butyl. (It should be noted that methoxysilanes such as $Si(OMe)_4$ are eye irritants and should be handled with care.) A more convenient route to such alkoxysilanes is via transesterification using $(EtO)_4Si$ (equation 28).

$$Si(OEt)_4 + 4MeCO_2Pr \longrightarrow Si(OPr)_4 + 4MeCO_2Et \qquad (28)$$

The preparation of mixed alkoxysilanes may be achieved by, for example, treating $SiCl_4$ with two equivalents of EtOH to give $(EtO)_2SiCl_2$ and then with a second alcohol to give $(EtO)_2Si(OR)_2$. Aryl oxides do not suffer so readily from the reaction between ArOH and HCl and may easily be prepared from $SiCl_4$ and an appropriate phenol. The simplest phenoxysilane, $(PhO)_4Si$, is remarkable in that it may be distilled in air at over 400 °C. Careful hydrolysis of $Si(OR)_4$ affords silicate anions such as $Si_2O_7^{6-}$, and $Si_3O_{10}^{8-}$, and so on, or they may be formed during the reaction of an alcohol with $SiCl_4$ owing to the presence of some water. By analogy with $SiCl_4$, the reaction between $(Cl_3Si)_2O$, $Cl_3SiO(SiCl_2)OSiCl_3$, or $Cl_3SiSiCl_3$ with anhydrous alcohol gives $[(RO)_3Si]_2O$, $(RO)_3SiO[Si(OR)_2]OSi(OR)_3$, and $(RO)_3SiSi(OR)_3$, respectively.

The hydrolysis of $(EtO)_4Si$ (and the subsequent polycondensation of Si–OH containing molecules) has been the subject of considerable investigation because of its importance in the fabrication of glasses and colloidal silica via the sol–gel process (*see* ***Sol–Gel Synthesis of Solids***). Hydrolysis of the Si–O bond in alkoxysilanes is also very widely used to attach silicon compounds to surfaces and in coupling reactions.[229,230] The fundamental reaction types involved in the formation of polymeric silica materials (via, for example, cyclic oligomers similar to those shown in Figures 4 and 5) from monomeric $(RO)_4Si$ compounds are shown in Scheme 43.

$$(RO)_3Si{-}OR + H_2O \xrightleftharpoons{\text{hydrolysis}} (RO)_3Si{-}OH + ROH$$

$$(RO)_3Si{-}OR + HO{-}Si(OR)_3 \xrightleftharpoons{\text{alcohol condensation}} (RO)_3Si{-}O{-}Si(OR)_3 + ROH$$

$$(RO)_3Si{-}OH + HO{-}Si(OR)_3 \xrightleftharpoons{\text{water condensation}} (RO)_3Si{-}O{-}Si(OR)_3 + H_2O$$

Overall process

$$(RO)_4Si + 2H_2O \longrightarrow SiO_2 + 4ROH$$

Scheme 43

The reaction rates, the importance of various intermediates, and the properties of the end product of hydrolysis are highly dependent on the presence of catalysts (e.g., mineral acids or ammonia), the steric and inductive effects of the R groups, the water:alkoxysilane ratio, and the solvent. These factors together with a mechanistic analysis of the reaction have been discussed in detail.[231–234] In recent years, the hydrolysis of a wide range of compounds of the general form $RSiOR^1_3$ (where R = an organic group and R^1 = Me or Et) has been used to prepare organically modified silicas (ORMOSILs) which have a variety of interesting properties.[235]

Alkoxysilanes react with organometallic reagents such as Grignard reagents and organolithium compounds to give organosilicon compounds (*see* ***Silicon: Organosilicon Chemistry***) (Scheme 44) in a manner similar to the halosilanes. These reactions are, however, slower and less vigorous and are useful starting materials in the production of organosilanes.

Alkoxysilanes may be converted back to chlorosilanes by treatment with, for example, PCl_5 or $AlCl_3$, and they react with carboxylic acids RCO_2H to give esters $(RCO_2)_4Si$. Disilyl sulfide, $(H_3Si)_2S$, reacts with MeOH or PhOH to give $MeOSiH_3$ and $PhOSiH_3$, respectively.[236,237] The Si–O–C angles are 120.6(9) and 121(1)°, respectively, somewhat lower than in disilyl ether. The structure of $MeOSiF_3$ prepared by the route shown in equation (29) has also been investigated and has an Si–O–C angle of about 132°.[238]

$$SiCl_4 + MeOH \longrightarrow MeOSiCl_3 \xrightarrow{SbF_3} MeOSiF_3 \qquad (29)$$

The structures of these compounds and related materials have been discussed.[239] The structure of $(MeO)_4Si$ is of S_4 symmetry with an Si–O–C angle of 122.3°. As in $MeOSiF_3$, the Si–O bond length is shorter than normal owing to several electronegative substituents being present.[240]

$$2RMgX + (RO)_4Si \longrightarrow R_2Si(OR)_2 + 2MgXOR$$
$$4RLi + (RO)_4Si \longrightarrow R_4Si + 4ROLi$$

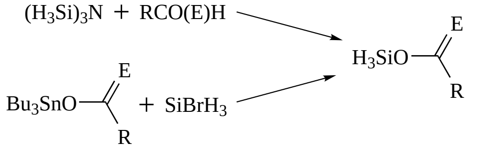
Scheme 44

5.5.5 *Silyl Esters and Thioesters*

Silyl esters may be formed using a variety of preparative routes as shown in Scheme 45.

Compounds containing both alkoxy and ester groups, $(RO)_nSi[(CO(O)R]_{4-n}$, may be made by redistribution reactions involving $Si(OR)_4$ and $(RCO)_2O$. Alkoxysilanes, $(RO)_4Si$, may also be prepared by passing dimethyl or diethyl carbonate over SiO_2/KOH at 500–600 K.[241] Silyl esters, $H_3SiO(C{=}O)R$, may also be prepared in the gas phase by reaction between $(H_3Si)_3N$ and RCO_2H or by reaction of H_3SiBr with n-$Bu_3SnO(C{=}O)R$ (R = H, Me, CF_3 etc.). The thioacetate $H_3SiO(C{=}S)Me$ has also been prepared by the butyltin method.[242] Short intermolecular distances are also found in $H_3SiO(C{=}E)Me$ (E = O or S), where zig-zag chains are formed in the solid state via Si···(E=C) interactions. The H_3Si group is *cis* to the carbonyl oxygen in both the solid and vapor phase.[120]

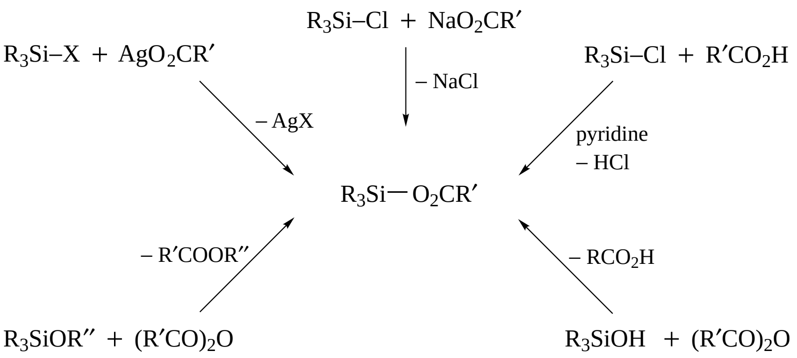
Silicon tetraacetate may be prepared by the reaction between $SiCl_4$ and acetic anhydride[243] and has a structure comprising discrete molecules with no bridging by acetate, although there is one short intramolecular distance between a carbonyl oxygen and the silicon in each molecule.[244,245] Silyl esters, $H_3SiOC(O)R$ (R = H, He, CF_3, etc.), and the thioacetate $H_3SiOC(S)Me$ may be prepared by either gas-phase reaction of $(H_3Si)_3N$ with organic acids or from H_3SiBr and tributyltin acetate, equation (30).[242,246] Treatment of $LiSeSiH_3$ with MeC(O)Cl affords the analogous selenoacetate $H_3SiOC(Se)Me$, which is in equilibrium with its isomer $H_3SiSeC(O)Me$[247] while the difunctional $H_2Si(OCOH)_2$ may be prepared from H_2SiBr_2 and $Bu_3SnOCOH$.[248]



(30)

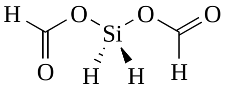
E = O or S

The structures of $H_3SiOCOH$ and $H_2Si(OCOH)_2$ have been determined in the gas phase.[242,249] In the monoformate the Si–O–C angle is 116.8° and the H_3Si group is twisted

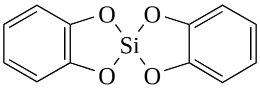


Scheme 45

away from a planar cis arrangement by 21°. The diformate has an Si–O–C angle of 120.4° with one formate group in a cis and one in a trans arrangement about the Si–O bond, as shown in (**8**).

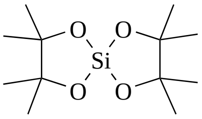


(**8**)

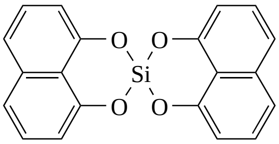


(**9**)

The reaction between catechol and Si/Cu alloy at high temperature and pressure affords the spiro compound (**9**) as a glassy white material.[250] The structure of (**9**) has been the subject of some dispute. Although it was originally thought to have a planar geometry at silicon this has not been confirmed, and it is likely that it has a normal tetrahedral arrangement as found in the related (**10**) and (**11**).[251,252]

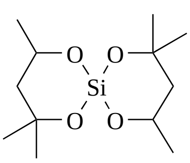


(**10**)

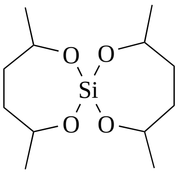


(**11**)

Compound (**10**) and the related spirocyclic compounds such as (**12**) and (**13**) may be conveniently prepared from the reaction between $(EtO)_4Si$ and a 1,2-, 1,3-, or 1,4-diol in the presence of a catalytic amount of metal alkoxide such as NaOMe or $(i\text{-PrO})_4Ti$.[253]



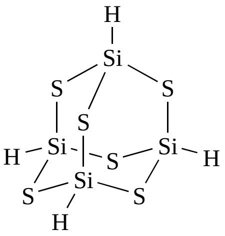
(**12**)



(**13**)

Tris(thioalkyl)silanes may be prepared by reaction between Cl_3SiH and thiols in a manner similar to the preparation of alkoxysilanes and are useful reagents for radical reductions of alkyl halides or alkenes in organic chemistry (Scheme 46).[254]

The reactions between $(H_3Si)_2E$ (E = S or Se) and H_2SiCl_2 or $HSiCl_3$ (Scheme 47) afford an interesting series of compounds containing several Si to chalcogen bonds such as $(HSi)_4S_6$ (**14**), which was found to have an adamantane-type structure.[255]



(**14**)

The reaction between $(CH_2SNa)_2$ and $SiCl_4$ gives the spirocyclic (**15**), which has a distorted tetrahedral arrangement

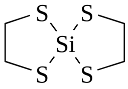
$$SiHCl_3 + 3RSH \xrightarrow{\text{pyridine}} (RS)_3SiH + 3py{\cdot}HCl$$
$$(RS)_3SiH \xrightarrow{\text{AIBN}} (RS)_3Si^{\bullet}$$
$$\text{radical reductions} \longleftarrow (RS)_3Si^{\bullet}$$

Scheme 46

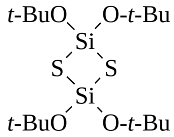
$$(H_3Si)_2E + H_2SiCl_2 \longrightarrow H_3SiESiH_2Cl \xrightarrow{(H_3Si)_2E} (H_3SiE)_2SiH_2$$
$$(H_3Si)_2E + HSiCl_3 \longrightarrow (HSi)_4E_6$$
$$E = S \text{ or } Se$$

Scheme 47

at silicon with the S–Si–S angles being in the range 100.1–124.7°.[256] The reaction of t-BuOH and SiS_2 gives a mixture of $(t\text{-BuO})_2Si(SH)_2$, $(t\text{-BuO})_3SiSH$, and (**16**) which, although planar, does not have a square Si_2S_2 ring but has endocyclic angles at Si and S of 97.8 and 82.2°, respectively.[257]



(**15**)



(**16**)

The $(t\text{-BuO})_3SiS$ group has been used as a ligand on various metals.[258] The bulky thiolate group is introduced by reaction of the thiol $(t\text{-BuO})_3SiSH$ with a suitable metal salt such as a nitrate or an oxide. The silver derivative is a cyclic tetramer, $[(t\text{-BuO})_3SiS]_4Ag$, while the thallium and lead derivatives form planar and nonplanar cyclic dimers, $[(t\text{-BuO})_3SiSM]_2$, respectively.[239] The reaction between $(t\text{-BuO})_3SiENa$ and $(t\text{-BuO})_3SiCl$ gives $[(t\text{-BuO})_3Si)]_2E$ (E = O or S), both of which are bent at the E atom.[259] By contrast, the Si–O–Si angle in the related peroxide, $[(t\text{-BuOO})_3Si]_2O$, is 180°.[260]

5.6 Silicon–Nitrogen Compounds

The structures of simple silylamines have been the subject of much discussion and investigation. This has been due in large part to the finding that $(H_3Si)_3N$ is, unlike its pyramidal $(H_3C)_3N$ analog, planar at nitrogen. The silicon compound is also a much weaker Lewis base than the carbon analog and this has been attributed to p_π–d_π bonding between the lone pair of electrons on the nitrogen and the vacant d-orbitals on silicon but ionic contributions and Si–C σ^* interactions with the Si–N bond are probably also important (see Reference 212). Such bonding would increase the Si–N–Si angles to 120° and reduce the donor properties of the lone pair. The chemistry and physical properties of Si–N compounds (excluding Si_3N_4) have been discussed in detail.[261,262]

5.6.1 Preparations of Compounds Containing Si–N Bonds

The reaction between ammonia and H_3SiCl or H_3SiBr affords $(H_3Si)_3N$ as a low-boiling colorless liquid (equation 31).[196,263] Disilylamine, $(H_3Si)_2NH$, which is also planar at nitrogen, is unstable as a liquid and disproportionates to give trisilylamine and ammonia, but it may be made by reaction of Ph_2NSiH_3 and ammonia in a transammination reaction.[135] Similarly, H_3SiNH_2 also disproportionates, but it can be prepared at low pressure in the gas phase from the reaction between H_3SiI and ammonia.[264]

$$6H_3SiX + 2NH_3 \xrightarrow{-6\,HX} 2(H_3Si)_3N \xleftarrow{-NH_3} 3(H_3Si)_2NH \qquad (31)$$

The reaction between halosilanes and ammonia or primary or secondary amines is the most widely used synthetic route to compounds containing Si–N bonds. Such reactions are greatly controlled by steric effects: if large groups are present on either the silicon or the amine, then less than full substitution may occur. For example, ammonia reacts with chlorosilanes to give a variety of products depending on the size of the chlorosilane (equation 32).

$$NH_3 + R_3SiCl \longrightarrow NH_4Cl + (R_3Si)_3N \quad R = H \qquad (32)$$
$$R = Et,\ \text{product} = \text{mainly } (R_3Si)NH_2 + \text{some } (R_3Si)_2\,NH;$$
$$R = Ph,\ \text{product} = R_3SiNH_2 \text{ only}$$

This is also the case for the reaction of polyhalosilanes with amines, where small groups on the nitrogen allow a higher degree of substitution to be achieved (Scheme 48).

This type of reaction is usually carried out using chlorosilanes because of their ready availability, but bromo- or iodosilanes are more reactive and may give better yields. Reactions of fluorosilanes with amines tend to give, because of the relatively high Lewis acidity of fluorosilanes, stable donor–acceptor adducts such as $SiF_4{\cdot}HNR_2$. Heating such adducts, however, does give F_3SiNR_2 (R = Me, Pr, Bu) species in good yield. A successful method to overcome the steric problems encountered above is to use an alkali metal or magnesium amide to carry out a metathesis reaction. For example, although the tetraamidosilane $Si(NHBu\text{-}t)_4$ is not available by the silyl chloride plus amine route (see Scheme 48), it may be obtained using a magnesium amide (equation 33). Here again the use of the more reactive halogens allows successful substitution by the bulky groups. For a more detailed discussion of this type of reaction, and Si–N compounds in general, see Lappert *et al.*[262]

$$4\,t\text{-BuNHMgBr} + SiBr_4 \longrightarrow Si(NH\text{-}t\text{-Bu})_4 + 4MgBr_2 \qquad (33)$$

Tetraaminosilanes may be prepared by several methods using either a secondary amine or a metal amide (Scheme 49).[265] Mixed amides may also be prepared.

The reaction between Me_2NH and H_3SiBr gives Me_2NSiH_3, which has an unusually high melting point of 276 K, about 120 K higher than the closely related compounds $NMe_{3-x}(SiH_3)_x$ ($x = 0$–3). The surprising properties of Me_2NSiH_3 are associated with its unusual structure, which is pentameric with N atoms at the corners of a pentagon and SiH_3 groups midway along the pentagon sides (Figure 8).[120]

$$SiCl_4 + 8NHMe_2 \longrightarrow Si(NMe_2)_4 + Me_2NHCl$$
$$SiCl_4 + 6NH_2\text{-}t\text{-Bu} \longrightarrow ClSi(NH\text{-}t\text{-Bu})_3 + 3t\text{-BuNH}_3Cl$$
$$SiCl_4 + 4HN\text{-}i\text{-Pr}_2 \longrightarrow Cl_2Si(N\text{-}i\text{-Pr}_2)_2 + 2i\text{-Pr}_2NH_2Cl$$

Scheme 48

$$SiCl_4 + 8R_2NH \longrightarrow (R_2N)_4Si + 4R_2NH_2Cl$$
$$SiCl_4 + n\,R_2NLi \longrightarrow Cl_{4-n}Si(NR_2)_n + LiCl \quad n = 1\text{–}4$$
$$SiCl_4 + 4R_2NMgBr \longrightarrow (R_2N)_4Si + 4MgBrCl$$
$$R = Me, Et, n\text{-Pr}, i\text{-Pr, etc.}$$

Scheme 49

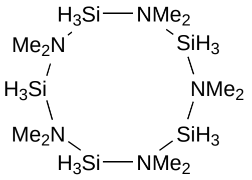


Figure 8 The pentameric structure of Me_2NSiH_3

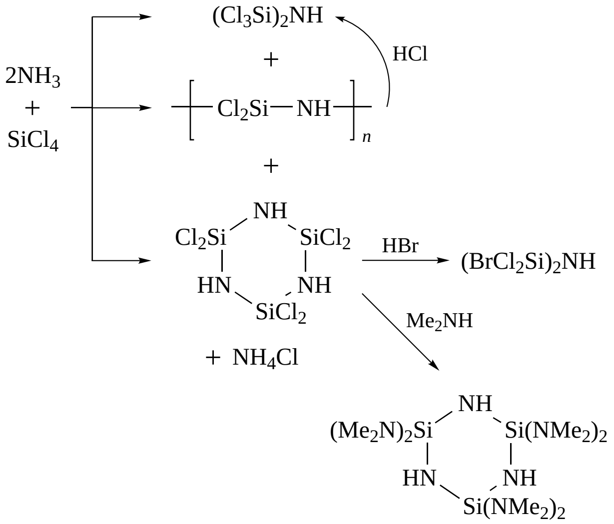
The nitrogen atoms also have a pyramidal geometry rather than the planar $(H_3Si)_3N$, and the N–Si–N angles are about 177°.

The controlled reaction of two equivalents of ammonia with one of $SiCl_4$ gives a mixture of monomeric, oligomeric, and polymeric products which may undergo further reactions typical of Si–N compounds (Scheme 50).[266]

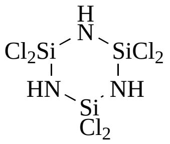


Scheme 50

The reaction between H_3SiBr and F_2PNH_2 in the vapor phase at room temperature gives $H_3SiNHPF_2$, which can be isolated and which reacts with a further equivalent of H_3SiBr to give $(H_3Si)_2NPF_2$.[267,268] The diphosphino compound $H_3SiN(PF_2)_2$ can be prepared in a similar manner (Scheme 51).[268] All three of the compounds are planar at nitrogen.[267,269]

The hexachloro monomer $(Cl_3Si)_2NH$ may react via $SiCl_3$, Cl, or H substitution reactions.[270] Heating the lithium compound (**17**) gives the cyclic dimer, presumably via elimination of LiCl and dimerization of the reactive intermediate $Cl_2Si{=}NSiCl_3$ (Scheme 52).

The cyclic trimer (**18**), formed by condensation reactions in a manner similar to cyclic siloxanes from SiOH compounds, has a planar Si_3N_3 skeleton with Si–N–Si and N–Si–N angles of 131 and 109°, respectively.[271]



(**18**)

5.6.2 *Structures of Silyl Amines*

Structural data for several silyl amines are given in Table 7. Detailed discussions are given in appropriate places throughout this section.

5.6.3 *Reactions of Silyl Amines*

Silyl amines usually react readily with water or alcohols to give compounds containing Si–OR groups (R = H, Me, Et, etc.) and with HCl to give a chlorosilane. The poor donor properties of $(H_3Si)_3N$ mean that it does not form adducts as readily as Me_3N, no adduct is formed with Me_3B, and only weak adducts are formed with BF_3 or BCl_3. Reactions of $(H_3Si)_3N$ are summarized in Scheme 53.[196]

5.6.4 *Silicon Nitride, Si_3N_4*

Silicon forms the widely studied nitride Si_3N_4 when heated at high temperature (>1400 °C) in a nitrogen

$$SiBrH_3 + NH_2PF_2 \longrightarrow H_3SiNHPF_2 \xrightarrow[Me_3N]{H_3SiBr} (H_3Si)_2NPF_2 + NMe_3HBr$$

$$SiBrH_3 + HN(PF_2)_2 \xrightarrow{NMe_3} H_3SiN(PF_2)_2 + NMe_3HBr$$

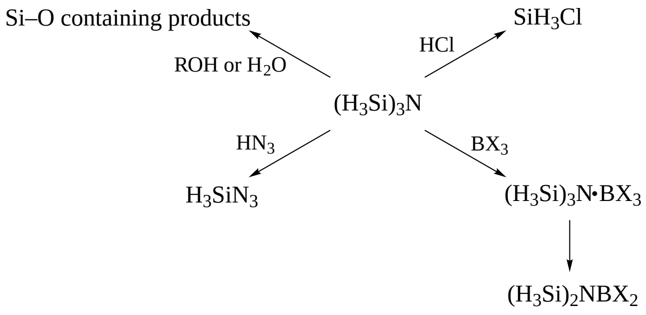


Scheme 53

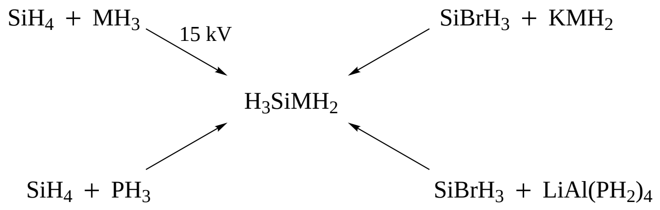
atmosphere. Interest in this ceramic material is due to its good refractory properties. The use of silicon nitride in the microelectronics industry and in the fabrication of solar cells has been discussed in detail.[274] Two main forms of Si_3N_4 are known, called α and β. Both structures are similar, comprising Si_4N tetrahedra, the difference being in how they are arranged in the crystal lattice. Interestingly, the NSi_3 groups within the structure are nearly planar, that is, similar to the arrangement found in $(H_3Si)_3N$.[275] Silicon nitride may be prepared in several ways, for example, Scheme 54.

5.7 Silicon, Phosphorus, Arsenic, and Antimony Compounds

Monosilyl compounds (H_3SiMH_2) of phosphorus and arsenic are known and they may be prepared in a variety of

$$3Si + 2N_2 \longrightarrow Si_3N_4$$
$$3SiO_2 + 6C + 2N_2 \longrightarrow Si_3N_4 + 6CO$$
$$3SiCl_4 + 4NH_3 \longrightarrow Si_3N_4 + 12HCl$$

Scheme 54

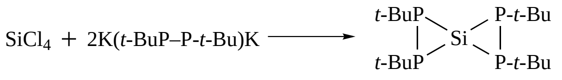


Scheme 55

ways (Scheme 55); similar preparative routes are successful in the preparation of $(H_3Si)_2EH$, $(H_3Si)_3E$, and $H_3SiSiH_2EH_2$ ($E = P$ or As).[196]

The mercury sensitized photolysis of a mixture of F_3SiSiF_3 and PF_3 affords $P(SiF_3)_3$ as a colorless air-sensitive liquid. It reacts with a deficiency of water to give $(F_3Si)_2PH$ and F_3SiPH_2 and with bromine to give PBr_5 and F_3SiBr.[276]

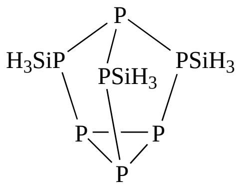
There are many cyclic compounds known containing P and Si atoms in the ring but the majority have organic substituents on the silicon. (Details of the structures of such compounds are available.[112]) An exception is the spirocyclic compound (**19**), formed using an alkali metal-phosphorus derivative (equation 34).[277]



(34)

(**19**)

The lithium phosphide Li_3P_7 also reacts with silyl halides and with H_3SiX ($X = Br$ or I) to form the tricyclic species (**20**).[278]



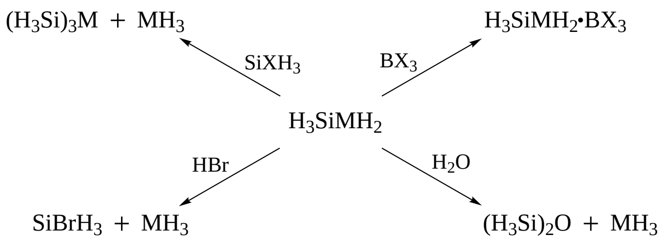
(**20**)

5.7.1 *Reactions of Silicon–Phosphorus, –Arsenic, and –Antimony Derivatives*

The reaction between SiH_4 and PH_3 gives H_3SiPH_2, which may be alkylated via H_3SiPLi_2 (Scheme 56).[279] Treatment of

$$H_3SiPH_2 + 2LiPEt_2 \longrightarrow 2HPEt_2 + H_3SiPLi_2 \xrightarrow{MeCl} H_3SiPMe_2$$
$$HSi(PEt)_3 + MeLi \longrightarrow MeSiH(PEt_2)_2 + LiPEt_2$$

Scheme 56



M = P or As

Scheme 57

$$MeLi + (H_3Si)_3E \longrightarrow (H_3Si)_2ELi + MeSiH_3$$
E = P or As
$$MeLi + (H_3Si)_2E \longrightarrow H_3SiELi + MeSiH_3$$
E = O, S, or Se

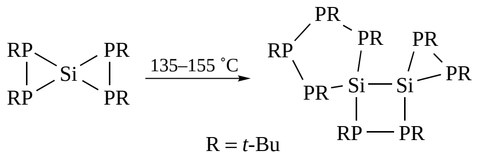
Scheme 58

Si–H containing silylphosphines, however, leads to cleavage of an Si–P bond and alkylation at silicon. These reactions, and many other interesting cyclic and acyclic phosphines, most of which contain alkyl groups on silicon, are discussed in more detail by Fritz.[280]

The silyl phosphorus and arsenic compounds react with a variety of reagents and form adducts more readily with Lewis acids than the silyl amines (Scheme 57).[196]

The reaction of MeLi with Group 15 (but not N) and Group 16 silyl compounds affords metal derivatives (Scheme 58).

When the spirocyclic compound (**19**) is heated, dimerization occurs to give an unusual dispirocyclic compound containing three-, four-, and five-membered rings containing silicon (equation 35).[281]



R = *t*-Bu

(35)

5.7.2 *Structures of Silicon–Phosphorus, –Arsenic, and –Antimony Derivatives*

Structural data for trisilyl compounds of the Group 15 elements are shown in Table 8. As would be expected, the

Table 8 Structural data for trisilyl compounds[196]

Compound	Si–H (Å)	Si–M (Å)	Si–M–Si (°)
$(H_3Si)_3N$	1.54	1.738	119.6
$(H_3Si)_3P$	1.50	2.247	95
$(H_3Si)_3As$	1.48	2.352	91.5
$(H_3Si)_3Sb$	1.394	2.557	88.6

Si–M bond length increases on going down the group. Only the amine is planar at nitrogen; the structures of $(H_3Si)_3E$ (E = P, As and Sb) show a steady decrease in Si–E–Si angle on going down the group,[282] any p_π–d_π interaction presumably being rather weaker on descending the group.[196] A more detailed discussion of these compounds is available.[112]

The structures of H_3Si–E derivatives (E = Li, Be, B, N, O, C, P, S, Cl, etc.) have been the subject of many theoretical investigations. Despite the fact that H_3SiNH_2 is unknown, it is calculated also to be planar at nitrogen.[283]

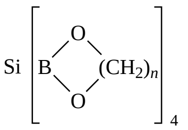
5.8 Compounds Containing Silicon to Boron Bonds

Compounds containing Si–B bonds are comparatively rare but the in situ coupling of $SiCl_4$ and $(MeO)_2BCl$ affords $Si[B(OMe)_2]_4$ which undergoes transesterification without cleavage of the Si–B bonds (equation 36).[284] The reaction between F_2Si: and BF_3 affords $F_3SiSiF_2BF_2$ and $F_3SiSiF_2SiF_2BF_2$.[285]

$$SiCl_4 + 4(MeO)_2BCl + 8Li \longrightarrow Si[B(OMe)_2]_4 + 8LiCl$$

$$\downarrow HO(CH_2)_nOH \qquad (36)$$

n = 2 or 3



5.9 Compounds Containing Si–C and Si–Si Bonds

The vast majority of compounds containing Si–C bonds are dealt with in another article (*see* ***Silicon: Organosilicon Chemistry***), although silyl cyanides are treated in Section 5.4.2 above. The perhydrosilanes such as $H_3Si(SiH_2)_nSiH_3$ are covered in Section 5.1.

The photodecomposition of SiH_4/GeH_4 mixtures affords H_3SiSiH_3 and H_3SiGeH_3 by insertion of the initially formed H_2Si: into a Si–H or Ge–H bond of SiH_4 or GeH_4, respectively.[286]

Treatment of $SiCl_4$ with $LiSnMe_3$ affords $Si(SnMe_3)_4$, which reacts with MeLi to give (**21**); the latter is useful for introducing the $Si(SnMe_3)_3$ ligand (in an analogous fashion to the widely used $Si(SiMe_3)_3$ ligand) into complexes such as (**22**) (Scheme 59). The Si–W distance in the tungsten complex is 2.652 Å.[287]

$$4LiSnMe_3 + SiCl_4 \xrightarrow{THF} Si(SnMe_3)_4 + 4LiCl$$

$$\downarrow THF,\ MeLi$$

$$(THF)_3LiSi(SnMe_3)_3 + Me_4Sn$$

(**21**)

$$\downarrow [NEt_4][(CO)_5MCl]$$

$$[NEt]_4[(CO)_5MSi(SnMe_3)_3] + 3THF + LiCl$$

(**22**) M = Cr, Mo, or W

Scheme 59

Numerous Group 14 carborane complexes have been prepared, in which the main group metal interacts with a C_2B_3 fragment in an η^5-fashion. Such complexes are usually formed by reaction of an alkali metal carborane with a silicon chloride (equation 37). (For a more detailed discussion of this work see Hosmane and Maguire.[288])

$$SiCl_4 + 2Li_2[\textit{nido}\text{-}7,8\text{-}C_2B_9H_{11}] \xrightarrow{C_6H_6} \textit{commo}\text{-}3,3'\text{-}(3,1,2\text{-}SiC_2B_9H_{11})_2 + 4LiCl \qquad (37)$$

5.10 Silicon Carbide

The preparation, manufacture, and reactions of SiC have been discussed in detail in Gmelin,[289] as have the electrical, mechanical, and other properties of both crystalline and amorphous of SiC.[290] Silicon carbide results from the pyrolysis of a wide range of materials containing both silicon and carbon but it is manufactured on a large scale by the reduction of quartz in the presence of an excess of carbon (in the form of anthracite or coke), (Scheme 60), and more recently by the pyrolysis of polysilanes or polycarbosilanes (for a review, see Reference 291). Although it has a simple empirical formula, silicon carbide exists in at least 70 different crystalline forms based on either the hexagonal wurtzite (ZnS) structure α-SiC, or the cubic diamond (zinc blende) structure β-SiC. The structures differ in the way that the layers of atoms are stacked, with Si being four-coordinate in all cases.

The industrial interest in SiC derives from its high mechanical and chemical stability as well as its hardness (9.5 on the Moh scale), which makes it a useful abrasive. When pure, α-SiC is an intrinsic semiconductor, but it may be doped

$$SiO_2 + 2C \longrightarrow Si + 2CO$$

$$Si + C \xrightarrow{2000\text{–}2500\ ^\circ C} SiC$$

Scheme 60

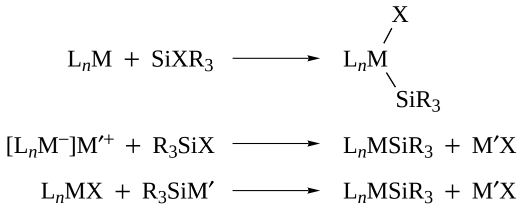
with various impurities to give an extrinsic semiconductor. β-SiC is also used as a high-temperature semiconductor.

6 TRANSITION METAL SILYL COMPLEXES

The interest in transition metal silyl derivatives stems largely from an interest in how such compounds compare with the very extensive organometallic chemistry of the transition elements and also because of the industrial importance of the *Hydrosilation* reaction used for the preparation of organosilicon compounds (*see* ***Silicon: Organosilicon Chemistry***). There is a variety of methods for preparing compounds containing transition metal to silicon bonds. The most common are oxidative addition of an Si–X bond (X is usually H) to a transition metal complex, the use of transition metal anions, and the use of silyl alkali metal derivatives (Scheme 61). There is a wide variety of compounds known and, as the principal focus of this article is silicon, they will be arranged according to the groups on silicon. Recent structural studies and developments in the chemistry of transition metal silyl compounds have been reviewed.[292–298]

6.1 Compounds Containing SiH_3 and Related Ligands

The Si–H bonds within a silane are generally more reactive toward *Oxidative Addition* than other Si–X bonds, for example, where X is halogen or SH. For example, the reactions between various H_3SiX species (X = H, Cl, or SiH_3) and *trans*-$[PtH_2\{P(C_6H_{11})_3\}_2]$ afford compounds (**23**)



Scheme 61

in which reaction at the Si–H rather than the Si–X bonds have occurred (equation 38).[299] The X-ray structure of (**23**; X = H) gives Pt–Si 2.382 Å; Si–H stretching frequencies are 2025 and 2020 cm^{-1}.

$$SiH_3X + trans\text{-}[PtH_2\{P(C_6H_{11})_3\}_2] \longrightarrow trans\text{-}[PtH(SiH_2X)\{P(C_6H_{11})_3\}_2] + H_2 \quad (\mathbf{23})\ X = H, Cl, \text{ or } SiH_3 \qquad (38)$$

Disilyl chalcogen compounds react in a similar manner (equation 39), to give both mononuclear complexes and bridged complexes (if excess platinum hydride precursor is used).[300]

$$(H_3Si)_2E + trans\text{-}[PtX(H)(PEt_3)_2] \longrightarrow trans[\text{-}PtX(PEt_3)_2(SiH_2ESiH_3)] + trans[\{\text{-}PtX(PEt_3)_2(SiH_2)\}_2E] + H_2$$
$$E = O, S, \text{ or } Se;\ X = Br \text{ or } I \qquad (39)$$

The silyl amines and phosphines also give similar complexes (Scheme 62).[301]

The salt elimination route is also a useful method, relying on the reaction between a silyl halide and a transition metal anion, for example, equation (40).[302] The IR spectra of such compounds are informative; values of 2141, 2136, and 2132 cm^{-1} for the disilyl compound and 2142 cm^{-1} for the silyl compound are found for the Si–H stretching frequencies.

$$H_3SiI + Na_2Fe(CO)_4 \longrightarrow (H_3Si)_2Fe(CO)_4 + (H_3Si)(H)Fe(CO)_4 \qquad (40)$$

In a similar manner, H_3SiI and H_2SiI_2 react with $NaCo(CO)_4$ to give silyl cobalt complexes (Scheme 63). The Si–Co bond in these complexes is cleaved by H–X species (X = F, Cl) and HgX_2 (X = Cl or I) to give H_3SiX and either $HCo(CO)_4$ or $Hg[Co(CO)_4]_2$. The IR stretches for $H_3SiCo(CO)_4$ are at 2164, 2160, and 2154 cm^{-1}.[303] The reaction between H_3SiI and $NaMn(CO)_5$ proceeds in a similar manner.

The metal–Si bond is inert towards HCl and HgX_2 (X = Cl or I) at room temperature. At higher temperatures, chlorosilyl derivatives are produced in the reaction with HCl (Scheme 64).[304] The thermal decomposition of the metal

$$(H_3Si)_2E + trans\text{-}[PtH(I)(PEt_3)_2] \longrightarrow trans\text{-}[PtI(PEt_3)_2\{H_2SiN(SiH_3)_2\}] + H_2$$
$$E = N \text{ or } P$$
$$PH_2(SiH_3) \text{ or } PH(SiH_3)_2 + trans\text{-}[PtI(H)(PEt_3)_2] \longrightarrow trans\text{-}[PtI(PEt_3)_2(SiH_3)] + PH_3$$

Scheme 62

$$2NaCo(CO)_4 \xrightarrow{2SiH_3I} 2H_3SiCo(CO)_4 + 2NaI$$

$$2NaCo(CO)_4 \xrightarrow{H_2SiI_2} H_2Si[Co(CO)_4]_2 + 2NaI$$

Scheme 63

$$H_3SiI + NaMn(CO)_5 \longrightarrow H_3SiMn(CO)_5 + NaI$$

$$H_3SiMn(CO)_5 \xrightarrow[75\,°C]{xHCl} H_{3-x}Cl_xSiMn(CO)_5 + xH_2 \qquad x = 1\text{–}3$$

Scheme 64

silyl complexes $[Co(CO)_4(SiH_3)]$, $[Fe(CO)_4(SiH_3)_2]$, and $[Mn(CO)_5(SiH_3)]$ at 500 °C gives the metal silicides CoSi, β-$FeSi_2$, and $MnSi$–Mn_5Si_3, respectively.[305] In the presence of Lewis bases such as Me_3N and pyridine, 1:2 adducts $(H_3Si)(B)_2M(CO)_n$ (M = Mn or Co, n = 5 or 4, respectively) are formed which are thought to have ionic structures of type $(H_3Si{\cdot}2B)^+$ $[M(CO)_n]^-$.[306]

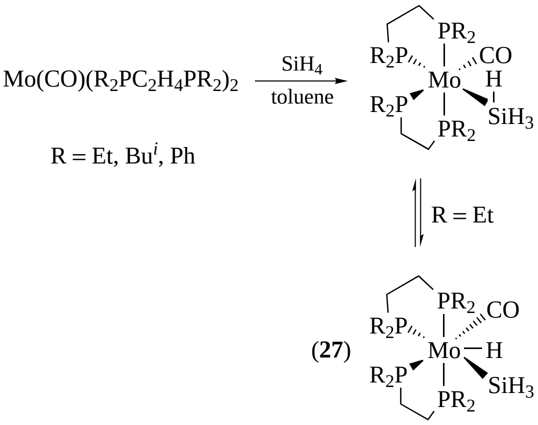
If more than one Si–H group is present in the silane, then photolysis may lead to bridging H_2Si groups, for example, the manganese complex (**24**), which has an Si–Mn distance of 2.434 Å and an Mn–Si–Mn angle of 124.4°; (Scheme 65).[307] The reaction between H_3SiK and Cp_2TiCl_2 (Scheme 65) affords the olive-green bridged complex (**25**), presumably via the disilyl complex $Cp_2Ti(SiH_3)_2$.[308]

The molecular structures of $H_3SiMn(CO)_5$, $H_3SiRe(CO)_5$, and $H_3SiCo(CO)_4$ have all been determined in the gas phase.[309–311] The Si–M bond distances are 2.407, 2.562, and 2.381 Å for the Mn, Re, and Co complexes, respectively. Although it is difficult to estimate what might be expected for these distances, they all seem relatively short. This has been attributed to d → d π-bonding using the vacant d-orbitals on silicon. More detailed discussions of transition metal SiH_3 complexes have been published.[292–298]

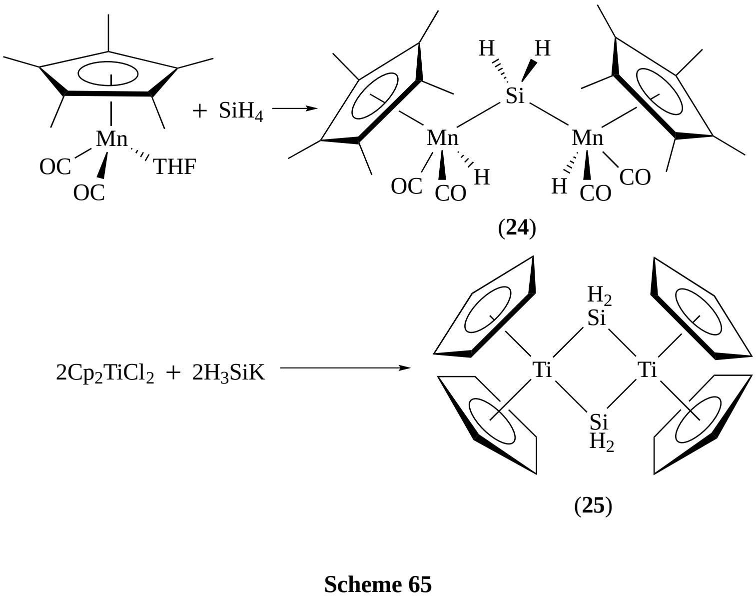
Silyl complexes also result from the reaction between a silyl anion and a metal halide, for example, in the formation of (**26**), which has an Si–H stretching frequency of 2103 cm^{-1} (equation 41).[312]

$$(\eta^5\text{-}C_5H_5)Fe(CO)_2Br + H_3SiK \longrightarrow \underset{(\mathbf{26})}{(\eta^5\text{-}C_5H_5)Fe(CO)_2SiH_3} + KBr \qquad (41)$$

The search for transition metal complexes that can activate alkanes has led to investigations into the potential of metal complexes to coordinate silanes. In 1995, the first SiH_4 complexes were prepared according to Scheme 66. These

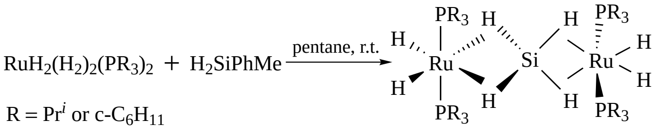


Scheme 66



Scheme 65

complexes have been characterized by multinuclear NMR spectroscopy and X-ray crystallography which show the metal center to have a distorted octahedral geometry and the CO and SiH_4 ligands to be cis to each other. For the complex containing the $(Et_2PCH_2)_2$ ligand an equilibrium between the η^2–SiH_4 complex and a hydrosilyl, (**27**), complex is found.[313] More recently, complexes, (**28**), in which an SiH_4 ligand bridges between two metals have been prepared, equation (42).[314] A variety of complexes are now known in which an Si–H bond is bound to the metal in an η^2–fashion; many of these contain organic substituents at Si, and their chemistry has been reviewed.[315–317]



(**28**)

(42)

6.2 SiX$_3$Containing Ligands (X = F or Cl)

Hexafluorodisilane breaks down in a radiofrequency glow-discharge to give trifluorosilyl radicals that react with a variety of metal atoms when co-condensed on a cold surface (equation 43). This method allows the synthesis of a range of homoleptic SiF_3 metal derivatives (*see Homoleptic Compound*).[318]

$$F_3SiSiF_3 \xrightarrow[\text{glow discharge}]{\text{rf}} 2F_3Si\bullet \xrightarrow[-196\,^{\circ}\text{C surface}]{\text{M atoms}} (F_3Si)_nM \qquad (43)$$

$$n = 2,\ \text{M} = \text{Te or Hg};\ n = 3,\ \text{M} = \text{Sb or Bi}$$

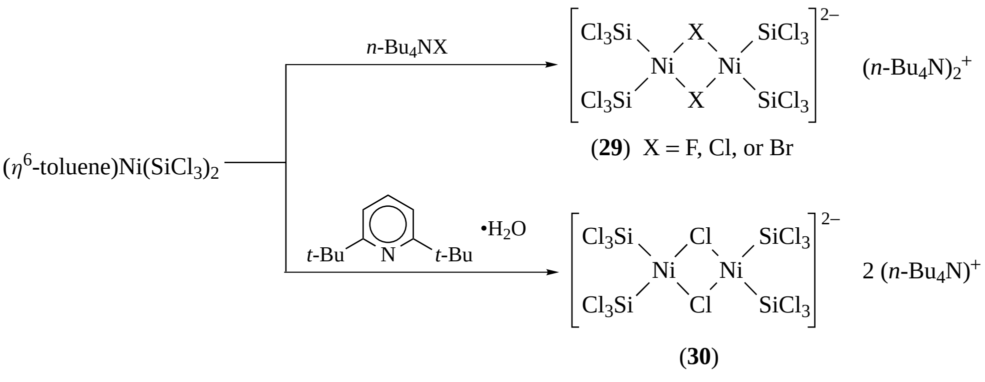
If other ligands are also co-condensed or are added to coordinatively unsaturated F_3Si–M species, then further complexes may be prepared, for example, (η^6-toluene)$Ni(SiF_3)_2$, $(F_3Si)_2Pd(PMe_3)_2$, $(F_3Si)_2Cd$·glyme, and $(F_3Si)_2Zn$·2(pyridine). The bis F_3Si complex $(F_3Si)_2Ni(PMe_3)_2$ is also prepared in this way; it has a trigonal bipyramidal geometry with the F_3Si ligand occupying the axial positions and having an average Si–Ni bond length of 2.182 Å.[318] The arene complexes (η^6-toluene)$Ni(SiF_3)_2$ and (η^6-benzene)$Ni(SiCl_3)_2$ react with CO to give rare examples of nickel(II) carbonyl complexes, $(X_3Si)_2Ni(CO)_3$ (X = F or Cl). The Cl_3Si compound has trigonal bipyramidal geometry, with the $SiCl_3$ group in axial positions, and an average Si–Ni bond length of 2.286 Å; the fluorine analog is likely to have a similar structure.[319,320] Treatment of (η^6-toluene)$Ni(SiCl_3)_2$ with alkylammonium salts (Scheme 67) gives the bridged species (**29**), while treatment with wet di-*t*-butylpyridine affords (**30**), which has an average Ni–Si distance of 2.171 Å and an Si–N–Si bond angle of 89.9°.[321]

The X-ray structure of $F_3SiCo(CO)_4$ (prepared from F_3SiH and $Co_2(CO)_8$) shows a Si–Co bond length of 2.226 Å, that is, slightly shorter than that in the trichlorosilyl analog (2.254 Å).[322] The Fe–Si distance in (η^5-C_5H_5)$FeH(SiCl_3)_2(CO)$ is 2.252 Å.[323] The reaction of $(PPh_3)_3RhCl$ with Cl_3SiH gives $RhHCl(SiCl_3)(PPh_3)_2$, which crystallizes with disordered $HSiCl_3$ solvate molecules in the lattice. It has a short Rh–Si distance of 2.203 Å, which is again indicative of some back donation of electrons from the metal to the vacant d-orbitals on silicon to give some partial π-bonding.[324]

The UV photolysis of $M_3(CO)_{12}$ (M = Fe, Ru, or Os) with excess Cl_3SiH gives *cis*- and *trans*-$M(CO)_4(SiCl_3)_2$ (except for M = Ru, when only the cis isomer is formed). The CO ligands are readily substituted by PPh_3 or arene ligands to give, for example, *mer*-$Ru(CO)_3(SiCl_3)_2$ and (η^6-$Me_3C_6H_3$)$Ru(CO)(SiCl_3)_2$.[325] The structure of (η^6-*p*-*t*-$Bu_2C_6H_4$)$Ru(CO)(SiCl_3)_2$ is of the 'piano stool' type (*see Piano Stool Structure*) having Ru–Si distances averaging 2.339 Å.[326] If $M_3(CO)_{12}$ (M = Ru or Os) are heated at 70–75 °C with Cl_3SiH, then both $M(CO)_4(SiCl_3)_2$ and the trinuclear $M_3H_3(CO)_9(SiCl_3)_3$ are formed.[327]

Various other metal carbonyl complexes react with Cl_3SiH, with mononuclear silyl complexes being formed from dinuclear starting materials (Scheme 68).[328]

Similarly, photolysis of $(PR_3)Fe(CO)_4$ (R = Ph or OPh) with $HSiCl_3$ gives $H(SiCl_3)(PR_3)Fe(CO)_3$ (via addition



(**30**)

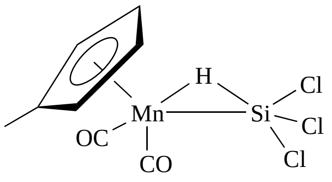
of Cl_3Si–H to the 16-electron species $(PPh_3)Fe(CO)_3$), which when treated with PPNCl give PPN salts of $[(SiCl_3)(PR_3)Fe(CO)_3]^-$ anions. Both of the anions are trigonal bipyramidal with both the phosphorus and silicon ligands in axial positions, and Fe–Si distances of 2.197 and 2.206 Å for R = Ph and OPh, respectively.[329]

The structures of $(Cp)(CO)LM(H)SiR_3$) complexes (R = Cl, L = CO, etc.), which are formed in photolytic experiments, are unusual in that they contain Mn–H–Si three-center bonds, for example, (**31**), in which the Si–H group may be regarded as being bound in an η^2-ligand position. (See Schubert[330] and References 315–317 for a more detailed discussion of η^2-coordination of Si–H bonds to transition metals.)



(**31**)

The salt elimination reaction between transition metal anions and halosilanes also gives the trihalosilyl products (equation 44).[331]

R = Br = X

$n = 2$, M = Fe, R = Cl, X = H

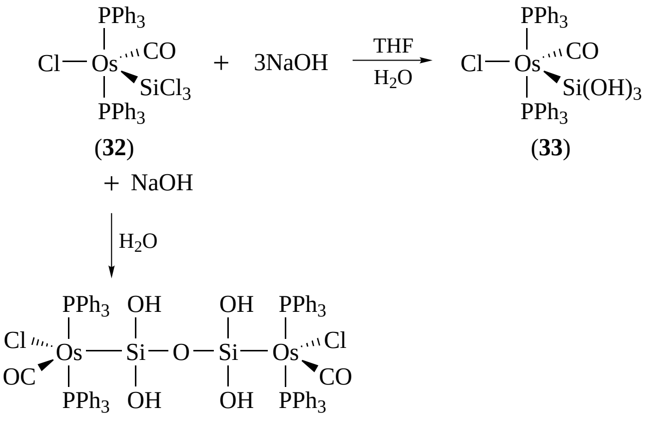
Some of these reactions are slow and give low yields, and Cl_3Si derivatives may more conveniently be prepared by chlorination of a $SiCl_2H$ ligand (equation 45).[332] The structure of $(\eta^5\text{-}C_5H_5)(CO)_2FeSiCl_3$ has an Fe–Si distance of 2.216 Å, while the related compound $(CO)_4CoSiCl_3$ has a trigonal bipyramidal structure with $SiCl_3$ in an axial position.[333,334]

$$Cp(CO)_nMSiHCl_2 \xrightarrow[50\,°C]{CCl_4} Cp(CO)_nMSiCl_3 \quad (45)$$

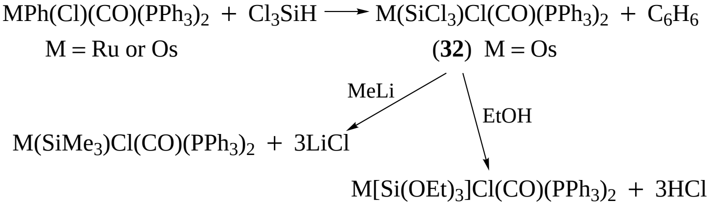
$n = 3$, M = Cr, Mo, or W; $n = 2$, M = Fe

The reaction between $MPhCl(CO)(PPh_3)_2$ species and Cl_3SiH also gives metal complexes. They undergo substitution reactions with alcohols and alkyllithium reagents to give SiR_3 species (Scheme 69).[335]

On treatment with three equivalents of water the osmium complex (**32**) affords the novel complex (**33**) containing an $Si(OH)_3$ ligand (Scheme 70). If only one equivalent of water is used, the bridging disiloxane complex (**34**) is formed (which is also formed from reaction between (**32**) and (**33**) with subsequent hydrolysis). The geometry of (**33**) is square pyramidal with the $Si(OH)_3$ group in the apical position and with an Si–Os distance of 2.319 Å.[336] The relatively recent interest in carrying out chemistry at such a coordinated SiX_3 ligand would seem to have great potential and further work



Scheme 70

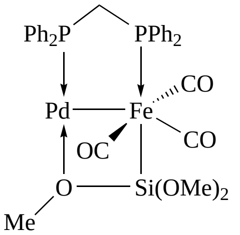


Scheme 69

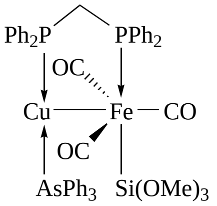
will undoubtedly see new synthetic routes to compounds unavailable by conventional methods of synthesis.[337]

6.3 Compounds Containing $Si(OR)_3$Ligands

The iron silyl compounds K[Fe(CO)$_3$(η^1-Ph$_2$PCH$_2$PPh$_2$){Si(OMe)$_3$}] and [FeH(CO)$_3$(η^1-Ph$_2$PCH$_2$PPh$_2$){Si(OMe$_3$)}] react with a variety of other transition metal complexes to give bimetallic compounds in which the Si(OMe)$_3$ group may act either to form an η^2-μ_2-SiO bridge or remain as a simple terminal group. For example, reaction of the iron hydride with *trans*-[PdCl$_2$(PhCN)$_2$] affords complex (**35**) in which the Si–Fe and Pd–O distances are 2.275 and 2.100 Å, respectively, while reaction with [Cu(AsPh$_3$)$_3$]NO$_3$ affords complex (**36**) which has an Si–Fe distance of 2.282 Å.[338,339]



(**35**)



(**36**)

Oxidative addition of (RO)$_3$SiH occurs (equation 46) when treated with RhH(PPh$_3$)$_4$ to give the silyl complexes (**37**).[340]

$$(RO)_3SiH + RhH(PPh_3)_4 \xrightarrow{-PPh_3} (RO)_3SiRhH_2(PPh_3)_3 \qquad (46)$$

(**37**)

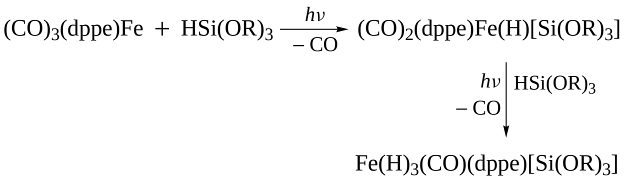
R = Me or Et

Similarly, reaction between (EtO)$_3$SiH and RhX(PPh$_3$)$_3$ (X = Cl, Br, or I) gives oxidative addition products (equation 47).[341]

$$(MPh_3)_3RhX + (EtO)_3SiH \xrightarrow{-MPh_3} (MPh_3)_2RhH[Si(OEt)_3]X \qquad (47)$$

M = P, As, or Sb, X = Cl; M = P, X = Br or I

Oxidative addition of alkoxysilanes to iron complexes also occurs.[342] On further treatment with (RO)$_3$SiH, a second



Scheme 71

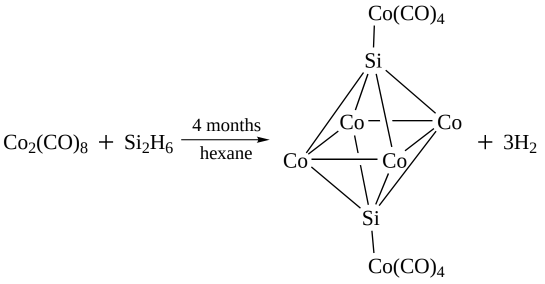
carbonyl ligand is lost and a trihydro complex is formed (Scheme 71). The structure of the R = OEt complex is trigonal pyramidal with an Fe–Si distance of about 2.25 Å.[343]

A less well-explored route to Si(OR)$_3$ containing complexes is by displacement of another silyl group from the transition metal center or by replacing an alkyl by an alkoxy group at silicon (Scheme 72).[344]

The preparation of transition metal complexes containing silanol groups as ligands can be achieved under mild conditions by oxidation of Si–H groups with dimethyldioxirane. For example, Cp*(CO)$_2$(PMe$_3$)WSiRH$_2$ may be oxidized to Cp*(CO)$_2$(PMe$_3$)WSiR(OH)$_2$ (where R = Me or OH) and, Cp(CO)$_2$(PMe$_3$)MoSiH$_3$ affords Cp(CO)$_2$(PMe$_3$)MoSi(OH)$_3$.[345–347]

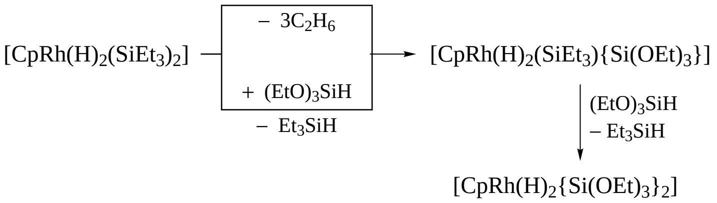
6.4 Clusters Containing Silicon

Silicon forms a variety of compounds containing clusters of transition metal atoms that exhibit a wide range of structures. Disilane reacts with Co$_2$(CO)$_8$ to give the cobalt cluster (**38**) in which the silicon is coordinated to five Co atoms (equation 48). The Si···Si distance of 2.817 Å is too long for a bond (normally about 2.35 Å) and the Si–Co distances average 2.336 Å.[348]



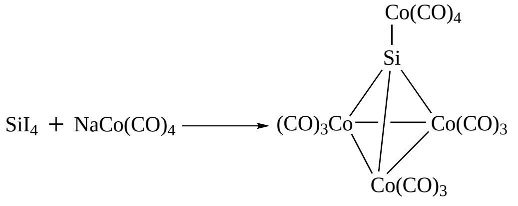
(48)

(**38**)



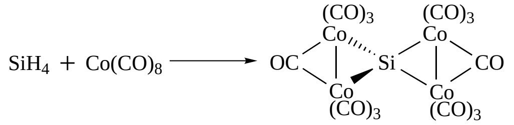
Scheme 72

The reaction between SiI_4 and $NaCo(CO)_4$ (equation 49) gives cobalt cluster (**39**) in which the silicon is coordinated to four cobalt atoms, the $Si–Co(CO)_3$ distances averaging 2.218 Å and the $Si–Co(CO)_4$ distance being 2.288 Å.[349] The reaction of SiH_4 with $Co_2(CO)_8$ (equation 50) gives the spiro complex (**40**) in which the Si–Co distance averages 2.288 Å.[350] Similarly, the reaction between SiI_4 and $NaM(CO)_5$ (M = Mn or Re) leads to tri- and tetra-substituted products (equation 51).[351]



(49)

(**39**)



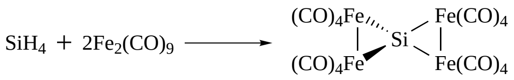
(50)

(**40**)

$$nNaM(CO)_5 + SiI_4 \longrightarrow I_{4-n}Si[M(CO)_5]_n \qquad (51)$$

M = Mn or Re; n = 3 or 4

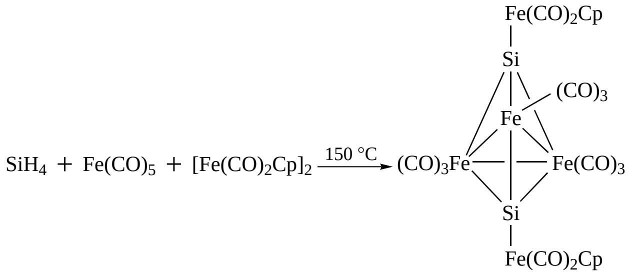
In a similar manner to the cobalt case, SiH_4 reacts with $Fe_2(CO)_9$ (equation 52) to give a spiro complex (**41**) containing no bridging COs and with an average Fe–Si distance of 2.345 Å.[352]



(52)

(**41**)

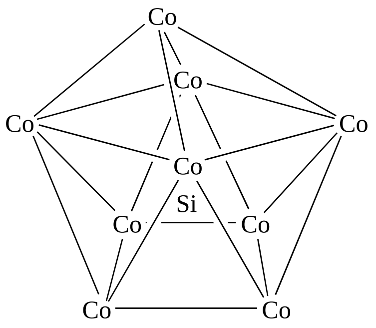
Reaction of SiH_4 with a mixture of iron carbonyl complexes (equation 53) leads to a mixed ligand cluster (**42**) in good yield in which the average $Si–Fe(CO)_3$ distance is 2.306 Å and the $Si–Fe(CO_2Cp)$ average distance is 2.250 Å.[353]



(**42**)

(53)

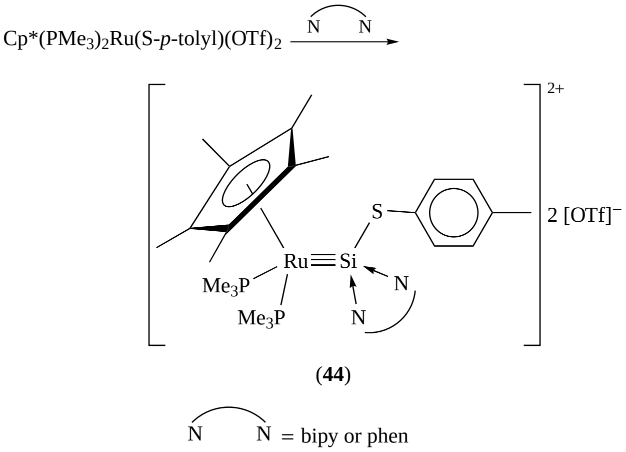
The reaction between μ_4-$Si[Co_2(CO)_7]_2$ and $[NEt_4][Co(CO)_4]$ affords an unusual mixed salt, $[NEt_4][\mu_8\text{-}SiCo_9(CO)_{21}][Co(CO)_4]$ (**43**). The silicon is encapsulated in the $[\mu_8\text{-}SiCo_9(CO)_{21}]^{2-}$ anion and lies almost equidistant from eight of the Co atoms in a capped square-antiprism with an average Si–Co distance of 2.299 Å.[354]



(**43**) A view of the $[\mu_8\text{-}SiCo_9(CO)_{21}]^{2-}$ anion (the CO groups are omitted for clarity)

6.5 Transition Metal Silylyne Complexes

Simple, terminal silylyne complexes, $L_nM{\equiv}SiR$, are very rare. However, as in the case of silylene ligands, the presence of a donor ligand at silicon greatly enhances the stability of such species. Thus, displacement of a good leaving group from silicon (equation 54) affords complexes (**44**) in which the silicon is coordinated by the bidentate donor ligands. The Si–Ru distance in the phenanthroline adduct is 2.269 Å which is, as would be expected, rather short although there are few compounds available with which to make comparisons. The Si···N distances are over 1.9 Å, which clearly indicates a dative coordination rather than the presence of an Si–N σ bond.[355]

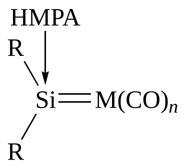


(54)

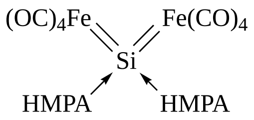
6.6 Transition Metal Silylene Complexes

The preparation of several three-coordinate silylene complexes has been discussed in Section 4. A variety of

four-coordinate complexes, (**45**), are also known in which the silicon is coordinated by a donor molecule such as HMPA or THF. These complexes are all formed by the salt elimination method, the dianions $[Fe(CO)_4]^{2-}$, $[Cr(CO)_5]^{2-}$, and $[W_2(CO)_{10}]^{2-}$ reacting with the appropriate R_2SiCl_2 compound. Treatment of $SiCl_4$ with two equivalents of $[Na_2Fe(CO)_4]$ similarly gives (**46**). These and other silylene complexes are discussed more fully elsewhere.[56,57,294,356]



(**45**)



(**46**)

M = Fe, n = 4; R = O-t-Bu, S-t-Bu, or Cl
M = Cr, n = 5; R = O-t-Bu, Cl, or OCH_2-t-Bu
M = W, n = 5; R = O-t-Bu

The bulky stable silylenes described in Section 3 may be used as ligands in a range of transition metal complexes. The complexes are formed mostly via simple ligand displacement reactions as shown in Scheme 73 although in some cases reactions occur involving reduction of halogenometal complexes.[43]

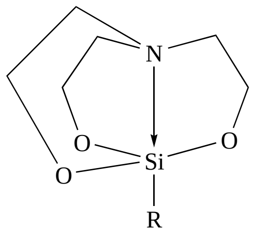
The chemistry of silylene complexes has become much more developed in the past 10 years as silylene complexes have been found to be important intermediates in reactions such as the dehydrogenative coupling of hydrosilanes, redistribution reactions, and the 'Direct Process' for the production of simple chlorosilanes. For reviews of this work, see References 43, 44 and 294. Several complexes have now been prepared in which there is a silene or disilene ligand ($R_2C{=}SiR_2$ or $R_2Si{=}SiR_2$ species)[56,57] but, since all these contain several Si–C bonds, they will not be discussed further here.

7 COMPOUNDS CONTAINING SILICON WITH HIGHER COORDINATION NUMBERS

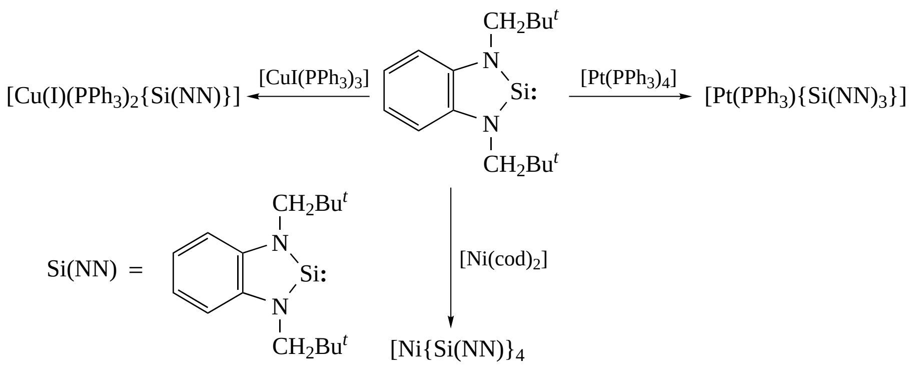
There are a large number of five- and six-coordinate silicon compounds, the extensive chemistry of which has been reviewed.[357–359] Many of these compounds contain Si–C bonds and so will not be described here. The study of such compounds is of interest because of the lack of analogous carbon chemistry and because of the intermediacy of species with greater than four-coordination in a variety of reaction mechanisms proposed for silicon. (Compounds containing seven-coordinate silicon are known; they usually have an Si–H group present and contain Si–C bonds. Such compounds are described in Reference 357.) There are also a small number of compounds containing silicon with even higher coordination number. For example, Mg_2Si has the antifluorite structure and eight-coordinate silicon and the cluster (**43**) in Section 6.4, contains Si coordinated by nine Co atoms.[354] Calculations on the structures of SiX_5 and SiX_6 species (X = H or alkali metal) are discussed in Reference 5.

7.1 Five-coordinate Compounds

The most widely studied of the neutral five-coordinate silicon compounds are the so-called 'silatranes' of general structure (**47**). They are of interest both because of their unusual structure, which incorporates a strong transannular N → Si bond, and because of their apparent physiological properties.[360]

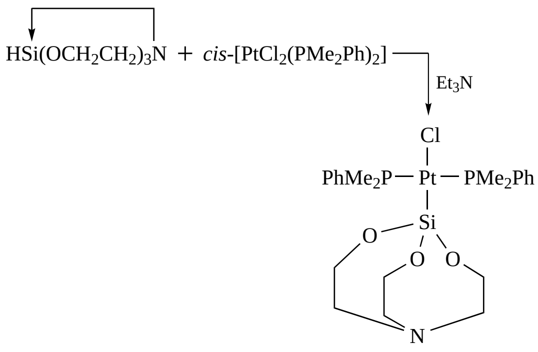


(**47**)



Scheme 73

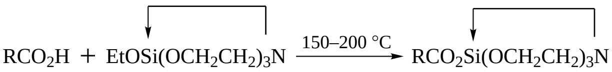
The silatranes are generally prepared by reaction of $N(CH_2CH_2OH)_3$ with an $RSi(OR')_3$ species (R = alkyl, aryl, etc., R′ = Me or Et). Most of the silatranes have organic R groups and so will not be further discussed here. Silatranes may also be prepared by reaction of triethanolamine with a silsesquioxane $(RSiO_{1.5})_n$ in the presence of a catalytic amount of KOH.[361] The reaction of silatrane itself with *cis*-$[PtCl_2(PMe_2Ph)_2]$ gives complex (**48**), in which there is a very long Si· · ·N distance and a planar nitrogen (equation 55). This, together with IR data, suggests that there is no strong N → Si interaction in the complex and that the silicon is four coordinate.[362]



(55)

(**48**)

The reaction of $N(CH_2CH_2OH)_3$ with $(EtO)_4Si$ affords ethoxysilatrane (**49**), which is remarkably stable towards solvolysis. It does, however, undergo reaction (equation 56) with carboxylic acids to give esters (**50**).[363]



(**49**) (**50**)

R = Ph or Me

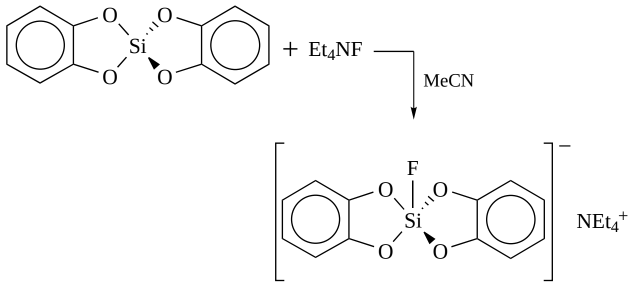
(56)

Reaction of ethoxysilatrane with a further equivalent of $N(CH_2CH_2OH)_3$ affords (**51**), which may be hydrolyzed to the silanol (**52**) (Scheme 74).[363]

The hydridosilane $HSi\overline{(CH_2CH_2O)_3N}$ may also be prepared in a similar manner from $HSi(OMe)_3$ and triethanolamine; the Si–H compound reacts with HF to give the fluorosilatrane.[364] The X-ray structure of 1-fluorosilatrane shows a N → Si distance of 2.042 Å, a little longer than that of 2.023 Å in the 1-chloro derivative.[365]

The interest in silatrane chemistry has led to the preparation of a range of related five-coordinate cyclic compounds that contain different coordination at the silicon or modification of the ring backbone. The synthesis of most of these compounds is achieved in the same way as the simple silatranes, that is, by the reaction of a trifunctional silane, $XSiY_3$ (where Y is a labile group such as halide, OMe, OAc) with a suitable trifunctional amine. (Representative examples of this interesting class of compounds are shown in Figure 9 below; their chemistry has been reviewed.[366])

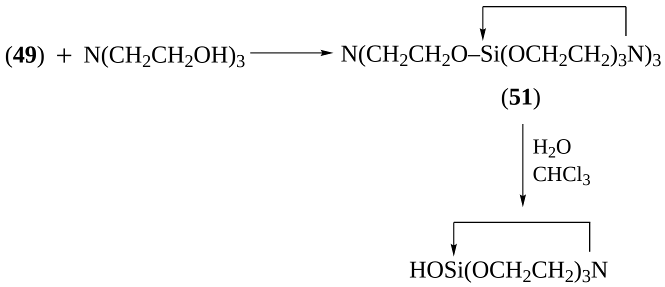
Although no four-coordinate Si compounds have been found to have planar geometry, the five-coordinate anion (**53**), prepared as shown in equation (57), has a geometry at silicon distorted very much away from trigonal bipyramidal towards square pyramidal geometry. The O–Si–O angles across the spirocyclic ring are about 166°; and 143°.[363] The structures of numerous silatranes have been determined and are discussed elsewhere.[112]



(**53**)

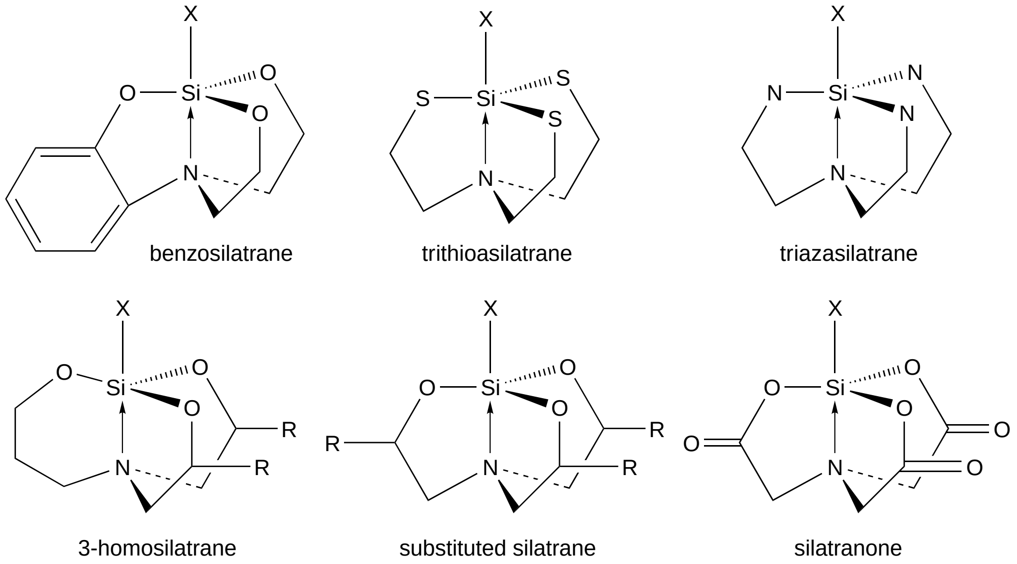
(57)

A variety of compounds derived from diethanolamine are also known and may be prepared in a similar way to the silatranes.[112] For example, equation (58) affords (**54**) in which



(**52**)

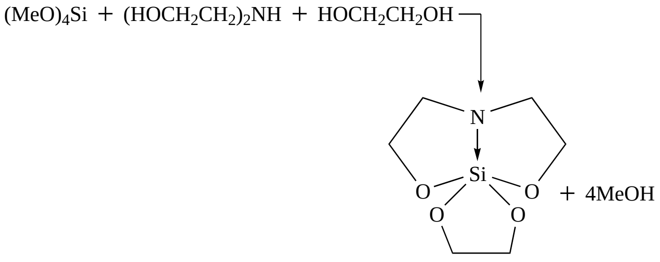
Scheme 74



R = organic group, X = H, halide, organic group etc.

Figure 9 Cyclic structures related to silatranes

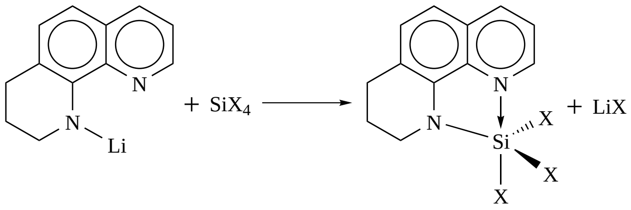
the N → Si distance is rather short, 2.004 Å.[367]



(54)

(58)

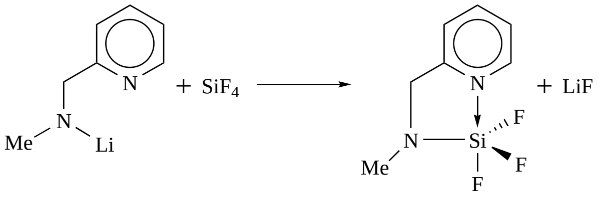
The reaction (equation 59) between lithium amides and $SiCl_4$ affords *N*-substituted silanes. The crystal structures of (**55**; X = F, Cl) clearly shows the intramolecular coordination of an aromatic nitrogen atom. As would be expected, the Si–N σ bonds are rather shorter (1.732 and 1.737 Å) than the N → Si distances (1.969 and 1.9484 Å for the fluoro and chloro derivatives, respectively).[112]



X = F or Cl **(55)**

(59)

In a similar way, reaction of (**56**) with SiF_4 (equation 60) affords (**57**), in which the Si–N and N → Si distances are again significantly different, being 1.701 and 1.974 Å, respectively.[368]

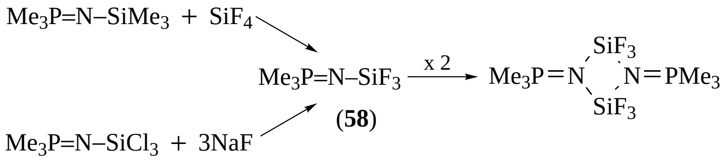


(56) **(57)**

(60)

The reaction of H_2SiCl_2 with Me_2NH gives ClH_2SiNMe_2, which is a monomer with four-coordinate Si in the gas phase. However, in the solid state it forms a centrosymmetric dimer in which the silicons are five-coordinate and in which there are two short (1.814 Å) and two long (2.054 Å) Si–N distances.[369] The phosphinimine (**58**) may be formed in two ways (Scheme 75) and in the solid state is shown to be a dimer, again with five-coordinate silicon atoms. The Si_2N_2 ring is planar with trigonal bipyramidal geometry at Si and has Si–N distances of 1.736 and 1.857 Å.[370,371]

The addition of a fluoride ion to various fluorosilanes gives salts with a five-coordinate silicon. Thus R_4NF addition to SiF_4 affords $[R_4N][SiF_5]$ (R = Et or Pr).[372] A crystallographic study of $[PhCH_2NMe_3][SiF_5]$ shows the silicon to have trigonal bipyramidal geometry.[373]

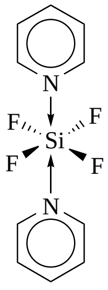


Scheme 75

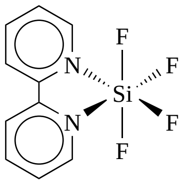
7.2 Six-coordinate Compounds

A wide range of adducts between halosilanes and tertiary amines are known. They are formed by mixing the amine and the halosilane and are usually white solids. For example, SiF_4 and $SiCl_4$ form 1:2 adducts with pyridine, SiH_2Br_2 forms a 1:4 adduct with pyridine, H_2SiH_2 forms a 1:1 adduct with Et_3N, and $HSiCl_3$ forms a 1:1 adduct with $(Me_2NCH_2)_2$.[374] Many of these adducts are ionic; for example, $SiH_2I_2·4py$ may better be represented as $[SiH_2·4py]^{2+}2I^-$, but the fluorosilane compounds are neutral adducts.[375]

The molecular structure of $SiF_4·2py$ (**59**) shows a centrosymmetric octahedral geometry at silicon with the pyridine molecules trans to each other and an Si–N distance of 1.93 Å.[376] Hexacoordinate geometry may also occur when using a chelating ligand such as bipyridine as in complex (**60**), where the N → Si distance averages 1.977 Å.[377]

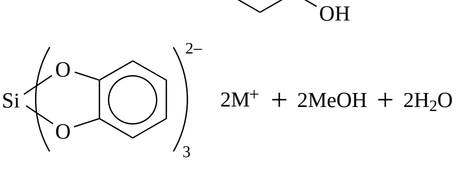


(**59**)



(**60**)

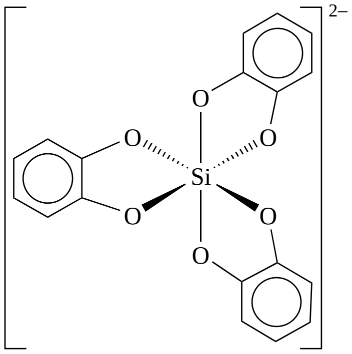
The alkali metal salts of the six-coordinate anion (**61**) may readily be prepared (equation 61) by using SiO_2 (or $Si(OMe)_4$) as starting material, thus forming monomeric silicon compounds from the polymeric SiO_2 without the need for the isolation of elemental silicon.[378]



(61)

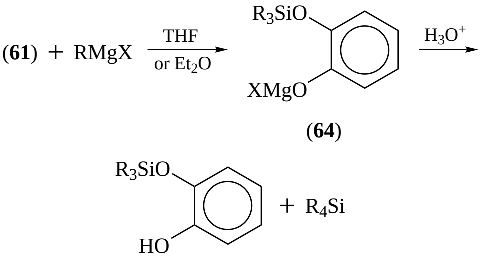
(**61**)

M = Na or K



(**61**)

The catechol derivatives (**64**) are versatile synthetic intermediates and they form readily with Grignard or alkyllithium reagents (equation 62). The products formed depend on the solvent and the nature of the R group but species (**62**) or (**63**) may be produced, the latter being formed when R is allyl, vinyl, alkynyl, or phenyl.[378]

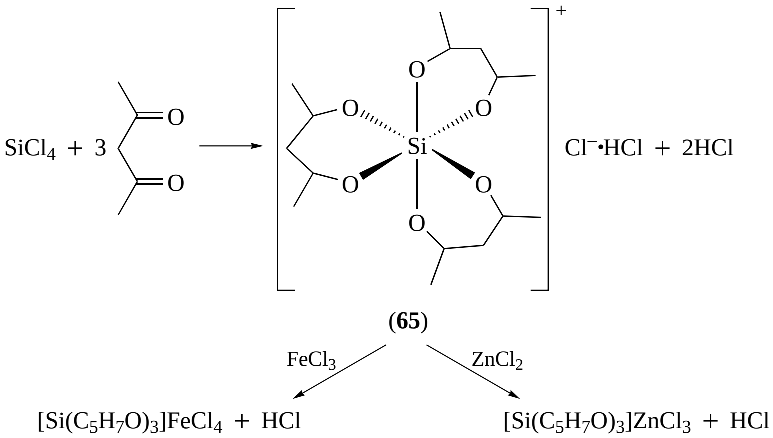


(62)

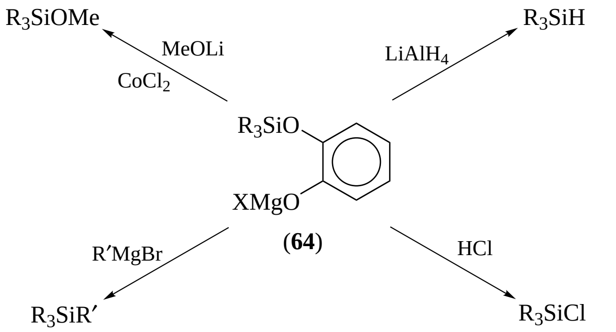
The catechol derivatives (**64**) are useful synthetic intermediates as they react with a variety of readily available reagents to give products as shown in Scheme 76.[378]

The tris(catecholate) complex (**61**) also reacts with $LiAlH_4$ to give SiH_4.[378] The structure of the tris(catecholate) complex $[C_5H_5NH]_2[(C_6H_4O_2)_3Si]$ has a slightly distorted octahedral symmetry for the dianion, with the O–Si–O angles being slightly less than 90°.[379]

Silicon, like many other elements, readily forms acetylacetonato (acac) complexes. Thus, reaction of $SiCl_4$ with 2,4-pentanedione (Scheme 77) affords the six-coordinate monocation (**65**). Other complexes may readily be prepared by addition of appropriate metal salts.[380]



Scheme 77



R = Et or *n*-Bu; R′ = Ph, Me, etc.

Scheme 76

The tris(oxalate) complex (**66**), which is very soluble in MeOH, may also be readily prepared (equation 63) using silver oxalate.[381]

$$SiCl_4 + 2Et_4NBr + 3Ag_2C_2O_4 \xrightarrow{\text{acetone}} \underset{(\mathbf{66})}{[Si(C_2O_4)_3]^{2-}}\, [Et_4N]_2{}^{+} + 4AgCl + 2AgBr \quad (63)$$

Tris chelate complexes such as $[(acac)_3Si]^+$ and (**61**) are potentially optically active and may be resolved by crystallization of suitable tartrate salts.[382,383] The reaction of $[NF_4][HF_2]$ with SiF_4 (equation 64) affords the six-coordinate (**67**) as a white crystalline solid that is stable at room temperature but decomposes at 90 °C.[384]

$$2[NF_4][HF_2]\cdot n HF + SiF_4 \longrightarrow \underset{(\mathbf{67})}{[NF_4]_2[SiF_6]} + 2(n+1)HF \quad (64)$$

The partial hydrolysis of $SiI_4(bipy)_2$ affords $[Si(OH)_2(bipy)_2]I_2\cdot 2H_2O$, in which the cation has *cis* octahedral geometry and each OH group is hydrogen bonded to one of the water molecules.[385]

The mixing of silicon tetrahalides with simple Lewis bases such as NMe_3 (NH_3 would react with Si, Cl, Br, or I bonds) or PMe_3 leads to the formation of a variety of both five- and six-coordinate complexes, for example, $SiF_4\cdot n B$ ($n = 1$ or 2, B = PMe_3 or NMe_3), $SiCl_4\cdot 2Me_3P$, $SiCl_4\cdot NMe_3$, and $Br_4Si\cdot 2Me_3P$. The geometry of these compounds has been studied in detail by IR and Raman spectroscopy, which suggest that the five-coordinate complexes are trigonal bipyramidal and the six-coordinate are trans octahedral.[386,387] An X-ray structural study of $SiCl_4\cdot 2PMe_3$ confirmed the trans octahedral geometry, showing Si–Cl bonds of about 2.25 Å and the Si–P distance as 2.26 Å.[388] However, an IR study of $SiF_4\cdot 2\,NH_3$ and $SiF_4\cdot 2N_2H_4$ suggests a cis octahedral structure for these adducts.[389] Compounds such as SiF_4·bipy or SiF_4·en containing bidentate chelating ligands are clearly constrained by the ligand geometry to be cis complexes. Perhalodisilanes and Si_3Cl_8 also react with chelating ligands to give 1:1 complexes such as Si_2X_6·bipy (X = F, Cl, or Br), Si_2X_6·phen (X = Cl or Br), and Si_3Cl_8·bipy. IR and NMR studies suggest that the plane of the chelating ligand is perpendicular to that of the Si–Si axis. In Si_3Cl_8, the bipyridyl ligand coordinates to the more Lewis acidic, $SiCl_2$, silicon.[390]

A range of diiodosilanes react (equation 65) with 2,2′-bipyridine to give ionic complexes (**68**).[391]

$$SiXYI_2 + 2bipy \xrightarrow{CHCl_3} \underset{(\mathbf{68})}{[SiXY\cdot 2\,bipy]^{2+}[I^-]_2} \quad (65)$$

XY = Cl_2, H_2, HCl, HI, or H(OMe)

Si^{4+} ions are found in octahedral complexes containing six neutral ligands such as $[Si(pyO)_6]I_4$ (equation 66).[392]

$$SiI_4 + 6pyO \xrightarrow{CHCl_3} [Si(pyO)_6]I_4 \quad (66)$$

Phenylene *N*-oxide also forms six-coordinate chelated complexes with SiX_4 (X = F, Cl, Br, and I).[393] Six-coordinate

$$SiI_4 + 3L_2 \longrightarrow [Si(L_2)_3]I_4$$

L = bipy or phen

$$SiI_4 + 6NMI \longrightarrow [Si(NMI)_6]I_4$$

Scheme 78

$$2SiF_4{\cdot}2NHMe_2 \xrightarrow{-\,2\,HF} 2SiF_3NMe_2 + 2NHMe_2$$

$$2SiF_4{\cdot}2NHMe_2 \xrightarrow{-\,4\,HF} SiF_2(NMe_2)_2$$

$$2SiF_4{\cdot}2NH_2R \xrightarrow{-\,2\,HF} (SiF_3)_2NR$$

R = H or Et

Scheme 79

Si^{4+} complexes may also be formed by reacting SiI_4 with bipyridine or phenanthroline in the melt (Scheme 78). 1-Methylimidazole reacts with SiI_4 to give a similar complex (Scheme 78).[394]

Tetrafluorosilane is the strongest Lewis acid of the halosilanes and is capable of forming stable adducts with primary and secondary amines without loss of HX, which would occur with chloro-, bromo-, or iodosilanes (Scheme 79). The adducts are, however, broken down at high temperatures and in the presence of reagents such as $LiAlH_4$, B_2H_6, and $NaBH_4$.[262,395]

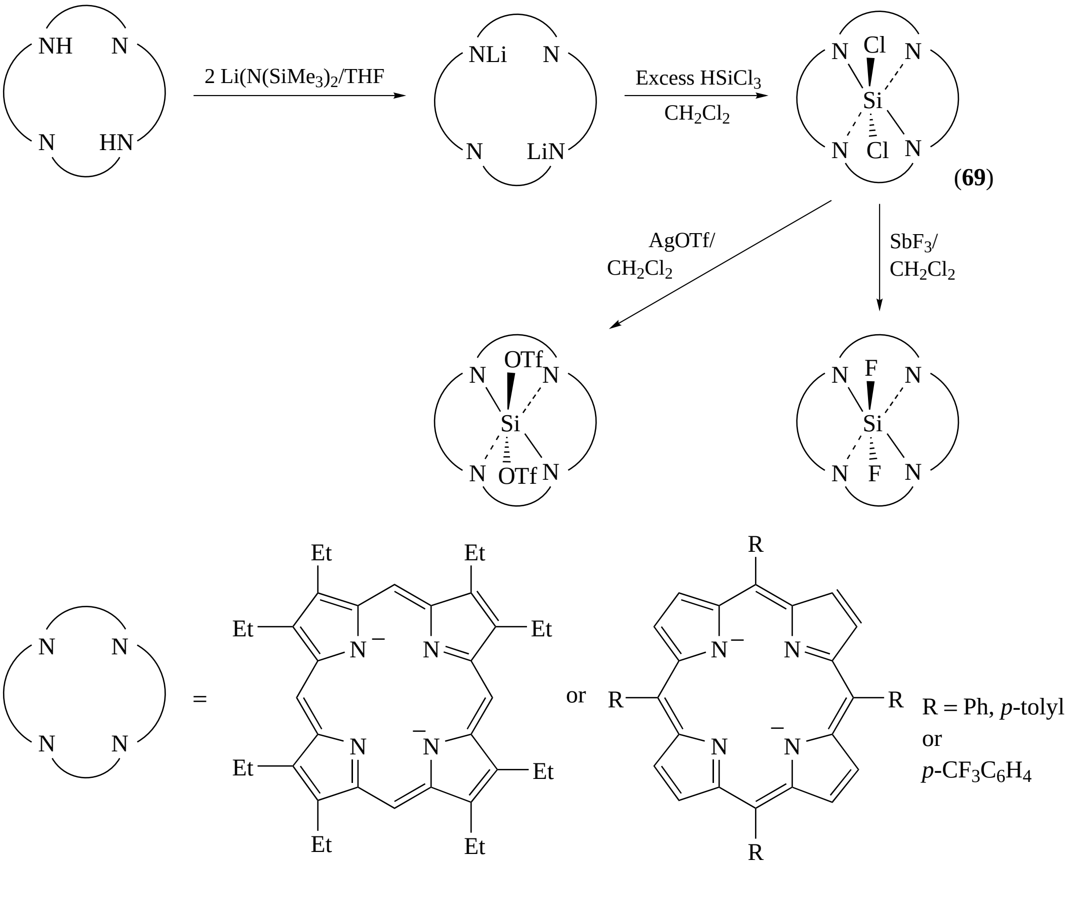
Both Na_2SiF_6 and $(NH_4)_2SiF_6$ may be used for the conversion of organosilicon chlorides to fluorides (equation 67).[396]

$$R_nSiCl_{4-n} + Na_2SiF_6 \text{ or } (NH_4)_2SiF_6 \longrightarrow R_nSiF_{4-n} \quad (67)$$

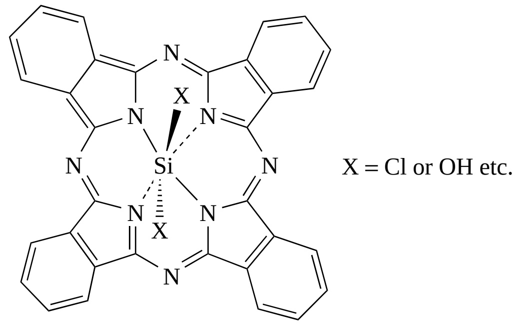
$n = 1, 2,$ or 3; R = alkyl or aryl

Porphyrin ligands may also be used to prepare a range of neutral, six-coordinate silicon compounds. Thus, deprotonation of a porphyrin with $LiN(SiMe_3)_2$ affords dianions that react readily with $HSiCl_3$ to give the corresponding dichlorides (**69**). These can then be treated with a variety of salts to give further derivatives (Scheme 80).[397]

Silicon-containing phthalocycanines (**70**) can form stacks and have interesting optical[398] and conducting properties.[399] The individual macrocycles can be connected via oxygen bridges from the silicon center, organic bridges, or by direct Si–Si bonds.[400]



Scheme 80



(**70**)

8 CHARACTERIZATION AND ANALYSIS OF INORGANIC SILICON COMPOUNDS

The compounds of silicon described in this article are generally monomeric and soluble in common solvents. They are, therefore, amenable to study by all of the commonly available methods for molecular characterization such as IR, UV, and NMR spectroscopy, mass spectrometry, and X-ray crystallography. Two of these methods, IR and ^{29}Si NMR spectroscopy, have been used with particular success.

The characteristic stretching frequencies for all of the common Si–X bonds have been studied in detail but perhaps the most useful is that of the Si–H bond. The Si–H stretch is usually strong and sharp and it occurs in the 2280–2080 cm^{-1} region of the IR spectrum, well away from most other bands. The precise position of the Si–H band is sensitive to the electronegativity of the substituents and a more detailed discussion of its position and that of bands due to other Si–X bonds can be found elsewhere.[401]

Silicon only has one naturally occurring isotope (^{29}Si) with a nonzero nuclear spin and ^{29}Si NMR spectroscopy has become one of the most widely used techniques for the identification of silicon compounds. Unfortunately, the natural abundance of ^{29}Si is only 4.7%, which combined with its long spin–lattice relaxation times, means that relatively long acquisition times may be needed to obtain high quality spectra. ^{29}Si NMR spectroscopy has been the subject of a number of reviews and tables of chemical shift data and coupling constants are available.[402–404]

Various methods for the determination of silicon, particularly from biological samples are available. The techniques usually involve decomposition of the compound to give silica or a silicate by either wet combustion or fusion with sodium peroxide. The silicate formed can then be determined colorimetrically, volumetrically, or gravimetrically.[401] Acidified ammonium heptamolybdate reacts only with monomeric $Si(OH)_4$ and not its oligomers to give a yellow silicomolybdic acid complex that can be determined spectrophotometrically. This method works for concentrations in the 1 to 1000 ppm range but concentrations down to 0.1 ppm can be determined if the yellow silicomolybdic acid is reduced to blue silicomolybdic acid.[405,406]

1 INTRODUCTION

Silicon exists as the second most abundant element after oxygen, in the form of silicates in the Earth's crust. Berzelius first isolated the element silicon in 1823. In the periodic table, silicon has the position just below carbon. Carbon can be found in nature in a pure state or in a variety of forms of organic compounds, whereas silicon cannot be found in a pure state and constitutes mineral compounds. Thus carbon and silicon characterize the organic and inorganic worlds, respectively. Fundamental atomic properties can be compared with other group 14 elements; some are given in Table 1 (*see also* ***Silicon: Inorganic Chemistry***). Silicon can be described as having an outer electron configuration $3s^2p^2$.

Organosilicon compounds can be defined as chemical species having carbon–silicon bond(s). Since there are no organosilicon compounds in nature, all organosilicon compounds are artificial and therefore we can say that human wisdom built organosilicon compounds. Historically, organosilicon compounds have been known since Friedel and Crafts prepared tetraethylsilane by the reaction of diethylzinc and silicon tetrachloride in 1863.

$$2(C_2H_5)_2Zn + SiCl_4 \longrightarrow (C_2H_5)_4Si + 2ZnCl_2 \quad (1)$$

Kipping, who has been frequently mentioned as the founder of organosilicon chemistry, used the Grignard reagents for the preparation of a variety of organosilicon compounds and investigated the properties of a wide range of compounds during the years 1898–1939. This period may be regarded as the first generation in organosilicon chemistry. Kipping summarized his investigation in rather a depressing tone that 'as moreover the few that are known are very limited in their reactions, the prospect of any immediate and important advance in this section of organic chemistry does not seem to be very hopeful' (Bakerian Lecture, 1936).

It was only after a short time that Eugene Rochow (US) and Richard Müller (Germany) simultaneously discovered the direct synthesis of methylchlorosilanes, in 1941–1942, that led to the booming silicone industry. New reactions and compounds have emerged since then. Perhaps the development until the late 1960s can be called the second generation of organosilicon chemistry. In that time, almost all known types of organosilicon compounds (silicon-functional compounds) were prepared and many fundamental reactions were described.

However, nothing was known of organosilicon reactive intermediates, double- and triple-bonded species, photochemistry, high-molecular weight polysilanes, and silicon polyhedranes. It was not until the late 1960s that organosilicon compounds received much interest as intermediates in organic synthesis. The nature of the effects that organosilicon groups exert on organic compounds was also systematically studied only in the past three decades. The author designates the period after 1970 as the third generation of organosilicon chemistry. Development of the organosilicon chemistry towards materials science is a notable fact from the end of the twentieth century.

The author will try, in this section, to introduce a concise summary of the basic organosilicon chemistry and an essence of the recent development.[1]

2 CLASSES OF COMPOUNDS AND NOMENCLATURE

The nomenclature of organosilicon compounds is based on the derivatives of silane, disilane, and higher polysilanes. When the silicon group is used as a substituent (silicon-containing radical), silyl, disilanyl, trisilanyl, and polysilanyl are used:

SiH_4 = silane, H_3Si- = silyl
SiH_3SiH_3 = disilane, H_3SiSiH_2– = disilanyl
$SiH_3SiH_2SiH_3$ = trisilane, $H_3SiSiH_2SiH_2$– = trisilanyl

Note that for H_3SiSiH_2- and $H_3SiSiH_2SiH_2$-, disilanyl and trisilanyl should be used instead of disilyl and trisilyl. The latter means two and three silyl groups, respectively. For substituted silanes, substituents are arranged in alphabetical order. Me_2SiCl_2 and $ClCH_2SiMe_3$ are named as dichlorodimethylsilane and chloromethyltrimethylsilane. However, Me_3SiCl may be named as either chlorotrimethylsilane or trimethylsilyl chloride. Since hydrogen attached to silicon is a functional group capable of reduction of inorganic as well as organic compounds and *Hydrosilation*, compounds such as Ph_3Si–H and Et_3Si–H are referred to as organosilicon hydrides, specifically as triphenylsilyl hydride and triethylsilyl hydride. The

Covalent radii (Å)	0.772	1.176	1.225	1.405	(1.750)
M−M bond energies (kcal mol^{-1})	82.6	46.4	38.2	39	
Relative electron densities [Atomic number/(covalent radii)^3]	13.1	8.6	17.4	17.8	15.3
Electronegativity (Pauling)	2.55	1.90	2.01	1.96	2.33
Electronegativity (Allred-Rochow)	2.50	1.74	2.02	1.72	1.55

general name of organosilane does not indicate the presence of the Si–H group.

Compounds having the general formula $H_3Si(XSiH_2)_n XSiH_3$ have the generic names silazanes (X = NH), silthianes (X = S), and siloxanes (X = O). The name silmethylenes ($X = CH_2$) may also be used. Examples are:

- $Me_3Si–NH–SiMe_3$ hexamethyldisilazane
- $H_3Si–S–SiH_2–S–SiH_3$ trisilthiane
- $Me_3Si–O–SiMe_3$ hexamethyldisiloxane
- $Me_3Si–CH_2–SiMe_2–CH_2–SiMe_3$ octamethyltrisilmethylene

Cyclic compounds having the formula $(SiH_2X)_n$ are called cyclosilazanes, cyclosilthianes, cyclosiloxanes, and cyclosilmethylenes for compounds with X = NH, S, O, and CH_2. The oxa-aza convention can be used for complex systems. For example, $Me_3Si–CHPh–SiMe(CH{=}CH_2)–O–SiMe_3$ may be named 2,2,4,6,6-pentamethyl-5-phenyl-4-vinyl-3-oxa-2,4,6-trisilaheptane.

Simple hydroxy derivatives are named as silanol:

Me_3SiOH trimethylsilanol
$PhSi(OH)_3$ phenylsilanetriol

Silicon-functional compounds are named by using appropriate prefixes or suffixes. Me_3SiNH_2 is trimethylsilylamine or aminotrimethylsilane. Organic compounds with silyl substituent(s) are usually named by organic nomenclature. Thus Me_3SiCH_2CN is named trimethylsilylacetonitrile. In organic chemistry, trimethylsilyl is often abbreviated as TMS. Thus TMSOEt indicates ethoxytrimethylsilane.

For commercially important methylsiloxanes and polymethylsiloxanes (silicones), a shorthand siloxane notation is used. Mono- di-, tri-, and tetra- (quarternary) functional $Me_3SiO_{1/2}$-, $–O_{l/2}SiMe_2O_{1/2}$-, $MeSi(O_{1/2}\text{-})_3$, and $Si(O_{1/2})_4$ groups are abbreviated as M, D, T, and Q. Therefore $Me_3Si–O–SiMe_3$, $Me_3Si–(OSiMe_2)_8–O–SiMe_3$, and $(Me_2SiO)_3$, are, for example, represented as M_2, MD_8M, and D_3, respectively.

Table 2 lists representative classes of organosilicon compounds with a typical example. The same classes of organic compounds are compared in the table.

3 SYNTHESIS

The following five types of reactions may prepare organosilicon compounds.

1. Silicon−carbon bond forming reactions.
2. Cleavage of the silicon−carbon bond to give silicon-functionalized silanes.
3. Substitution reactions on silicon to give silicon-functionalized silanes.
4. Preparation of carbon functionalized silanes.
5. Synthesis of polysilanes (silicon−silicon bond formation).

3.1 Silicon–carbon Bond Forming Reactions

3.1.1 Direct Synthesis (The Rochow Process)

Direct synthesis is the reaction of alkyl or aryl chloride and silicon in the presence of a proper catalyst. Mostly, methyl chloride is subjected to the reaction at 250−350 °C in a fluid bed with fine particles of silicon mixed with a copper catalyst (equation 2).[2]

$$MeCl + Si \xrightarrow{Cu} Me_nSiCl_{4-n} \qquad (2)$$

Operating conditions are usually optimized to give dichlorodimethylsilane, Me_2SiCl_2, required for the production of methylsilicones. Nevertheless, mixtures of chlorosilanes are always obtained, as listed in Table 3. Boiling points being very close each other, an extensive fractionating system is employed to separate these chlorosilanes in the silicone industry.

3.1.2 Reactions of Organometallic Reagents and Si–X

The most important laboratory method of the preparation of particular organosilicon compounds is the reaction of an appropriate chlorosilane and a Grignard reagent (equation 3).

$$R_3SiCl + R'MgBr \longrightarrow R_3SiR' \qquad (3)$$

Table 2 Comparisons of representative classes of Si and C compounds

Carbon		Silicon	
Single bonded compounds			
R_3C–H	Alkane	R_3Si–H	Silane
R_3C–F	Fluoroalkane	R_3Si–F	Fluorosilane
R_3C–CI	Chloroalkane	R_3Si–I	Chlorosilane
R_3C–Br	Bromoalkane	R_3Si–Br	Bromosilane
R_3C–OH	Alcohol	R_3Si–H	Silanol

Table 3 Monomer composition of the direct synthesis products

Compound	% composition[a]	Bp (·C)
Me_4Si	0.01–0.5	26.6
$MeSiHCl_2$	1–6	41
Me_3SiCl	1–5	58
$MeSiCl_3$	3–10	66
Me_2SiCl_2	75–93	70

[a]Composition of the products depends on operating conditions.

$SiCl_4$, $SiHCl_3$, and various methylchlorosilanes are used in the reaction. When silicon carries more than two chlorine atoms, stepwise reaction occurs. Therefore partial alkylation (or arylation) is possible under carefully controlled conditions but, for that purpose, alkoxysilanes can conveniently be used because the reactivity of the last alkoxy group toward Grignard reagents is very low (equation 4).

$$MeSi(OEt)_3 + 2RMgBr \longrightarrow MeR_2SiOEt \quad (4)$$

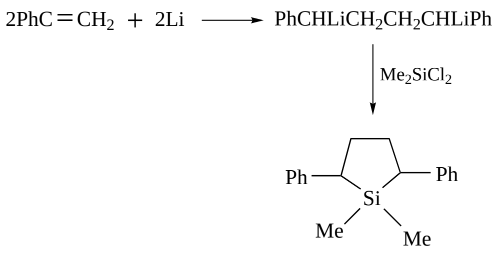
The relative reactivity of SiX toward Grignard reagent is shown in the following order: Si–CN > SiCl > SiOR > Si–OSi > SiH. Poly-Grignard reagents from X–$(CH_2)_n$–X give normal products when n is larger than 4. In the case of $n = 1$, in situ Grignard reactions can be utilized (equation 5).

$$2Me_3SiCl + CH_2Cl_2 \xrightarrow[\text{THF}]{\text{Li (in situ)}} (Me_3Si)_2CH_2 \quad (5)$$

Organolithium compounds can also be used conveniently for the preparation of silanes. Reactivity of the lithium reagents is higher than the corresponding Grignard reagents, as demonstrated by the following example. The reaction of $HSiCl_3$ and i-PrMgCl results in the formation of i-Pr_2SiHCl, but the reaction with i-PrLi gives rise to i-Pr_3SiH. Preparation of t-butyldimethylchlorosilane from dimethyldichlorosilane requires the use of t-BuLi but an interesting accelerating effect of CN^- has been observed for the reaction of chlorosilanes with bulky t-BuMgCl. The reaction may proceed through a pentacoordinate intermediate (equation 6).[3]

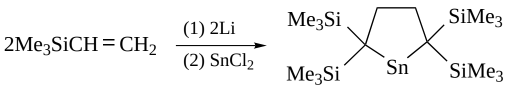
$$Me_2SiCl_2 + t\text{-BuMgCl} \xrightarrow[\text{THF, reflux}]{\text{CuCN}} t\text{- BuMe}_2SiCl \quad (6)$$

Dilithium reagents derived by reductive coupling of alkenes such as styrene and 1,1-diphenylethylene are important for the preparation of ring compounds (equation 7).

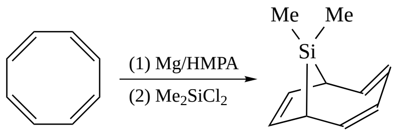


(7)

A similar dilithium reagent derived from 1,1-bis(trimethyl silyl)ethylene has been used for the protecting ligand of the first monomeric stannylene[4] (equation 8) and later, of various kinetically stabilized species (vide infra). Cyclooctatetraene undergoes 1,4-disilylation as shown below (equation 9).



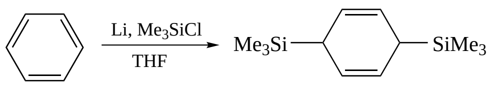
(8)



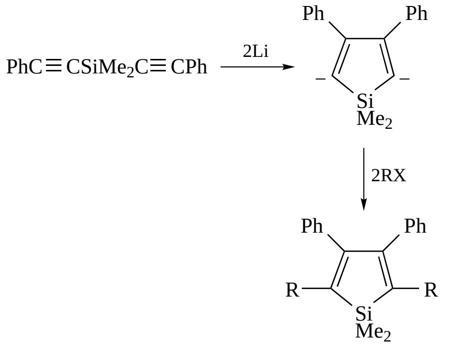
(9)

Closely related to the Birch reduction, benzene, and other aromatic compounds afforded reduction-silylation products (equation 10).[5] Electron-transfer reactions of bis(phenylethynyl)dimethylsilane gives 2,5-dianion of 3,4-diphenylsilole that is a useful intermediate to variously substituted siloles (equation 11).[6]

Examples using other organometallic reagents are illustrated in equations (12) and (13).



(10)



(11)

$$Me_3SiCl + o\text{-}Cl\text{–}C_6H_4Me + 2Na \longrightarrow o\text{-}(Me_3Si)C_6H_4Me + 2NaCl \quad (12)$$

$$Me_3SiCl + BrCH_2CO_2Et \xrightarrow{Zn} Me_3SiCH_2CO_2Et \quad (13)$$

3.1.3 *Reactions of Silylmetals*

Since silicon is a positive element, covalent bonds of most silicon compounds polarize as Si^{+}-X^{-}. However, silicon can form bonds with alkaline and alkaline earth metals to give silylmetals in which silicon compounds polarize as Si^{-}-M^{+}. These silylmetals are the source of silyl anions and react with haloalkanes to give the corresponding organosilanes (equation 14).

$$Me_3SiNa + C_5H_{11}Cl \xrightarrow[DMI]{} Me_3SiC_5H_{11} \quad (14)$$

Preparation of phenyl-substituted silyl anion is a simple process either from chlorosilanes or disilanes (equation 15).[7] Trimethylsilyl anions can he prepared from hexamethyldisilane by reaction with RM (RM=MeONa,[8] MeLi[9]) in a strongly basic solvent such as HMPA (hexamethyl phosphoramide).

$$2PhMe_2SiCl \xrightarrow{2Li} PhMe_2SiSiMe_2Ph \xrightarrow{2Li} 2PhMe_2SiLi \quad (15)$$

$$Me_3SiSiMe_3 + RM \longrightarrow Me_3SiM + Me_3SiR \quad (16)$$

$$RM = MeONa, MeLi$$

For the purpose of preparing trimethylsilylmetals, DMI (*N*,*N*-dimethylimidazolidinone) has been introduced as an efficient aprotic solvent. In fact, the choice of the solvent is important for the reaction (equation 14). In HMPA, electron transfer predominates to give products only in low yield, while in DMI the yield is almost quantitative.[10]

Silyllithium compounds may also be prepared by the transmetalation reaction between silylmercury and Li. The requisite silylmercury may be prepared from the corresponding chlorosilane or hydrosilane. The latter can be applied to the synthesis of polysilanyllithium. Equation (17) is an example.[11]

$$(Me_3SiSiMe_2)_2Hg \xrightarrow{2Li} 2Me_3SiSiMe_2Li \quad (17)$$

Diethylamino-substituted silyllithium is prepared successfully and used for the preparation of silicon-functional compounds (equation 18).[12]

$$Ph_2Si(NMe_2)Cl \xrightarrow[\text{THF, 0 °C}]{\text{Li (dispersion)}} Ph_2Si(NMe_2)Li \xrightarrow{Ph_2SiCl_2} Ph_2Si(NMe_2)SiMe_2SiPh_2(NMe_2) \quad (18)$$

A combination of trimethylsilyllithium, MeMgBr, and a manganese salt is reported to be equivalent to $(Me_3Si)_2MnMe$ that shows an interesting reaction (equation 19). Further recent development on silyl anion chemistry will be described in Section 5.1.

$$(Me_3Si)_2MnMe + Me_3Si-C\equiv C-SiMe_3 \longrightarrow (Me_3Si)_2C=C(SiMe_3)_2 \quad (19)$$

3.1.4 *Hydrosilation (Addition of Hydrosilane to Alkenes and Alkynes)*

Addition reactions of hydrosilanes to alkenes shown in the following general scheme are one of the most frequently utilized reactions for the preparation of organosilanes (equation 20).[13]

$$R_3SiH + R'CH{=}CH_2 \longrightarrow R_3SiCH_2CH_2R' \quad (20)$$

The reactions are further classified into three major categories: radical chain reactions, transition metal catalyzed reactions, and base-catalyzed reactions. In the radical chain reactions, dibenzoyl peroxide, di-*t*-butyl peroxide and α,α'-azobisisobutyronitrile (AIBN) are used most frequently as an

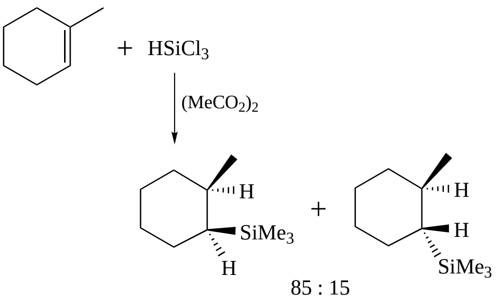
$$HSiCl_3 + In\bullet \longrightarrow Cl_3Si\bullet + InH$$

$$Cl_3Si\bullet + R{-}CH{=}CH_2 \longrightarrow R\dot{C}HCH_2SiCl_3$$

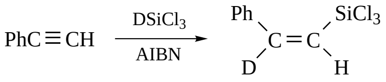
$$R\dot{C}HCH_2SiCl_3 + HSiCl_3 \longrightarrow RCH_2CH_2SiCl_3$$

Scheme 1

initiator. The characteristics of the reaction follow general free-radical reactions. Thus the regiochemistry of addition is an anti-Markovnikov fashion to produce the more stable radical. The trans-addition is generally observed for addition. Relative reactivity of hydrosilanes is determined by the polarity and bond dissociation energy of the Si–H bond. The order of the reactivity is: $HSiCl_3 > HSiRCl_2 > HSiR_2Cl > HSiR_3$. Reactive hydrosilanes such as $HSiCl_3$ are used most commonly (Scheme 1, and equations 21 and 22).



(21)



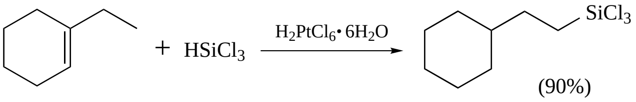
(22)

Hydrosilation reactions catalyzed by transition metal complexes have wide scope and applicability and hence used most conveniently for the silicon–carbon bond formation. Chloroplatinic acid, platinum on carbon or alumina, platinum(II) and platinum(0) complexes, $Co_2(CO)_8$, $NiCl_2{\cdot}(PPh_3)_2$ and $RhCl(PPh_3)_3$ are effective catalysts, among others. In particular, chloroplatinic acid, $H_2PtCl_6{\cdot}6H_2O$, known as Speier's catalyst, is the most commonly used and efficient catalyst, especially for the hydrosilation of alkenes. This catalyst, which is used as a solution in isopropyl alcohol, is quite efficient, only a minute amount in the range $10^{-5}-10^{-8}$ mole per mole of hydrosilane being necessary. Therefore the catalyst is not normally recovered from the product in the commercial process even though platinum is a precious metal. The Pt^0 catalyst, $Pt_2(H_2C{=}CSiMe_2OSiMe_2CH{=}CH_2)$, is also used extensively.

The reaction is also utilized for cross-linking between vinyl-substituted siloxanes and oligomeric hydrosilanes in the production of room-temperature vulcanizable silicone rubber. Reaction can be carried out without solvents, but common solvents such as benzene, toluene, dichloromethane, THF, and acetonitrile can be employed as well. A wide variety of 1-alkenes are hydrosilated regiospecifically to give the corresponding terminal addition products in high yields. Usually, reactions take place exothermically (equation 23).

(23)

Regiospecificity of the reaction is normally high but with some alkenes, such as styrene, considerable amount of the β-isomer (38.5%) is produced exceptionally in addition to the α-isomer (58.7%). Interestingly, alkenes having an inner double bond undergo hydrosilation with isomerization to give exclusively terminal products, as shown in equation (24).



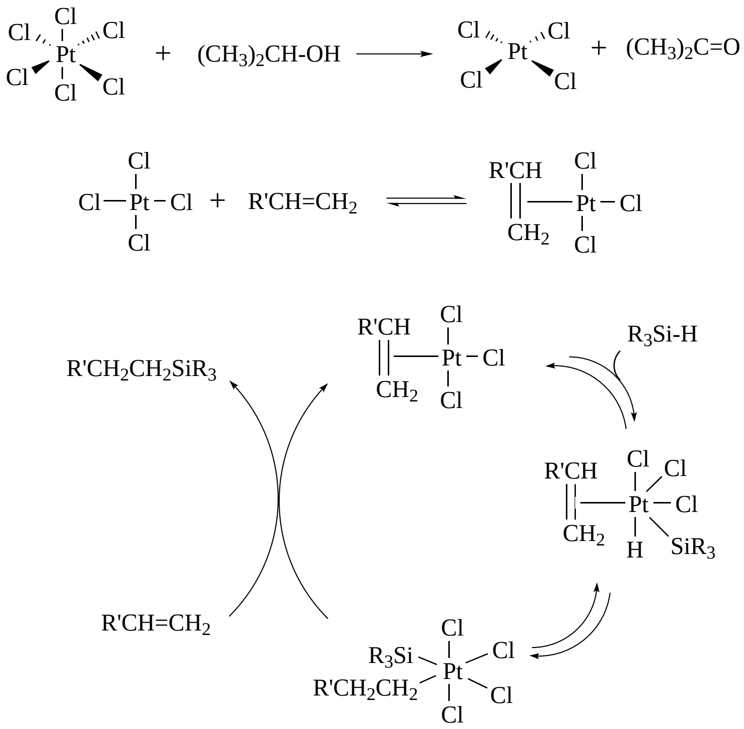
(24)

Isomerization does not take place on the products. No isomerization of alkenes occurs with the action of chloroplatinic acid alone, but recovered alkenes from a silane-alkene mixture often contain isomers of the alkene. D-H exchange is observed for the recovered hydrosilane from the hydrosilation mixture with $DSiCl_3$. These facts suggest the mechanism outlined in Scheme 2, which is known as the Chalk-Harrod mechanism.[14] The mechanism involves oxidative addition of hydrosilane to the active species of the catalyst, coordination of alkene, followed by $\sigma - \pi$ conversion, and reductive elimination of the product.

The Chalk-Harrod mechanism has been accepted for many years as a typical example of a homogeneous catalysis process. However, it has been recently suggested that the formation of colloidal platinum could be the key step in the action of Speier's catalyst.[15] Hydrosilation reactions with other catalysts such as $Co_2(CO)_8$, $NiCl_2(PPh_3)_2$, and $RhCl(PPh_3)_3$ are definitely homogeneous and probably follow the Chalk-Harrod mechanism. The step of reductive elimination is indicated to go with retention of configuration on carbon, the overall stereochemistry at silicon being also retention. Acetylenes gave syn addition products as shown in equations (22) and (25).

(25)

Alkenes with a variety of substituents such as acetal, amine, amide, carbamate, ester, ether, isocyanate, ketone, oxirane, and sulfide can be hydrosilated, usually without affecting the functional group. However, this is not always true; for example, allyl chloride gives a considerable amount of the reduction product (see equation 26). Table 4 lists representative examples of hydrosilation. It is not so remarkable in the case of radical hydrosilation, but reactivity is high for hydrosilane, which has electronegative group in the case of transition metal catalyzed hydrosilation.



Scheme 2

Table 4 Hydrosilation of unsaturated compounds

Unsaturated compound	Hydrosilane	Catalyst	Product (% yield)

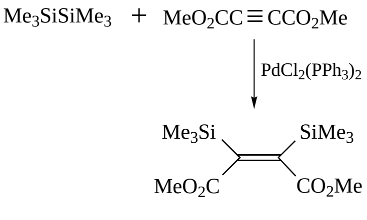
$$HSiCl_3 + CH_2{=}CHCH_2Cl \xrightarrow{H_2PtCl_6\cdot 6H_2O} Cl_3Si(CH_2)_3Cl + CH_2{=}CHCH_3 \quad (26)$$

The $[2\sigma + 2\pi]$ addition reaction of disilanes and acetylenes is closely related to hydrosilation. The prototype of the reaction is shown in the next example (equation 27).[16,17] The cis addition is established similar to hydrosilation.



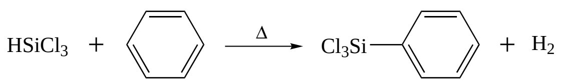
(27)

Base-catalyzed addition is almost limited to the addition of trichlorosilane to acrylonitrile. *t*-Amines and phosphines are used as catalysts (equation 28).

$$HSiCl_3 + CH_2{=}CHCN \xrightarrow{base} Cl_3SiCH_2CH_2CN \quad (28)$$

3.1.5 *Condensation of Hydrosilanes with Hydrocarbons and Halogenated Hydrocarbons*

Trichlorosilane reacts with benzene in the vapor phase at 400–500 °C to give trichlorophenylsilane. Reaction temperature falls to 270–350 °C and yield improves by addition of a catalyst such as BF_3 and BCl_3 (equation 29).



(29)

Under UV irradiation, Cl_2 catalyzes the reaction of trichlorosilane and benzene to give phenyltrichlorosilane in yield higher than 87%. The reaction of benzene with dichloromethylsilane gives $CH_3(C_6H_5)SiCl_2$ under the similar conditions in 65% yield. It is suggested that a radical process is involved in the reaction. Silation of aromatic compounds with well-defined silyl radicals generated in solution gives detailed information about the nature of homolytic aromatic silation.[18] It is noteworthy that the addition of silyl radicals to aromatics is a reversible process and therefore, product distribution depends on the reaction temperature[19] (Scheme 3).

Dehydrochlorinative coupling of hydrosilane with aryl or alkenyl chloride is utilized in the industrial synthesis of trichlorophenylsilane, methyldichlorophenylsilane, trichlorovinylsilane, and dichloromethylvinylsilane (equations 30 and 31). These reactions are usually carried out in the vapor phase at high temperature and accompanied by side reactions such as redistribution and reduction.

$$HSiCl_3 + C_6H_5Cl \xrightarrow{500-600\,^\circ C} C_6H_5SiCl_3 + HCl \quad (30)$$

$$HSiCl_3 + CH_2{=}CHCl \xrightarrow{500-600\,^\circ C} CH_2{=}CHSiCl_3 + HCl \quad (31)$$

The reaction of 2-chloropropene, trichlorosilane, and amine in the presence of a catalytic amount of copper(1) chloride proceeds smoothly under mild conditions to give allyltrichlorosilane in high yield[20] (equation 32).

$$HSiCl_3 + CH_2{=}CHCH_2Cl \xrightarrow[R_3N]{CuCl} CH_2{=}CH_2CHSiCl_3 \quad (32)$$

3.1.6 *Other Reactions*

A variety of reactions generate new silicon–carbon bonds, although most of them are not utilized in the systematic synthesis of organosilicon compounds. Representative and interesting examples are shown in the following.

(Chloromethyl)trichlorosilane is formed in 60% yield by the reaction of tetrachlorosilane and diazomethane in ether at low temperature (equation 33).

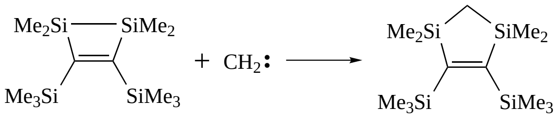
$$SiCl_4 + CH_2N_2 \longrightarrow Cl_3SiCH_2Cl + N_2 \quad (33)$$

Second and third methylenations are possible but with increasing difficulty. The reaction of trialkylsilane with a Simmons-Smith reagent gave the methylenation product. The reactivity of tri-n-butylsilane toward iodomethylzinc iodide is much higher than cyclohexene. Indeed, trialkytsilanes are good trapping reagents for divalent species such as carbene and silylene (equations 34 and 35).

$$Et_3SiH + ICH_2ZnI \longrightarrow Et_3SiCH_3 + ZnI_2 \quad (34)$$

$$Me_2Si\colon + Et_3Si\text{-}H \longrightarrow Et_3Si\text{–}SiMe_2\text{–}H \quad (35)$$

Methylene insertion into a silicon–silicon bond is also possible for a reactive Si–Si bond (equation 36). Insertion reactions of divalent silicon species, silylene, also occur to the same substrate. Silylene forms a new silicon–carbon bond with a variety of substrates, which will be described later.



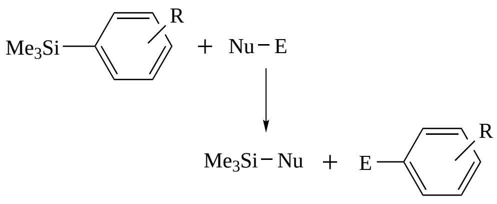
(36)

3.2 Synthesis of Silicon-functionalized Silanes by Cleavage of the Silicon–Carbon Bond

Silicon–carbon bonds are cleaved by the action of various reagents, and electronegative groups such as halogen and alkoxy are introduced into the silicon part. Therefore these reactions are utilized for introduction of functionality into silicon. Cleavage of the Ar–Si bonds is simple with electrophilic reagents. Halodesilation is important for the preparation of chlorosilanes (equation 37).

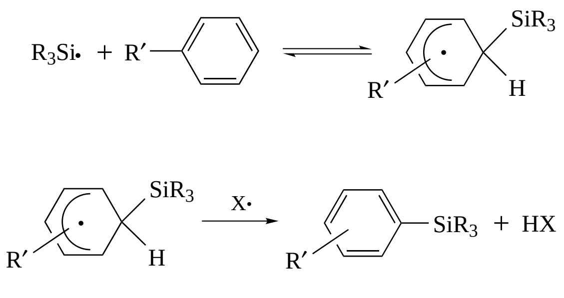
$$Ph_3SiLi + Me_3SiCl \longrightarrow Ph_3SiSiMe_3 \xrightarrow{HCl/AlCl_3} Cl_3SiSiMe_3 \quad (37)$$

Arylsilanes undergo ipso-desilylation by electrophilic attack with E–Nu to give Ar–E and Nu–SiR_3. The reaction is useful for the preparation of both aryl derivatives and silicon-functionalized silanes (equation 38).



(38)

Nu – E = D – Cl, CH_3CO – Cl / $AlCl_3$, Br – Br, *t*-Bu – Cl / $AlCl_3$, NO_2 – OH / Ac_2O, etc



Scheme 3

The chlorodemethylation reaction with a 1:1 mixture of acetyl chloride and aluminum chloride is a standard procedure for the preparation of chlorosilanes in the laboratory (equation 39).

$$Me_3SiSiMe_3 \xrightarrow{CH_3COCl\,/\,AlCl_3} Me_3SiSiMe_2Cl$$
$$Me_3SiSiMe_3 \xrightarrow{2CH_3COCl\,/\,AlCl_3} ClMe_2SiSiMe_2Cl \qquad (39)$$

In the presence of a catalytic amount of aluminum chloride, hydrogen chloride, or trimethylchlorosilane also undergoes cleavage of the Si–C bond. The latter is an example of a redistribution reaction (equation 40). Facile cleavage of the allyl-silicon bond has been utilized for the preparation of iodotrimethylsilane (equation 41).[21]

$$Me_3SiSiMe_3 + Me_3SiCl \xrightarrow{AlCl_3} Me_3SiSiMe_2Cl + Me_4Si \qquad (40)$$

$$CH_2{=}CHCH_2SiMe_3 + I_2 \longrightarrow CH_2{=}CHCH_2I + Me_3SiI \qquad (41)$$

The silicon–carbon bond can also be cleaved by strong nucleophiles to give the corresponding carbanions, which may be utilized as the source of carbon nucleophiles in synthesis (equations 42 and 43).

$$(Me_3Si)_2CH_2 + NaOMe \xrightarrow{HMPA} Me_3SiCH_2^-Na^+ + Me_3SiOMe \qquad (42)$$

$$CH_2{=}CHCH_2SiMe_3 + F^- \longrightarrow CH_2{=}CHCH_2^- + Me_3SiF \qquad (43)$$

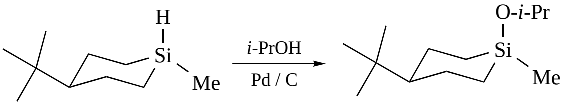
3.3 Synthesis of Silicon-functional Silanes by the Substitution Reactions on Silicon

Silicon centers having electronegative group(s) (leaving group(s)) receive nucleophilic attack easily to give the substitution products. Chloro, alkoxy, and sometimes hydride groups are common leaving groups on silicon. Substitution reactions with carbon nucleophiles serve for the formation of carbon–silicon bonds as described in Section 3.1.2. These reactions are mechanistically related to the corresponding reactions at the carbon center, so that S_N1 and S_N2 notations are frequently used also for the reaction at silicon center. However, rigorously speaking, it should be noted that S_N reactions are defined to the carbon centers. Accordingly, for example, the reaction of Me_3SiCl with $PhCH_2Li$ to give Me_3SiCH_2Ph should be designated as the S_E reaction at the carbon center. It is convenient, however, to assign this reaction as S_N2 at the silicon center. To give a clear and accurate explanation, these reactions may be designated as S_N2(Si) or S_N2-Si. Hydrosilanes also undergo radical chlorination (equation 45). Mechanism and reactive intermediates of these reactions will be described later; here, synthetically useful examples are listed (equations 44–52).

$$Et_3SiCl \xrightarrow{LiAlH_4} Et_3SiH \qquad (44)$$

$$R_3SiH + CCl_4 \xrightarrow{(PhCO_2)_2} R_3SiCl + CHCl_3 \qquad (45)$$

$$Et_3SiH + I_2 \longrightarrow Et_3SiI + HI \qquad (46)$$



(47)

$$Me_3SiCl + H_2O \longrightarrow Me_3SiOH + HCl \qquad (48)$$

$$Ph_2Si(OEt)_2 + 2PhCOCl \longrightarrow Ph_2SiCl_2 + 2PhCO_2Et \qquad (49)$$

$$Me_3SiCl + 3NH_3 \longrightarrow Me_3SiNHSiMe_3 + 2NH_4Cl \qquad (50)$$

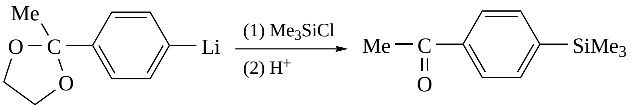
$$Me_3SiCl + AgCN \longrightarrow Me_3SiCN + AgCl \qquad (51)$$

$$MePhSiCl_2 + 2MeOH \longrightarrow MePhSi(OMe)_2 + 2HCl \qquad (52)$$

3.4 Preparation of Carbon Functional Silanes

Carbon functional silanes are compounds having substituent(s) with functional group(s) on carbon(s). Me_3SiCH_2Cl, $Me_3SiCH_2CH_2CH_2\,NH_2$, and $Ph_3SiCOPh$ are examples. Preparations of these compounds are classified in two ways: (1) introduction of an organic group with functional group(s) to the silicon center, and (2) introduction of functional group(s) to a hydrocarbon substituent of silanes. The former is typically shown in the next two examples. In principle, any group can be introduced into the silicon center, provided that the corresponding lithium or Grignard reagents can be derived for those groups (equations 53 and 54).

$$MeOCH_2CH_2CH_2MgCl + Me_3SiCl \longrightarrow MeOCH_2CH_2CH_2SiMe_3 \qquad (53)$$

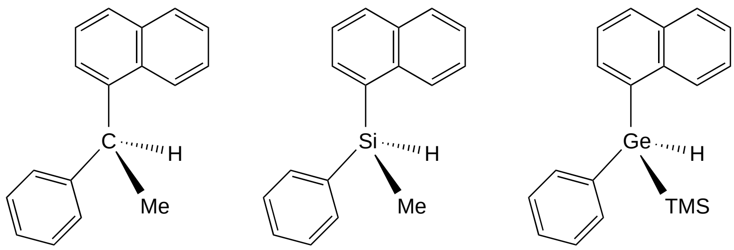


(54)

The latter is essentially an organic transformation, and all the known reactions can be applied. However, one should bear in mind that the elimination reaction involving the organosilyl group is rather facile with both strong electrophiles and nucleophiles and that the trialkylsilyl group exerts specific electronic effects, which will be described later.

3.5 Silicon–Silicon Bond Formation

The formation of the Si–Si bond occupies a special position in organosilicon chemistry. Silicon is one of the few elements, which can form stable catenated compounds. Besides high-molecular weight polysilanes, oligomeric polysilanes are a very important class of compounds that are related to silylenes,



$[\alpha]_D$ 7.5° $[\alpha]_D$ 34.9° $[\alpha]_D$ 26.7°

Figure 1 Isoconfigurational series

organosilylmetals, silicon–silicon double-bonded species, and photochemistry.

Wurtz coupling reactions of chlorosilanes are the main route to the silicon–silicon bonded compounds. For example, hexamethyldisilane can be prepared by refluxing trimethylchlorosilane with lithium sand in THF (97%). Lithium may be substituted by sodium by using a mixture of HMPA–THF as the solvent. Linear and branched oligosilanes can be prepared by the same method (equations 55–57).

$$2Me_3SiCl + 2Li \xrightarrow[THF]{} Me_3SiSiMe_3 + 2LiCl \qquad (55)$$

$$4Me_3SiCl + SiCl_4 \xrightarrow[THF]{Li} (Me_3Si)_4Si \qquad (56)$$

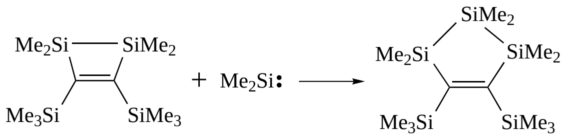
$$Me_3SiCl + n\ Me_2SiCl_2 \xrightarrow[THF]{Li} Me_3Si(Me_2Si)_nSiMe_3 \qquad (57)$$

The intermediate of the reaction may be the silyl-alkali metal species, so that the reaction of the silyl-alkali metal derivatives with chlorosilane resulted in the formation of the silicon–silicon bonded compound (equation 58).

$$Ph_3SiLi + Me_3SiCl \longrightarrow Ph_3SiSiMe_3 + LiCl \qquad (58)$$

Silylene insertion into the Si–H bond as well as silylene insertion into the Si–Si bond forms new silicon–silicon bonds (equations 59 and 60).

$$Et_3SiH + Me_2Si\mathbf{:} \longrightarrow Et_3SiSiMe_2H \qquad (59)$$



(60)

Finally, the coupling reaction of two silyl radicals gives the corresponding disilane. In this respect, mercury sensitized dehydrogenative coupling of hydrosilane is noteworthy. Other methods of forming polysilanes, related to the formation of high-molecular weight polysilanes, will be described later.

4 STRUCTURE AND BONDING

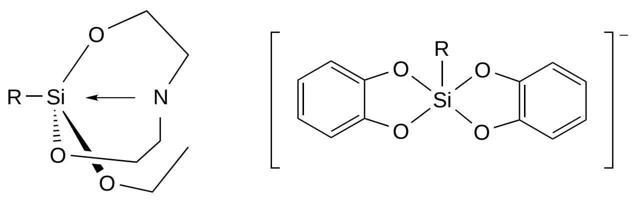
4.1 Tetrahedral Compounds

The geometry of most organosilanes is tetrahedral using the sp^3 hybridized orbitals on silicon. Like carbon, optically active silanes are possible when central chirality exists. A series of monofunctional optically active silanes can be prepared and used for stereochemical studies. These are the methyl(naphthyl)phenylsilyl derivatives, which are commonly abbreviated to R_3Si^*X.[22] Together with the similar germanium compound, the isoconfigurational series of compounds are shown in Figure 1.

4.2 Penta- and Hexacoordination

Contrary to carbon, silicon can form penta- or hexacoordinated compounds. The formation of such higher coordinated silicon compounds is frequently explained in terms of incorporation of d orbitals to form either sp^3d or sp^3d^2. However, a three-center four-electron bond can also describe the bonding. Both descriptions require electronegative substituents for stable complexes. Indeed, higher coordinated silicon compounds are made with electronegative substituents such as Cl, F, NR_2, and RO (Figure 2).

Electronegative atoms adjacent to silicon would contract the d orbitals and transfer electrons to form a dative bond. This concept is called pπ-dπ or (p-d)π bonding (*see* $p_\pi - d_\pi$ *Bonding*) and has been used to explain a number of unique



$[CH_2=CH-CH_2-SiF_4]^-$ $[C_6H_5SiF_5]^{2-}$

Figure 2 Penta- and hexacoordinated silicon compounds

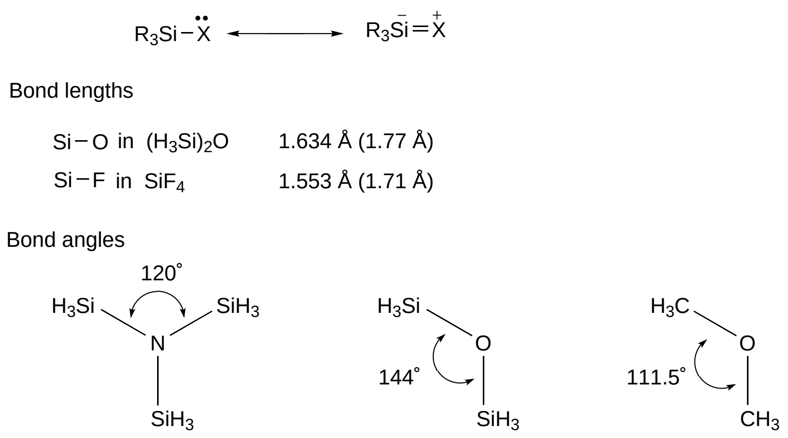


Figure 3 Examples of anomalous bond lengths and angles. Numbers in parentheses are calculated values

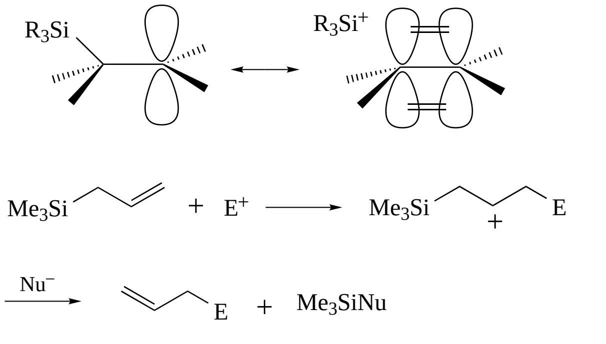
structural features such as shorter experimental bond lengths than calculated for Si–O and Si–F, planarity about nitrogen of $(H_3Si)_3N$, and the wider bond angle of disilazane than dimethylamine.[23] However, there is controversy over the theoretical proposals of (p-d)π bonding. The shorter bond lengths of silicon to electronegative elements may be explained by a larger contribution of ionic structures such as R_3Si^+ X^-. Thus contribution of $\sigma^*-\pi$ conjugation may also be significant (Figure 3), as will be described later.

4.3 σ–π Conjugation

Organosilicon reactions, which involve carbenium ion formation or development β to silicon, are much accelerated (β effect). This substituent effect of the silyl group is referred as hyperconjugation or $\sigma-\pi$ conjugation. This effect is extremely important in controlling the regiochemistry and reactivity in a number of reactions in which a positive charge is developing. Reactions of allylsilanes are typical examples and are used extensively in organic synthesis (Scheme 4).[24]

The $\sigma-\pi$ conjugation effect is spectroscopically best documented in a number of compounds such as allylic and benzylic silanes. The following examples demonstrate the



Scheme 4

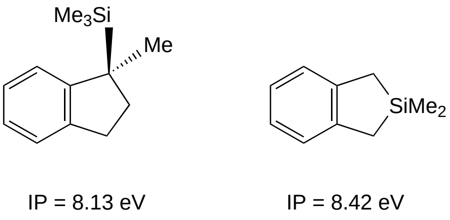


Figure 4 Stereoelectronic effect in $\sigma-\pi$ conjugation

effect most convincingly. Thus ionization potentials (IP) of 1-trimethylsilylindan, where $\sigma-\pi$ conjugation due to the trimethylsilyl group is possible, is lower than that of 2-silaindan in which the carbon–silicon bond is placed in the π nodal plane and hence $\sigma-\pi$ conjugation is impossible (Figure 4).

The σ(Si–Si)-π conjugation is equally important. The effect was first evidenced by the discovery of unusually large bathochromic shifts in UV spectra of pentamethylvinyldisilane ($\lambda_{max} = 223$ nm) and phenylpentamethyldisilane ($\lambda_{max} = 231$ nm) compared with those of trimethylvinylsilane ($\lambda_{max} = 178$ nm) and trimethylphenylsilane ($\lambda_{max} = 211$ nm), respectively.[17,25] The importance of σ(Si–Si)-π conjugation has been demonstrated also in charge transfer and photoelectron spectra and finally confirmed by the stereoelectronic effect.[26] 1,1,2.2-Tetramethyl-3,4-benzo-1,2-disila-3-cyclopentene has both C–Si and Si–Si bonds in the nodal plane of the π system, so that no $\sigma-\pi$ conjugation is possible. Indeed, the characteristic ^1L_a band of Ph–Si–Si at 231 nm disappeared (Figure 5).

4.4 σ^*–π Conjugation

Silicon can stabilize α-carbanions or polarized α-metalloids in spite of the electropositive nature of silicon. Such stabilization has been accounted for involving (p-d)π bonding.

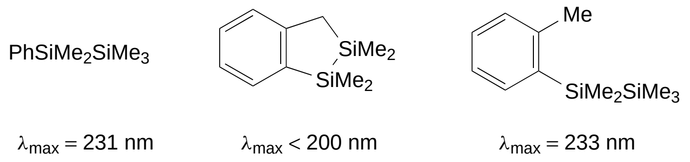

Figure 5 UV spectra of phenyldisilane derivatives showing σ(SiSi)$-\pi$ conjugation

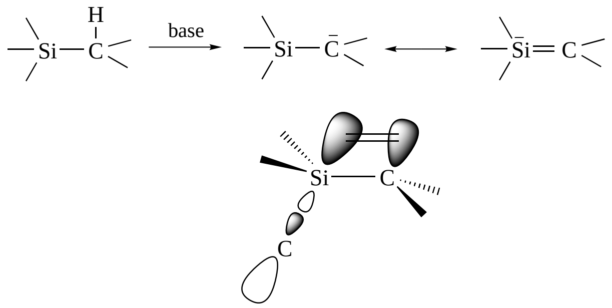
However, more recently, stabilization for α-carbanions or polarized α-metalloids is explained in terms of the $\sigma^*-\pi$ conjugation (Scheme 5).

α-Carbanions or α-metalloids are important as a source of carbanions and are used frequently in organic synthesis (vide infra).

The trialkylsilyl group exerts effects to appropriately substituted π-electron systems in two ways as electron donor and acceptor. The R_3SiCH_2-group shows a strong electron-donating effect to the adjacent π-electron systems by the mechanism of σ(Si–C)-π hyperconjugation. For example, photoelectron spectroscopy indicated that the HOMO energy level of trimethylallylsilane was raised from ethylene. On the other hand, the trialkylsilyl group can behave as an electron acceptor to directly bonded π-electron systems owing to $\sigma^*-\pi$ conjugation. In planar silyl-substituted alkenes, no strong σ(Si–C)-π conjugation exists but a lowering effect to the LUMO was indicated by electron-transmission spectra for vinyltrimethylsilane.



Scheme 5

Figure 6 shows relative orbital energies of trimethylvinylsilane and allyltrimethylsilane compared with ethylene.[27] The fact that IP of trimethylvinylsilane is lower than that of ethylene indicates the electron-donating effect of the trialkylsilyl group that is due to the lower electronegativity of silicon than carbon. But at the same time, the LUMO of trimethylvinylsilane is lowered. The HOMO of allyltrimethylsilane is raised relative to ethylene. These facts give the grounds that trimethylvinylsilane is susceptible to nucleophilic attack, whereas allyltrimethylsilane is reactive towards electrophiles.

The steric effect of the trimethylsilyl group is rather small when it stands singly but the cumulative steric effects should

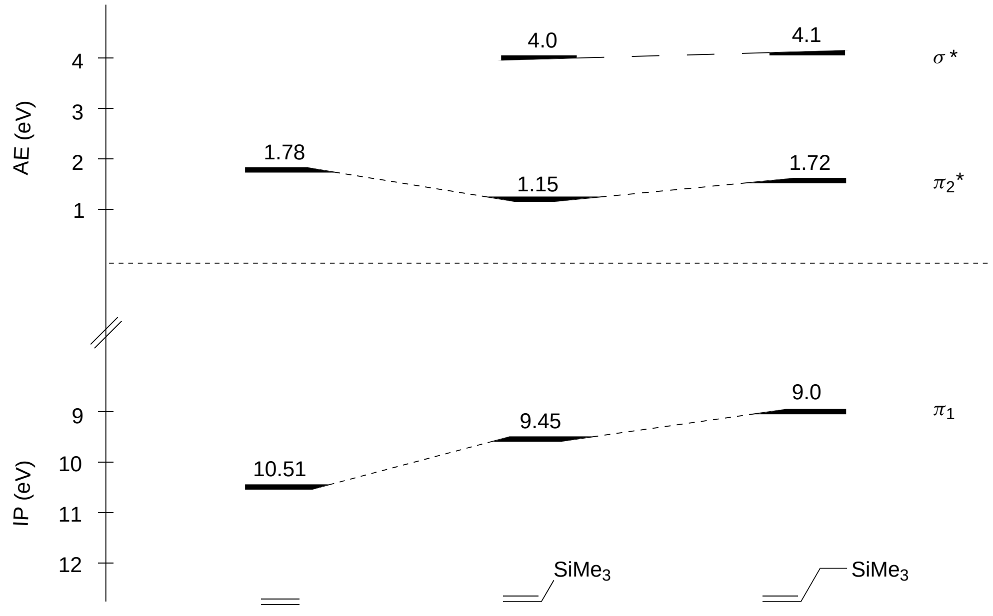


Figure 6 Relative HOMO–LUMO ievels determined by ionization energy (lP) andattachment energy (AE)

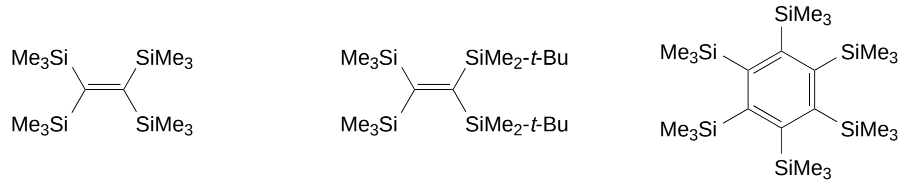

Double bond is twisted by 29.5°. Double bond is twisted by 49.6°. Boat form benzene

Figure 7 Over-crowded π-electron systems

be very large when the trimethylsilyl group substitutes the molecule extensively. Both tetrakis(trimethylsilyl)ethylene[28] and hexakis(trimethylsilyl)benzene[29] cannot maintain the π-systems planar to show interesting chemical and physical properties. Olefinic carbons of both tetrakis(trimethylsilyl)ethylene and 1,1-bis(*t*-butyldimethylsilyl)-bis(trimethylsilyl)ethylene are strictly coplanar with silicon substituents but twist of double bonds are 29.5° and 49.6°, respectively. These are most twisted olefins. Hexakis(trimethylsilyl)benzene is a boat-form benzene and undergoes facile isomerization (Figure 7).

4.5 Bond Lengths and Bond Energies

Table 5 lists selected bond lengths of tetracoordinated silicon-element and the corresponding carbon-element bonds. As noted before, the bond lengths for silicon bonded to elements more electronegative than carbon tend to be shorter than the calculated values.

Bond lengths of silicon can also be affected by the coordination number of the compound to some extent. The representative values are listed in Table 6. All the Si–X bonds become longer in higher coordinated states.

Selected bond dissociation energies are compiled in Table 7. Although bond lengths of silicon compounds are longer than the corresponding carbon compounds, silicon forms stronger bonds than carbon.[30]

5 REACTIONS AND REACTIVE INTERMEDIATES

Organosilicon compounds receive attack of nucleophilic, electrophilic, and homolytic reagents. The latter is related to the formation of radicals and divalent species. Organosilicon reactive intermediates corresponding to free radicals, carbenium ions, carbanions, and carbenes play important roles in these reactions. These are silyl radicals,[31] silylium

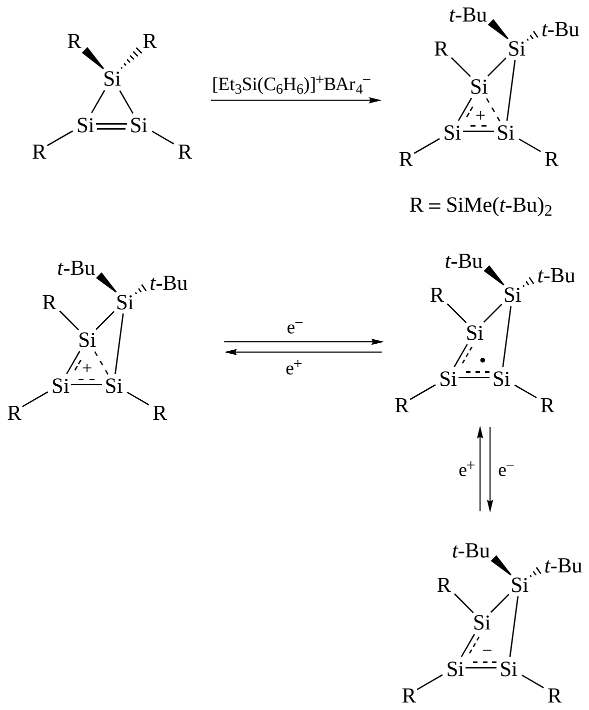
ions,[32] silyl anions,[33] and silylenes.[34] Reaction patterns and reactivities of these reactive intermediates largely resemble those of carbon intermediates. The stereochemistry and mechanism of substitution reactions at silicon can be compared with those at carbon but are much more complicated.

5.1 Ionic Reactions

Silylium ions or silico cations are formed more readily than carbenium ions in the vapor phase by electron impact, as evidenced by the fact that the base peak of the mass spectra of trimethylsilyl derivatives is almost always the trimethylsilylium. This means that silicon can support a positive charge more strongly than carbon owing to its more electropositive nature. However, there is too little evidence of the formation of trivalent silylium ions in solution. Two factors may account for the facts: the counter anions normally used to the stabilized carbenium ions (such as perchlorate and tetrafluoroborate) bind to silicon strongly (silicophilic), and bond lengths of silicon and substituents are 1.5 times longer than those of the corresponding carbon compounds, so that the requisite steric congestion for the $S_N1(Si)$ over the $S_N2(Si)$ mechanism is lacking. A recent study shows that the attempted generation of silylium ions with nonnucleophilic borate counter anions resulted in the formation of silylium ion-solvent complexes. However, these results do not exclude the generation of 'free' silylium ions under proper conditions. Indeed, the crystal structure of $Et_3Si^+ BAr_4$ ($Ar{=}C_6F_5$) has been determined, where the interaction of the 'silylium ion' with the solvent toluene is minimal (equation 61).[35]

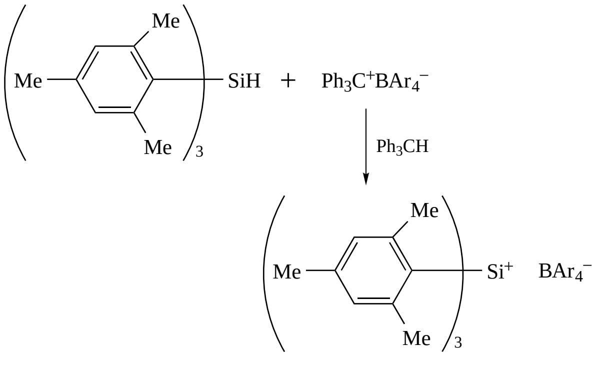
$$R_3SiH + Ph_3C^+BAr_4^- \xrightarrow{Ph_3CH} [R_3SiOEt_2]^+BAr_4^- \quad (61)$$

A solvent-free but delocalized silylium ion has been prepared recently.[36] Interestingly, the silylium ion undergoes reversible redox reaction to give the corresponding radical and anion (equation 62).[37] The silylium ion is indicated to be a homotrisilacyclopropenium ion. In fact, 1,3-length of the silylium ion is much shorter than that of the corresponding radical.[38]



(62)

With a bulkier substituent (2,4,6-trimethylphenyl = Mes), $Mes_3Si^+ B(C_6F_5)_3$ is indicated as an isolated silylium in solution[39] and very recently the cation is proved to be a completely free silylenium ion (equation 63).[40]



(63)

The $S_N2(Si)$ mechanism at silicon is quite common. However, the fundamental difference between carbon and silicon in the S_N2 mechanism is the fact that the pentacoordinate structure with attacking and leaving nucleophiles is not the transition state but an intermediate in silicon, contrary to carbon. In fact, in some cases, stable silicon compounds with the pentacoordinate structure can be isolated (see Figure 2). This fact is mainly due to the longer bond lengths of silicon compounds, where five ligands can be accommodated around the silicon atom.[41] Existence of stable pentacoordinate intermediates makes the stereochemistry of $S_N2(Si)$ reactions very complicated; not all S_N2 reactions at silicon occur with inversion, while at carbon inversion of the configuration is observed without exception. Thus, the larger size of silicon compared with carbon permits the attack of nucleophiles (*see Nucleophile*) from different directions, not only from the back side to result in inversion but from the flank side to give the retention product (Table 8).

Generally speaking,[42] reactions of silicon compounds with poor leaving groups such as H and OR result in retention of configuration. Inversion occurs only with strongly charge-delocalized reagents such as Ph_2CHLi (soft nucleophiles), whereas with a good leaving groups like Cl or Br, inversion is observed. The leaving groups F and SR show intermediate behavior, leading to either inversion or retention according to the attacking nucleophiles: inversion with allyllithium, benzyllithium, and $LiAlH_4$ (soft nucleophiles), but retention with alkyllithium and alkoxides (hard nucleophiles) (Hard & Soft Acid-base Theory).

The results are best explained in terms of interaction between the HOMO of the nucleophile and the LUMO of the substrate.[43] As shown in Figure 8, the flank-side attack to give the retention product corresponds to the interaction of the nucleophile with the large lobe on silicon. This attack corresponds, at the same time, to interaction with the orbital of the leaving group in an unfavorable out-of-phase fashion. The back-side attack with inversion involves interaction with the small lobe on silicon but no out-of-phase interaction. Determination of the stereochemistry depends on the equilibrium between these two directions. Hard nucleophiles have small, contracted, and high lying valence orbitals, so that overlap with the orbital of the leaving group

Table 8 Stereochemical behavior of $R_3Si^*–X$ in the reaction with nucleophiles

X	Nucleophile (solvent)	Product	Stereochemistry[a]
H	KOH (xylene)	$R_3Si^*–OK$	RN
	RLi (R = Me, Bu, THF)	$R_3Si^*–R$	RN

[a]RN = retention, IN = inversion.

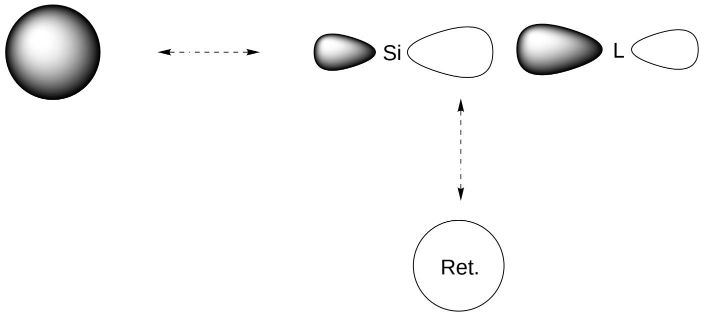

Figure 8 Frontier orbital interactions at S_N2 reactions of silicon

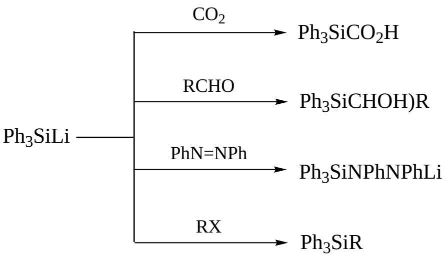
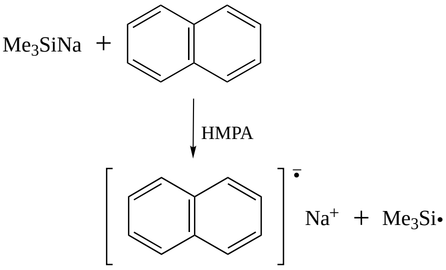
is very small to result in the flank-side attack. On the other hand, soft nucleophiles have usually large, diffused, low-lying delocalized orbitals, which may interact equally with orbitals of substrate and leaving group when the flank-side attack occurs. Therefore the back-side attack predominates to favor inversion products.

Silyl anions (silyl-alkali metal derivatives) have been prepared as described in equations (15–17). Reactions of triphenylsilyl anions with electrophiles give the expected products.[44] Silyl anions have a considerable configurational stability (equation 64).



(64)

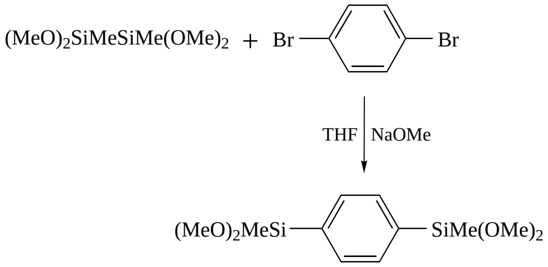
Trimethylsilyl anions also give the substitution products by the reaction with alkyl chloride in almost quantitative yield (equation 14), but considerable amounts of electron-transfer products are produced as well in HMPA. Indeed, Me_3SiNa/HMPA is an excellent reagent to produce anion radicals (Table 9) from aromatic hydrocarbons for ESR (electron spin resonance) studies (equation 65).[45]



(65)

Silyllithium forms polymeric structures in the solid state, the structure being dependent on the nature of the silyl group. Trimethylsilyllithium is hexameric with a Li_6 skeleton of a highly folded chair in the solid state.[46] Pentamethyldisilanyllithium is tetrameric with a tetrahedral Li_4 skeleton. Four pentamethyldisilanyl groups occupy the center of the face to interact with three lithium atoms.[47] The structure of non-solvated monomeric silyllithium, $(t\text{-}Bu_2MeSi)_3SiLi$, is nearly planar. The Si–Si bond lengths are significantly shortened (av. 2.3632 Å) relative to those of $(t\text{-}Bu_2MeSi)_3SiH$ (av. 2.450 Å), indicating the existence of hyperconjugation between the central anionic p orbital and adjacent Si–Cσ*-orbitals.[48] Probably, this is also the origin of planarity of the silyl anion similar to the case of trisilylamine.

Silicon-functional silyllithium should be interesting intermediates to a variety of silicon-functional compounds. Chlorine substituted silyllithium is unstable to undergo α-elimination to give silylenes. Alkoxy-substituted silyllithium may be generated *in situ* reaction conditions and undergoes useful substitution reaction (equation 66).[49]



(66)

Diethylamino-substituted silyllithium is much more stable and useful for the preparation of silicon-functional compounds as described before (equation 18).

1,2-Dilithiosilanes have been known.[50] 1,1-Dilithiosilanes are interesting species and silole dianion was first reported.[51]

Table 9 ESR parameters for silyl radicals[31,55,57]

		Coupling constants (mT)			
Radical	g value	α-H	β-H	γ-H	^{29}Si
$H_3Si\cdot$	2.0032	0.784			19.0
$MeH_2Si\cdot$	2.0032	1.211	0.821		18.1
$Me_2HSi\cdot$	2.0031	1.729	0.730		18.3
$Me_3Si\cdot$	2.0031		0.634		18.3
$Et_3Si\cdot$	2.0030		0.569	0.016	
$Me_3SiSiMe_2\cdot$	2.0037		0.821	0.047	13.7
$Me_3SiSiMeH\cdot$	2.0037	1.630	0.815	0.030

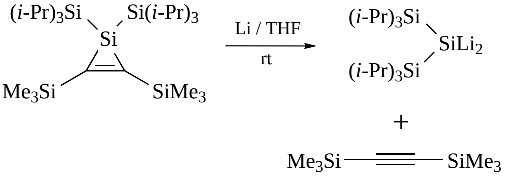
(67)

1,1-Dilithiosilanes with bulky substituents such as Tbt(Dip)$SiLi_2$ (Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl] phenyl, Dip = 2,6-diisopropylphenyl)[52] and (i-$Pr_3Si)_2SiLi_2$[53] have been reported recently.



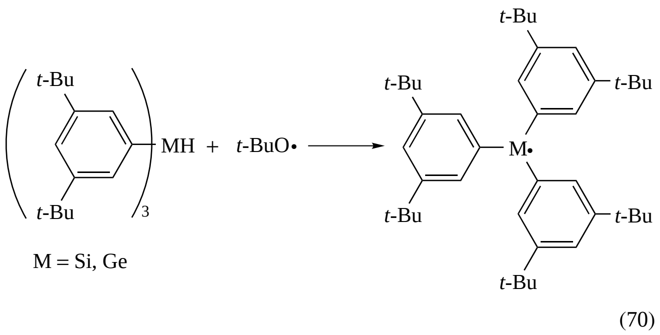
(68)

5.2 Homolytic Reactions (Silyl Radicals and Silylenes)

Silyl radicals can be generated most conveniently by hydrogen abstraction from the corresponding hydrosilane.[29]

$$R_3SiH + t\text{-BuO}\bullet \longrightarrow R_3Si\bullet + t\text{-BuOH} \qquad (69)$$

ESR spectra of several silyl radicals have been recorded and the ^{29}Si hyperfine coupling constants indicate that silyl radicals are nonplanar, contrary to organic radicals. Table 8 lists ESR data of representative silyl radicals. Comparison of ESR data of $Ar_3M\cdot$ (Ar = 3, 5-di-t-butylphenyl, M = C, Si, and Ge), which give relatively stable radicals, is interesting. The g values and hyperfine coupling constants, A_{o-H} and A_{p-H} (in Gauss), are as follows: $Ar_3C\cdot$ (−40 °C), 2.0026, 2.58, 2.80; $Ar_3Si\cdot$ (−50 °C), 2.0027, 0.95, 1.17; $Ar_3Ge\cdot$ (−70 °C), 2.0056, 0.60, 0.95. The spin densities at the central atoms of $Ar_3M\cdot$ are estimated to be 0.50 (M = C), 0.78 (M = Si), and 0.82 (M = Ge), indicating increasing nonplanarity with increasing localizing spin density on the central atom from carbon to germanium (equation 70).[54]

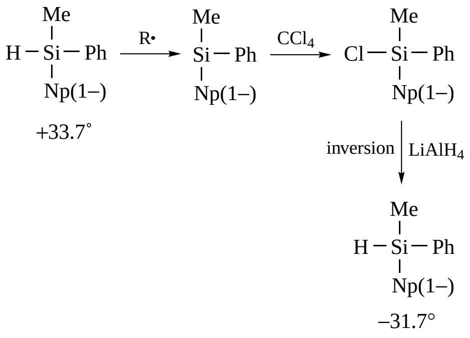


(70)

$$R_3Si\bullet + R'\text{-Br} \longrightarrow R_3SiBr + R'\bullet \qquad (71)$$

Generation of stable (persistent) silyl radicals has been an interesting target. $Ph_3Si\cdot$ is, contrary to $Ph_3C\cdot$, not persistent owing to longer Si–C bond lengths and tendency to undergo *ipso*-substitution. The trimesitylsilyl radical is fairly persistent to be able to observe good ESR spectra (equation 70). According to the general trick to elongate the lifetime of the free radicals, introduction of bulkier substituents produces longer-lived radicals such as triisopropylsilyl radical.[55] The (t-$BuMe_2Si)_3Si\cdot$ radical is shown to be much more persistent in solution[56] and finally (t-$Bu_2MeSi)_3Si\cdot$ has been isolated as a crystal.[57] The molecular structure is shown to be planar. One-electron oxidation of the corresponding silyl anion or one-electron reduction of the corresponding bromosilane is better than hydrogen abstraction to produce radicals because of lesser steric requirement in the reaction.

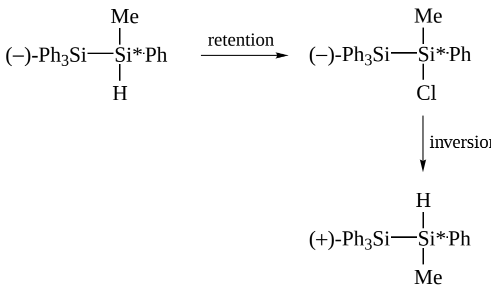
The reaction of silyl radicals with haloalkanes constitutes the H/halogen exchange reaction together with the hydrogen abstraction reaction (equations 69 and 71) but, alternatively, the reaction is also convenient for the production of alkyl radicals. A number of alkyl radicals have been generated and studied by ESR. Interestingly, the silyl radicals derived from an optically active hydrosilane undergo chlorine abstraction reaction mostly with retention of configuration.[58]



(72)

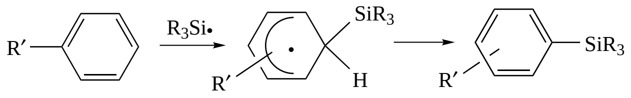
The configurational stability of the silyl radical may be best explained in terms of the pyramid structure and slower rate of inversion than abstraction of chlorine. The origin of the pyramidality of the silyl radical is the difference between electronegativities of central and substituent elements. This argument may be supported by the following evidence. Thus in the case of fluorinated methyl radicals, $\bullet CH_3$, $\bullet CH_2F$, $\bullet CHF_2$, and $\cdot CF_3$, structures change from planar to almost tetrahedral.[59] The planar structure (and low inversion barrier) of (t-$Bu_2MeSi)_3Si\cdot$ may depend on there being no difference in electronegativities between central and substituent elements. Delocalization of unpaired electron owing to σ*-p conjugation should contribute to some extent. On this matter, it is noteworthy that chiral disilanyl radical undergoes chlorine abstraction from carbon tetrachloride with retention of

configuration but in low optical yield.[60]



(73)

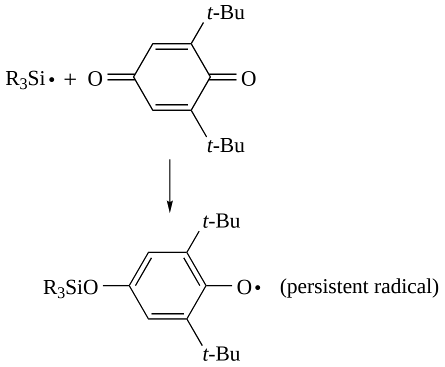
Addition of the silyl radical to carbon−carbon double bonds is an elementary reaction of radical hydrosilation (Scheme 1). Homolytic aromatic silation also occurs involving silyl radicals. Silyl radicals are nucleophilic owing to the high SOMO energy, as evidenced by the directive effects in the hemolytic aromatic substitution.[17,61] The intermediate cyclohexadienyl radicals have been observed by ESR.



(74)

Addition of the silyl radicals to carbonyl compounds occurs at the oxygen site (equations 75 and 76). The latter reaction is utilized also for spin trapping of silyl radicals (equation 76).

(75)



(76)

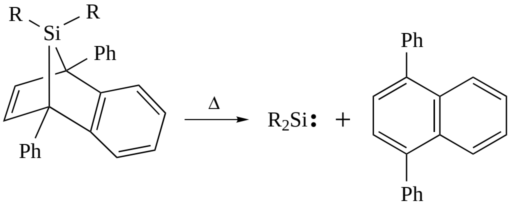
Recently, radicals have increasingly been used in organic synthesis, especially for cyclization of alkenyl radicals generated from the corresponding halides. Tin hydrides have been used for this purpose before but $(Me_3Si)_3SiH$ is now used because it is environmentally safer.

Silylenes, the silicon analogs of carbenes, may be generated thermally[62] and photochemically[63] from appropriate polysilanes (equations 77 and 78).

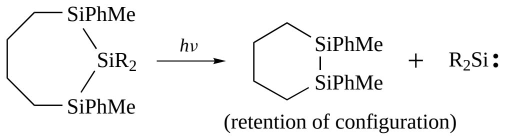
$$MeOSiMe_2SiMe_2OMe \xrightarrow{\Delta} Me_2Si\!: + (MeO)_2SiMe_2 \quad (77)$$

$$(SiMe_2)_6 \xrightarrow{h\nu} Me_2Si\!: + (SiMe_2)_5 \quad (78)$$

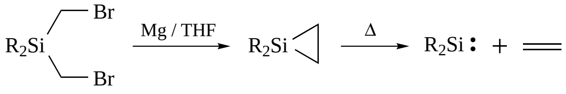
Other important reactions for generating silylenes are shown in equations (79),[64] (80)[65] and (81).[66]



(79)



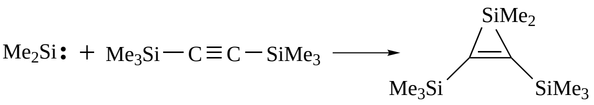
(80)



(81)

Major reaction patterns of silylenes are insertion into the O–H (equation 82), Si–H (equation 59) and Si–Si bonds (equation 60), addition to multiple bonds (equation 83), rearrangement (equation 84), and dimerization. Dimerization of the bis(mesityl)silylene (equation 85) opened a pathway to the first isolable disilene.[67]

$$R_2Si\!: + R'OH \longrightarrow R_2Si(OR')H \quad (82)$$



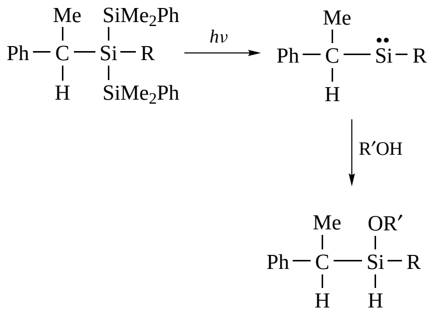
(83)

(84)

$$2Ar_2Si\!: \longrightarrow Ar_2Si{=}SiAr_2 \quad (85)$$

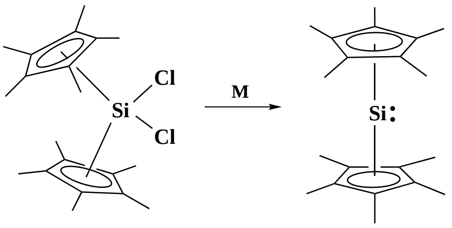
Ar = mesityl (2,4,6-trimethylphenyl)

Silylenes with two different substituents, R^1R^2Si, are prochiral, and insertion into an alcoholic RO–H bond should create chirality on the silicon. In particular, if one of the two substituents is chiral, a diastereotopic face can be defined and diastereoselective addition can be expected. Quite recently, the first example of diastreoselective addition of alcohol to diastereotopic silylene has been reported.[68]



(86)

Even if it is not as stable as heavier members of the 14 group elements, divalent silicon species has some stability. Isolation of stable silylenes has been an interesting target in organosilicon chemistry. The first stable Si(II) species is silicocene, $(Me_5C_5)_2Si$, shown below.[69]



(87)

More recently, remarkably stable five-membered silylenes are reported (Figure 9).[70]

In these silylenes, electron donation to the vacant orbital of the silylenes from adjacent nitrogen atoms (n-π conjugation) should be the important factor in addition to the steric protection by bulky groups. It is interesting to argue whether stabilization owing to the aromaticity (6π electron system) for the unsaturated cyclic silylene (4 electrons from 2 nitrogen lone pair and 2π electrons from the double bond) really exists. It is suggested that unsaturated silylene is $58\,\mathrm{kJmol^{-1}}$ more stable than the saturated analog. Nonetheless, the saturated cyclic silylene is a fairly stable and unreactive species.

Similar cyclic and sterically protected silylene has been prepared recently (equation 88).[71] The silylene must be stabilized to some extent by σ-π conjugation instead of n-π conjugation for other stable cyclic silylenes shown in Figure 9. Indeed the silylene undergoes facile rearrangement (equation 88).

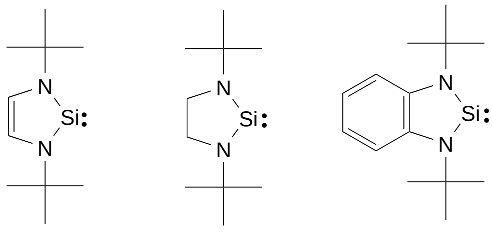


Figure 9 Stable five-membered silylenes

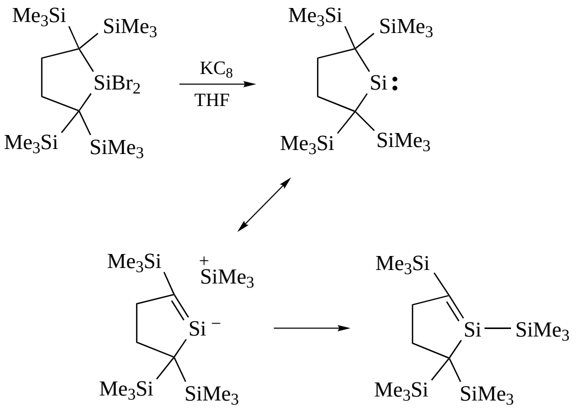
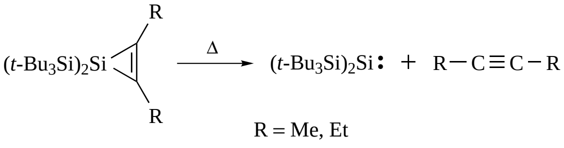


(88)

The carbon analog of silylenes, carbenes R_2C, can be either singlet or triplet electronic ground state depending on the electronic and steric characteristics of the substituents on the carbene center. Silylenes behave mostly as singlet species. In spite of several efforts, no clear evidence for the possibility of a triplet ground state of silylenes.[72] Bulky substituents should widen the bond angle to stabilize the triplet state. Thus it is predicted by computational studies that $(t\text{-}Bu_3Si)_2Si$: has a triplet ground state.[73] According to this prediction, very recently, $(t\text{-}Bu_3Si)_2Si$: has been generated by the photolysis of the corresponding silacyclopropene (equation 89). The ESR spectra as well as its chemical behavior indicate a triplet ground state for the silylene.[74]

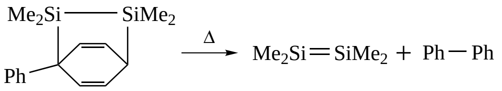


(89)

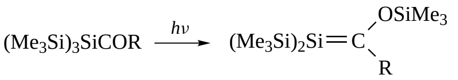
5.3 Formation and Reactions of Multiply Bonded Species

Because of the close relationship between silicon and carbon, many attempts have been made to try to synthesize species containing multiple bonds to silicon (Si=C, Si=O, Si=Si, etc.). However, it was not until 1967 that compelling evidence was presented that Si=C might exist in the thermal reaction of 1,1-dimethyl-1-silacyclobutane (equation 90).[75] The first evidence for the existence of Si=Si as transient intermediate was provided in the thermolysis of bridged disilane derivatives (equation 91).[76] Since then, many studies have been published on these unsaturated species, but it was in 1981 that synthesis and characterization of relatively stable crystalline compounds containing Si=C (silene) (equation 92)[77] and Si=Si (disilene) (equation 85) were reported (equations 90–92).

(90)



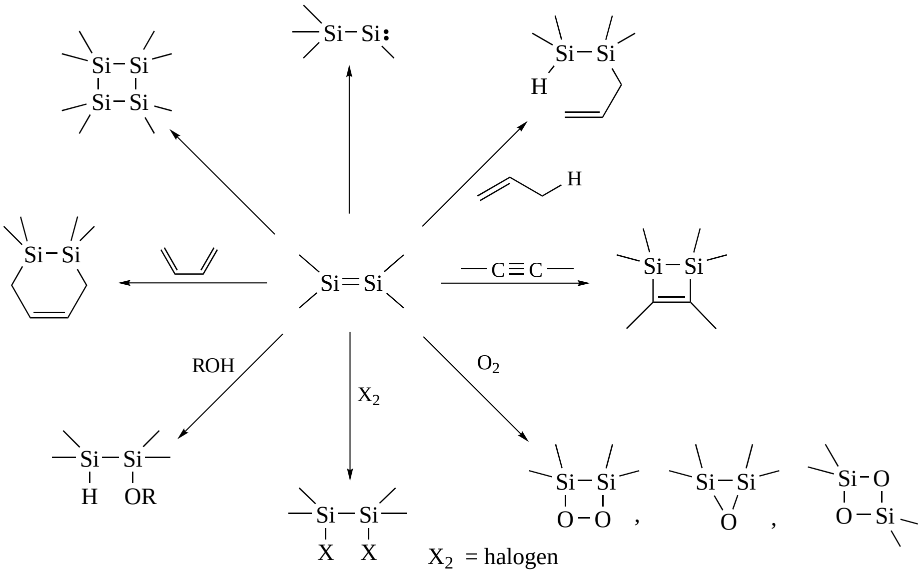
(91)



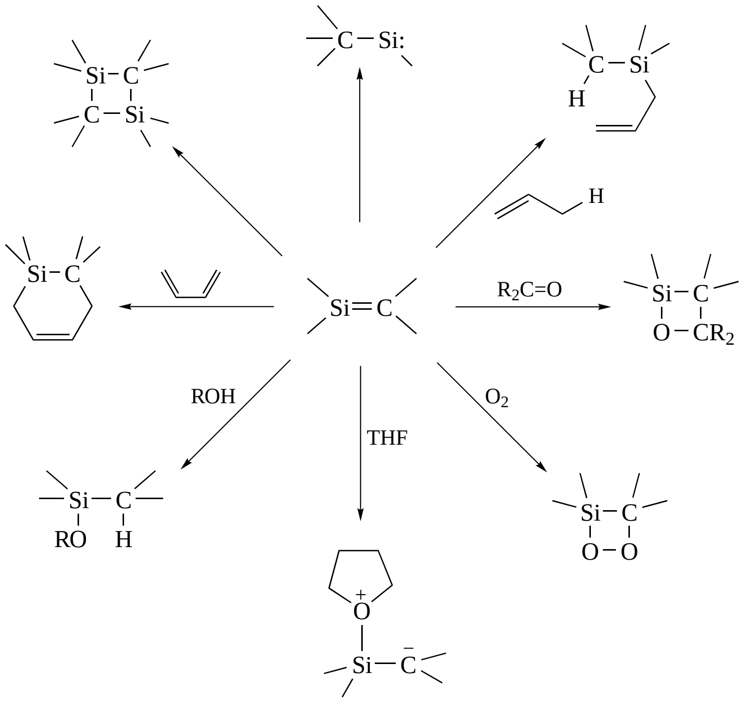
(92)

R = 1-adamantyl, CEt_3

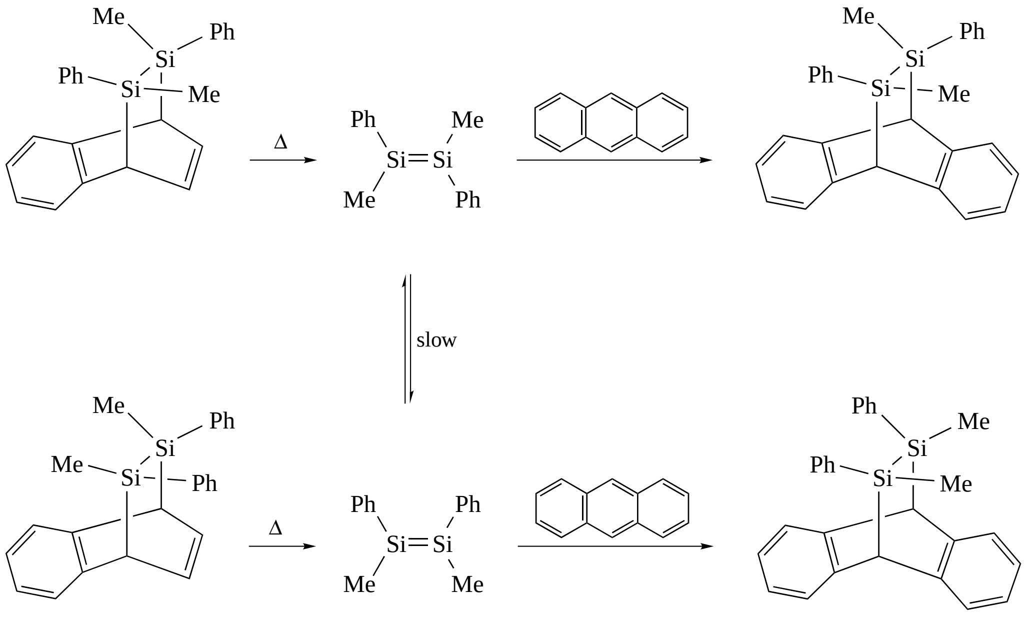
Until now, the chemistry of multiply bonded silicon has developed explosively. Methods of generation, reactivity, and structure of compounds containing multiply bonded silicon are well documented in reviews.[78] These are $R_2Si{=}SiR_2$ (disilene), $R_2Si{=}CR_2$ (silene), $R_2Si{=}NR$ (silanimine), $R_2Si{=}O$ (silanone), $R_2Si{=}P$ (silaphosphene), and $R_2Si{=}S$ (silanethione). Typical reactions of disilenes and silenes are summarized in Schemes (6) and (7).



Scheme 6



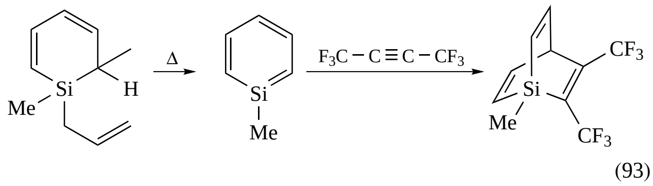
Scheme 7



Scheme 8

Existence of geometric isomerism and estimate of the rotational barrier are fundamental properties of double bonds. Not only thermally stable disilenes but reactive disilenes such as cis- and *trans*-PhMeSi=SiPhMe can retain geometrical configuration during the reaction.[79] As shown in Scheme 8, *trans*-1,2-diphenyldimethyldisilene can be trapped with anthracene with retention of configuration (96:4) at 300 °C. A similar result was obtained with the cis precursor to give the product of configurational retention (94:6). Slightly less stereospecific results were obtained by increasing the temperature to 350 °C. Activation energy of at least $25.8 \pm 5\,\text{kcal mol}^{-1}$ is calculated for the cis-trans isomerization.[80]

Notable advances in the last decade are isolation of kinetically stabilized silicon-containing double-bonded species.[81] As we have seen already, a variety of sterically bulky substituents have been utilized to stabilize silicon-centered reactive intermediates. This kinetic stabilization is the key issue also to isolate silicon double-bonded species. For example, the synthesis of isolable silicon analog of benzene and other aromatic compounds has been a target for a long time. One example is shown below for the generation of transient silabenezene.[82]

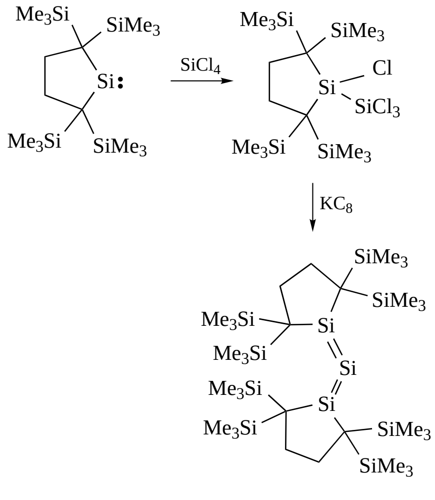


(93)

By using a very bulky substituent, Tbt (2,4,6-tris[bis(trimethylsilyl)methyl]phenyl), 2-silanaphthalene,[83] silabenzene[84] and other related compounds are prepared (Figure 10).

Tetrasilabutadiene,[85] trisilacyclopropene (cyclotrisilene), and tetrasilacyclobutene (cyclotetrasilene) are isolated and the structures are determined by X-ray crystallography.[86]

Compounds of triply bonded silicon or *sp*-hybridized silicon have been indicated as intermediates in some reactions,[87] but they have been elusive for a long time. Very recently, a trisilaallene derivative with a formally *sp*-hybridized silicon atom has been isolated as a stable crystalline compound (equation 94).[88] Contrary to linear original allenes, the trisilaallene is a bent molecule.



(94)

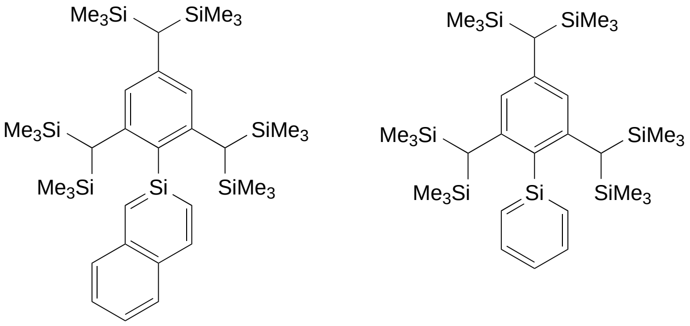


Figure 10 Kinetically stabilized silaaromatics

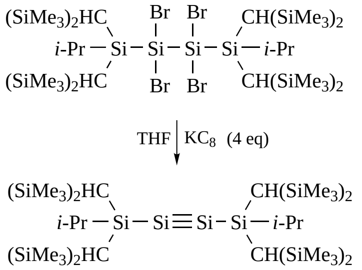
More recently, a stable compound containing a silicon–silicon triple bond (disilyne) has been isolated as emerald green crystals (equation 95).[89] 1,1,4,4-Tetrakis[bis(trimethylsilyl)methyl]-1,4-diisopropyl-2-tetrasilyne is thermally stable up to 100 °C in the absence of air. The observed Si–Si triple bond length is 2.0622(9) Å, which is shorter than the average Si–Si (2.39 Å, Table 6) and Si=Si (2.14 Å)[81] but the degree of shortening is smaller than those observed for carbon analogs. In fact, the disilyne is not a linear molecule as acetylene but has a trans bent structure with a bond angle of 137.44(4)°. The disilyne is reactive and reacts with two equivalent of bromine at room temperature to give the starting tetrabromide in 94% yield.



(95)

5.4 Silicon Polyhedranes

Closely related to disilynes, $(RSi)_2$, silicon polyhedranes of the type $(RSi)_{2n}$ are also interesting molecules for synthesis. A theoretical consideration of Croup 14 polyhedral compounds, X_nH_n, on the level of HF/6-31G*, where $n = 4$ (tetrahedrane), $n = 6$ (prismane), and $n = 8$ (cubane), suggested that the cubane and prismane structures possess a lower degree of strain energy than the carbon analogs.[90] Thus it may be reasonable to assume that the cubane and prismane analogs of the heavier atoms should be accessible and therefore they are appropriate synthetic targets. However, for the synthesis of strained polyhedranes, proper choice of both starting compounds with a suitable bulky substituent and metals as reducing reagent is of crucial importance, and therefore hexasilaprismane and octasilacubane have been synthesized rather recently.[91] The crystal structures of tetrakis(tri-*t*-butylsilyl)tetrasilatetrahedrane,[92] hexakis(2,6-diisopropylphenyl)hexasilaprismane[93] and octakis(2,6-diethylphenyl)octasilacubane[94] were determined (Figure 11).

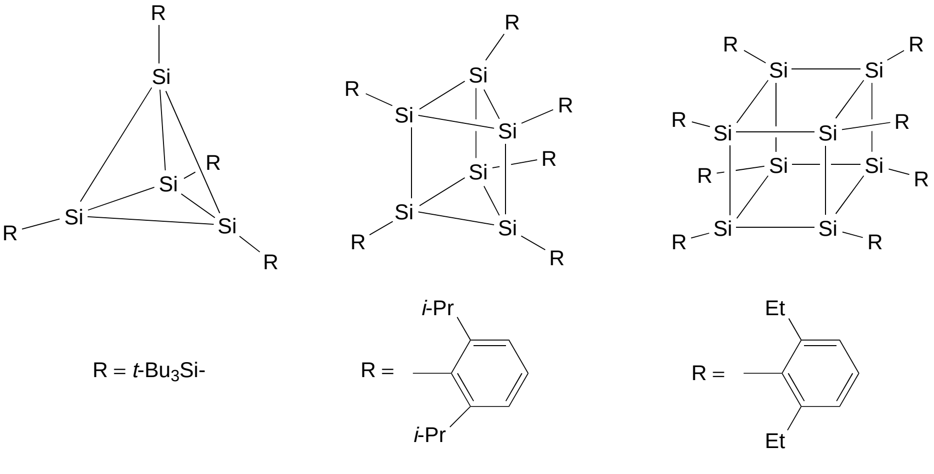


Figure 11 Silapolyhedranes

6 APPLICATIONS

Organosilicon chemistry has several areas of important applications. Owing to the limitation of the scope of this section, those will be described briefly.

6.1 Polymers

6.1.1 Silicones

Silicones are polymers with a polysiloxane backbone. The simplest one is polydimethylsiloxane, MD_nM, exhibiting the basic structure of the silicones. The methyl group may be substituted by another one such as phenyl, vinyl, and hydrogen. Wohler, who assumed that oxygen was bound to silicon by a double bond similar to that in ketones, introduced the name silicone. Silicones are fluids, resins, or elastomers; they can be greases or rubbers. Silicone oils mostly have the structure of MD_nM. Rubbers are of the same composition as oils but the degree of polymerization in rubbers is several thousands, much higher than oils. Resins contain T units for the three-dimensional network structure. The initial process of silicone production is hydrolysis of chlorosilanes. Hydrolysis of trimethylchlorosilane gives trimethylsilanol (equation 48) followed by the formation of MM. Hydrolysis of dimethyldichlorosilane is very rapid to give linear and cyclic polysiloxanes depending upon reaction conditions.

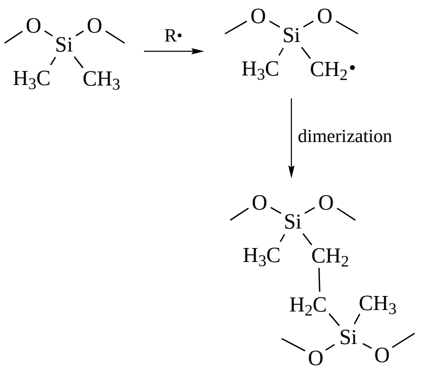
$$2Me_3SiOH \longrightarrow Me_3SiOSiMe_3(MM) + H_2O \qquad (96)$$

$$Me_2SiCl_2 + H_2O \longrightarrow HO\text{-}D_n\text{-}H \;\;\text{and}\;\; D_3 + D_4 + D_5 \qquad (97)$$

Elastomers and nonsilanol terminated fluids are produced by base-catalyzed polymerization of low-molecular weight siloxanes. Polydimethylsiloxanes are also produced by ring opening polymerization of D_3, D_4, and D_5. In the presence of MM or MDDM (endcapper), silicones MD_nM are formed; otherwise, silanol terminated polysiloxanes may be obtained.

The polydimethylsiloxanes (PDMS) exhibit characteristic properties useful for practical applications: transparent, colorless, thermal stability, oxidative stability, chemical stability, shear stability, dielectric stability, low viscosity change on temperature, nonflammability, low surface tension, high compressibility, water repellant, biologically inactive, and so on. They are used in adhesives, cosmetics, electrical systems, as damping oils, lubricants, polishing oils, in heat exchange, diffusion pumps, textile finishing, and so on. A part of the methyl group of silicones can be replaced by other groups to produce modified silicones, which are now used in almost all industrial products.[95,96]

Silicone rubbers are made by adding an inert filler (mostly silica) to highly viscous PDMS gum, followed by curing in the presence of catalysts. The cure process is a cross-linking reaction of silicone chains and initiated by peroxide (radical process), typically benzoyl peroxide, *m*-chlorobenzoyl peroxide, and di-*t*-butyl peroxide. Major reactions responsible to the cross-linking are generation of free radical and coupling (equation 98). Generation of the $SiCH_2\cdot$ requires hydrogen abstraction and becomes more difficult when the system becomes more viscous. Then some group such as vinyl is introduced to facilitate the reaction. This process is called heat cure or high-temperature vulcanization (HTV) and the resulting rubber is used in electric, mechanical, automobile, medical, and food industries.



(98)

Silicone rubber has a very characteristic and useful way of vulcanization at low temperature. Liquid silicone rubbers of low viscosity polysiloxanes having reactive functional groups, undergo cross-linking by condensation or addition reactions. Cross-linking (curing) can be done at room temperature so that these rubbers are called RTV (room temperature vulcanizing) rubbers. Some typical reactions utilized for the production of RTV are shown in Scheme 9. They find a wide range of applications in molding, sealing, electrical insulation, and so on. People may be familiar with RTV at the dentist for the molding of an artificial tooth and/or inlay.

Silicones are exceptionally thermally stable without acidic or basic substances. Silicones are now used increasingly in cosmetics and personal care fields. Therefore, the fate of silicones (mostly dimethylsilicones) under ambient conditions may be a matter of environmental concern. Fortunately, it is shown that M-D_n-M polymers depolymerize to $Me_2Si(OH)_2$ rather rapidly in soil and water under high dilution conditions. Then $Me_2Si(OH)_2$ undergoes stepwise demethylation to T units and finally to Q units (silicic acid). The final degradation of $Me_2Si(OH)_2$ to SiO_2 and CO_2 occurs within a few months to year.[97] Therefore, silicones are concluded to be quite safe materials.

$$R_3SiOH + HOSiR_3 \longrightarrow R_3SiOSIR_3 + H_2O$$

$$R_3SiOH + ROSiR_3 \longrightarrow R_3SiOSIR_3 + ROH$$

$$2R_3SiOR + H_2O \longrightarrow R_3SiOSIR_3 + 2ROH$$

$$2R_3SiOCOCH_3 + H_2O \longrightarrow R_3SiOSIR_3 + 2CH_3COOH$$

$$2R_3SiON{=}C(CH_3)_2 + H_2O \longrightarrow R_3SiOSIR_3 + 2(CH_3)_2C{=}NOH$$

$$2R_3SiOC(CH_3){=}CH_2 + H_2O \longrightarrow R_3SiOSIR_3 + 2(CH_3)_2C{=}O$$

Scheme 9

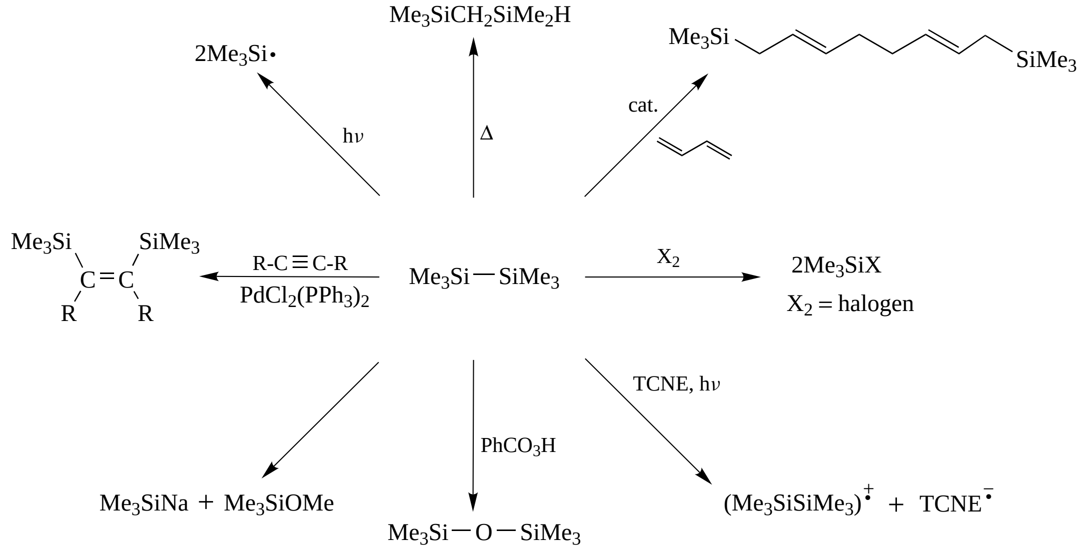
6.1.2 Polysilylenes (Polysilanes)

Permethylpolysilylene was prepared in 1949 by the sodium condensation of Me_2SiCl_2, but the products were insoluble, infusible, and intractable. As a result, these polymers have been neglected until the finding that polydimethyisilylene can be converted to polycarbosilane (PCS) at high temperature by thermal rearrangement. PCS is soluble and meltable. Melt spun PCS fibers can be converted to silicon carbide fibers, which are the most heat-resistant fibers so far.[98] Inspired by this observation, many studies on polysilylenes have been carried out and it was found that homopolysilylenes having substituents other than methyl and most copolymers are soluble. Since then, polysilylenes have been investigated extensively in the past decade because of their potential applications in the field of materials science.[99] The polysilylenes exhibit characteristic properties useful for practical applications. Applications of polysilylenes in SiC precursors, microlithography,[100] and reprography[101] show that polysilylenes are promising as advanced materials for the high technology of the next generation.

The Si–Si bonds in polysilylenes can also react with a variety of reagents. Typical examples are shown in Scheme 10 in which reactions of hexamethyldisilane, as a model compound, are indicated.

Polysilylenes are usually prepared by the Wurtz-type reductive coupling of dichlorosilanes with alkali metals.

$$R_2SiCl_2 + 2Na \longrightarrow (R_2Si)_n + 2NaCl \qquad (99)$$



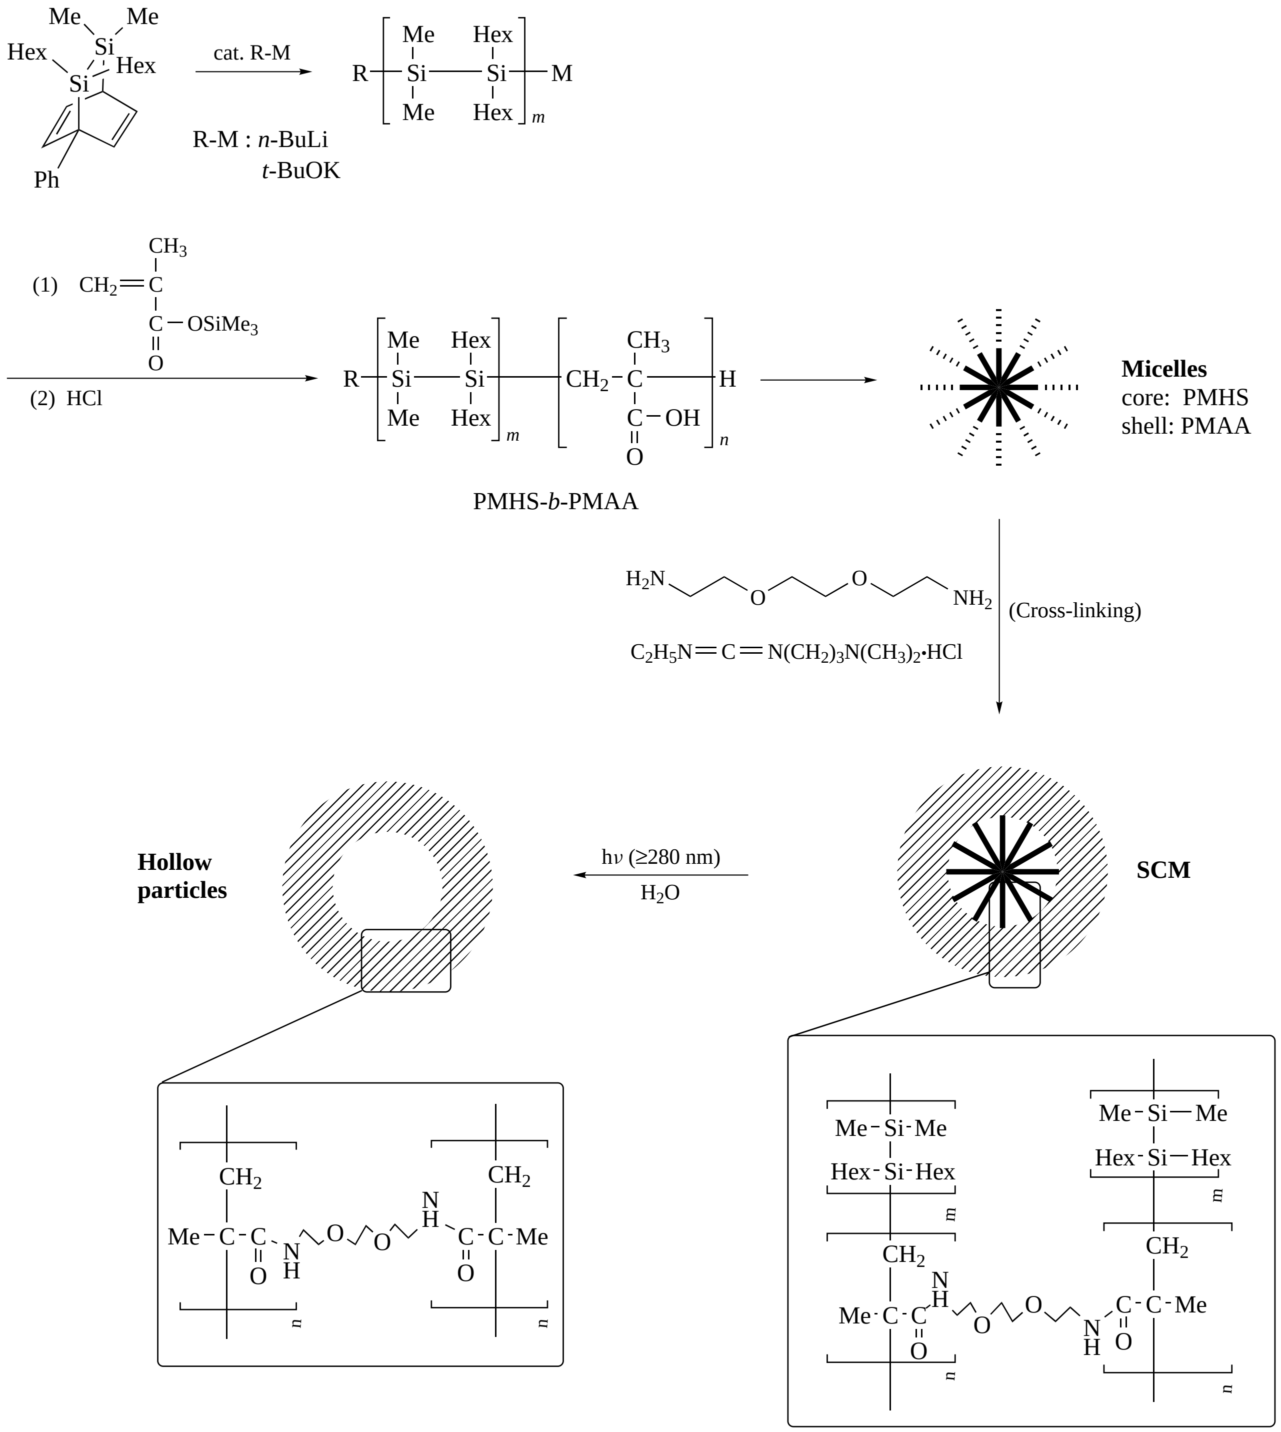
Scheme 10

Although many kinds of polysilylene have been prepared by this method, the structure of the polymers is difficult to control.[102] Molecular weight and polydispersity are also unmanageable.[103]

Recently, several new methods of preparing polysilylenes have been reported. Transition metal catalyzed dehydrogenative coupling of hydrosilanes, especially of $RSiH_3$, is promising (equation 100), although at this moment only oligomeric polysilylenes are available.[104]

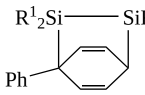
$$RSiH_3 \xrightarrow{\text{cat.}} (RSiH)_n + H_2 \qquad (100)$$

The anionic polymerization of masked disilenes, that is, l-phenyl-7,8-disilabicyclo[2.2.2]octa-2,5-diene derivatives, is



Scheme 11

also a new promising method for preparing polysilylenes with highly controlled structures (equation 101).[105] Indeed, a highly ordered alternating polysilylene copolymer, poly(1,1-dihexyl-2,2-dimethyldisilene) $(SiHex_2SiMe_2)_n$ (PMHS), has been synthesized for the first time by this method; an interesting thermochromism was observed for alternating polysilylene copolymers with a highly ordered structure.[106]



$$+\ \mathrm{RLi} \longrightarrow \mathrm{R{-}(SiR^2{}_2SiR^1{}_2)_{\mathit{n}}{-}Li} \qquad (101)$$

The anionic polymerization of masked disilenes proceeds *via* living anions, and therefore block copolymerization with a conventional vinyl monomer is possible. Recently, interesting hydrophobic block copolymer of PMHS with poly(2-hydroxyethyl methacrylate) (PHEMA) and poly(methacrylic acid) (PMMA) have been prepared (Scheme 11). These polymers can be self-assembled and are transformed into polysilane micelles,[107] shell cross-linked micelles (SCM),[108] and nanometer-sized hollow particles.[109]

6.2 Organic Synthesis

Applications of organosilicon compounds in organic synthesis are growing very rapidly. This topic has been discussed by several extensive reviews[110] and only some typical examples are listed here. However, it is meaningful to emphasize the importance of factors with which organosilicon compounds can be used for organic synthesis. These are: (a) silyl groups as proton substitutes, (b) stabilization of b carbocations by σ-π conjugation, and (c) stabilization of a carbanions by σ^*–π conjugation. The nature of the latter two factors is discussed in Section 4.

6.2.1 Silicon as Proton Substitutes

Historically, silation of ROH to $ROSiR_3$, was the first successful application of organosilicon compounds in organic chemistry. This kind of derivatization procedure has been used extensively for hydroxylic compounds such as sugars to give volatility in GLC (gas-liquid chromatography) and MS (mass spectrometry) applications.[111] In the beginning, the reaction of ROH with trimethylchlorosilane (TMSCl) in the presence of a stoichiometric amount of pyridine in toluene or benzene is employed for silation. A combination ofhexamethyldisilazane (HMDS) and TMSCl in a nonpolar solvent is more effective reagents.

$$3\mathrm{ROH} + (\mathrm{Me_3Si})_2\,\mathrm{NH} + \mathrm{Me_3SiCl} \longrightarrow 3\mathrm{ROSiMe_3} + \mathrm{NH_4Cl} \qquad (102)$$

Other commonly used trimethylsilation reagents are: *N*,*O*-bis(trimethylsilyl)acetamide (BSA), *N*-trimethylsilylacetamide, *N*-trimethylsilylimidazole (TMSI), and *N*,*N*-bis(trimethylsilyl)urea (BSU) (Figure 12).

The rate of hydrolysis of $ROSiR'_3$, that is, the hydrolytic stability of silylated compounds, depends on the steric bulkiness of R′. An approximate order of steric bulkiness of common silyl groups is as follows: (Note that the order depends on the nature of the reaction and alcohols).[112] Me_3Si (TMS) < $PhMe_2Si$ < Et_3Si (TES) < t-$BuMe_2Si$ (TBDMS) < i-Pr_3Si (TIPS) < t-$BuPh_2Si$ (TBDPS) < t-Bu_3Si (supersilyl) < $(cyclohexyl)_3Si$. Therefore, t-$BuMe_2Si$- and t-$BuPh_2Si$- are frequently used as strong protecting groups in organic synthesis.

Hydrosilanes, R_3SiH, can be viewed as 'silylated hydrogen' and used as a reducing reagent. Hydrosilation (equation 20) resembles hydrogenation in this sense. Reduction of prochiral ketones through hydrosilation has been investigated extensively with platinum and rhodium complexes having

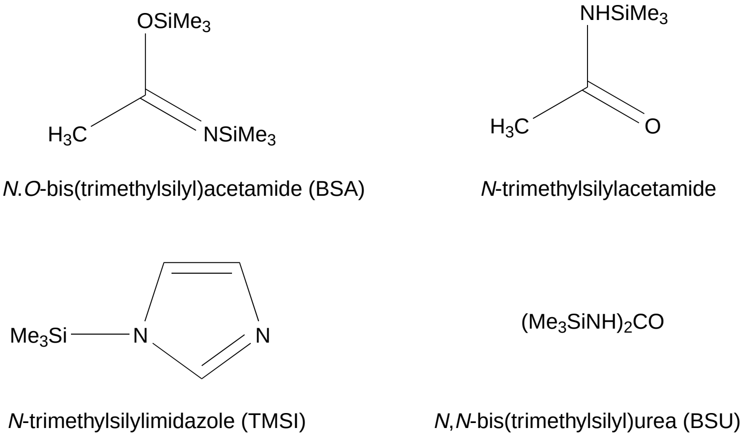


Figure 12 Commonly used trimethylsilation reagents

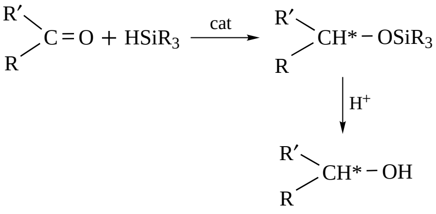
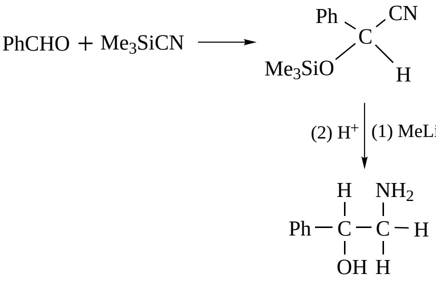
chiral ligand(s).[113]



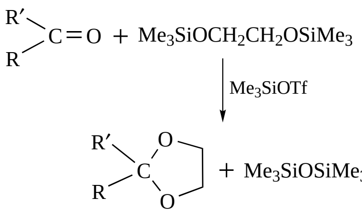
(103)

Trimethylsilyl cyanide (TMSCN) and trimethylsilyl azide ($TMSN_3$) are safe and convenient replacements for hydrogen cyanide and hydrogen azide, respectively, which are otherwise inconvenient or hazardous to handle.



(104)

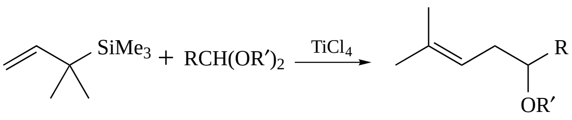
Trimethylsilyl esters of Bronsted acids such as trimethylsilyl triflate and trimethylsilyl iodide are useful as catalysts for trimethylsilyl transfer reactions. An example is given in equation (105).



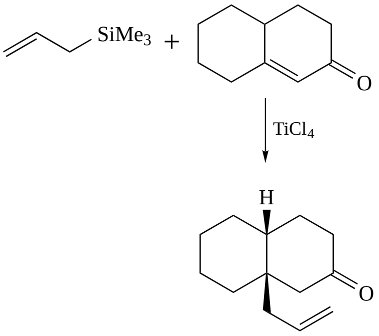
(105)

6.2.2 *Stabilization of β Carbocations*

The most important and representative examples of this category are the reactions of allylsilanes (Scheme 4 and equations 106 and 107).

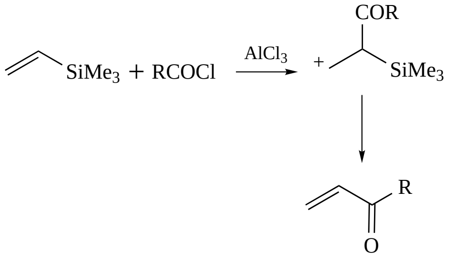


(106)

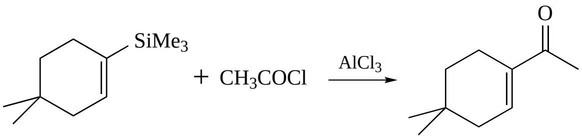


(107)

The regiochemistry of electrophilic attack to vinylsilanes is also controlled by the trimethylsilyl group.

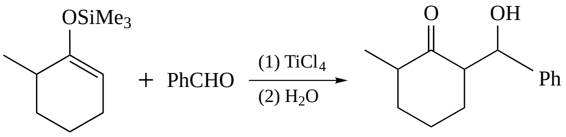


(108)

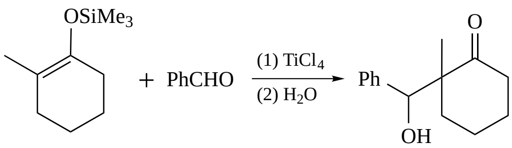


(109)

Silyl enol ethers are useful for regioselective aldol-type condensation.[114]



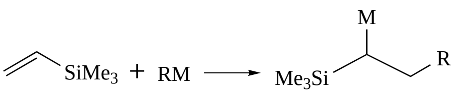
(110)



(111)

6.2.3 *Stabilization of α Carbanions*

α-Metalated organosilanes can be prepared by addition of an organometallic compound to vinylsilanes, proton abstraction, halogen-metal exchange, and transmetalation (equations 42, 112–114).



(112)

$$Me_3SiCH_2\text{-}H + BuLi \xrightarrow[TMEDA]{} Me_3SiCH_2Li \quad (113)$$

$$Me_3SiCH_2\text{-}Cl + Mg \longrightarrow Me_3SiCH_2\text{-}MgCl \quad (114)$$

These α metalated organosilanes react with carbonyl compounds to give methylenated products.[115]

1 INTRODUCTION

The chemical symbol Ag is derived from the Latin *argentum*, which in turn originates from the Greek *ἀργός*, meaning shiny or glistening. Silver is a rather rare element in the earth's crust, and its abundance is only about 0.07 part per million. Native silver as a compact mass and 'horn silver' (chlorargyrite, AgCl), originating from chemical reduction and the action of salt water, often occur among sulfidic ores such as acanthite (Ag_2S, the chief mineral), stromeyerite (CuAgS), proustite ($3Ag_2S{\cdot}As_2S_3$), stephanite ($5Ag_2S{\cdot}Sb_2S_3$), and margyrite ($Ag_2S{\cdot}Sb_2S_3$). Nowadays about 60% of silver is produced as a by-product in the processing of nonferrous metal ores such as galena (PbS) and copper pyrite ($CuFeS_2$), and the rest by cyanide leaching of silver ores and recovery from coins and industrial scrap. Final purification is usually carried out by electrolysis.[1]

The photographic film industry accounts for about one-third of the world's consumption of silver. It is also used in making jewelry, silverware, artwork, mirrors, electrical and electronic contact points, and high-capacity Ag–Zn and Ag–Cd batteries. The metal and its compounds are useful as catalysts in organic synthesis. In medicine, silver sulfadiazine is effective for the treatment of burns.

Silver has a cubic close-packed structure ($a = 408.626$ pm, space group $Fm\bar{3}m$) and is the best conductor of heat and electricity among all metals. Being ductile and very malleable, it can be hammered into thin foils, which transmit blue-green light.

The chemistry of silver is in accord with its electronic configuration $4d^{10}5s^1$.[1–3] Silver is chemically less reactive than copper except toward sulfur and hydrogen sulfide, which rapidly tarnish lustrous silver surfaces. Silver is immune to nonoxidizing acids such as hydrochloric acid, but it dissolves readily in dilute nitric acid. However, concentrated nitric and sulfuric acids attack it only at higher temperatures owing to the formation of a rather insoluble protective layer of $AgNO_3$ or Ag_2SO_4. It dissolves easily in cyanide solutions in the presence of oxygen owing to a large shift in the silver potential (from $+0.80$ V to -0.31 V) in forming the complex $[Ag(CN)_2]^-$. Some important properties of silver are listed in Table 1.[3,4]

2 SUBVALENT SILVER COMPOUNDS

Silver having a formal oxidation state smaller than one occurs in compounds with the most electronegative elements, namely, fluorine and oxygen. Disilver monofluoride (silver subfluoride), Ag_2F, is formed in the reaction between finely divided silver and AgF in liquid hydrogen fluoride. It can also be obtained electrolytically from AgF at low current densities, crystallizing on the silver cathode as bronze-colored platelets. Ag_2F decomposes into Ag and AgF above 100 °C. It has an *anti*-CdI_2 structure in which double layers of Ag ('metallic' Ag···Ag bond lengths lie in the range 2.814–2.996 Å) alternate with layers of AgF (Ag–F bond length is 2.451 Å). The compound is a good electrical conductor.

Trisilver oxide (silver suboxide), Ag_3O, which conducts electricity, is made by heating AgO to 80 °C in a silver vessel in the presence of H_2O under a pressure of 4×10^8 Pa. Ag_3O has an *anti*-BiI_3 structure in which oxygen occupies 2/3 of the octahedral holes in a hexagonal close-packed array of silver, in which the Ag–O bonds are 2.29 Å, while the Ag···Ag bonds are about 2.88 Å. Pentasilver orthosilicate, Ag_5SiO_4, is formed by hydrothermal reaction of silver powder with amorphous SiO_2 under high oxygen pressure.[5] Crystal-structure analysis showed that it should be formulated as $[Ag_6]^{4+}(Ag^+)_4(SiO_4{}^{4-})_2$, being composed of a packing of octahedral $Ag_6{}^{4+}$ clusters along with isolated Ag^+ and tetrahedral $SiO_4{}^{4-}$ ions. Silver also forms rare zero-valent carbonyl compounds $Ag(CO)_3$ and $Ag_2(CO)_6$, which exist only at low temperatures (10 and 30 K, respectively).

3 SILVER(I) COMPOUNDS

This is the dominant oxidation state of silver, and the Ag(I) ion with spherically symmetric configuration $4d^{10}$ exhibits a range of coordination numbers from 2 to 6. Silver(I) is stable in aqueous solution as $[Ag(H_2O)_2]^+$. However, the soft Ag(I) cation has a relatively low affinity

for the hard aqua ligand, so nearly all its crystalline inorganic salts are anhydrous except for AgF and $AgClO_4$.

Silver alkyls and aryls, together with silver(I) complexes of cyclic polyenes and alkynyl ligands, are generally classified under organometallic compounds. Stable silver(I) carbonyl complexes that have been characterized by X-ray analysis include $[Ag(CO)\{B(OTeF_5)_4\}]$, $[Ag(CO)_2\{B(OTeF_5)_4\}]$, and $[Ag(CO)\{HB[3,5\text{-}(CF_3)_2pz]_3\}]$.[6] Silver acetylide ($Ag_2C_2$) complexes are described in Section 3.6.

3.1 Halides and Pseudohalides

Silver halides can be prepared directly by addition of X^- to Ag^+ solutions, although AgF is usually prepared from silver oxide and hydrofluoric acid. The color and insolubility of silver halides in water increase in the order Cl < Br < I. Both AgCl and AgBr have the rock salt structure, though they are insulators. AgI has both zinc blende and wurtzite forms. The ultrahigh light-sensitivity of these halides (AgF only to the ultraviolet), particularly AgBr, is the basis for their use in photography. The formation of the linear $[H_3N\text{–}Ag\text{–}NH_3]^+$ complex can be used for the separation of mixed silver halides. Aqueous ammonium carbonate is sufficient to dissolve AgCl to give $[Ag(NH_3)_2]Cl$, while AgBr can be extracted with aqueous ammonia, in which AgI is sparingly soluble.

The halides AgX (X = Cl, Br, I) react with halide anions X^- to give a series of discrete anionic complexes $[Ag_mX_n]^{(n-m)-}$.[7–9] Examples of such iodo complexes are shown in Figure 1.

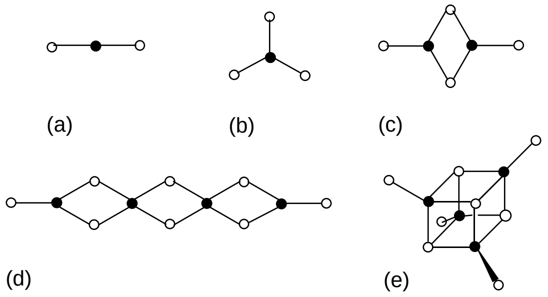

Figure 1 Structures of discrete iodoargentate complexes: (a) $[AgI_2]^-$; (b) $[AgI_3]^{2-}$; (c) $[Ag_2I_4]^{2-}$; (d) chain-like $[Ag_4I_8]^{4-}$; (e) cubane-like $[Ag_4I_8]^{4-}$

Polymeric species $[(Ag_mX_n)^{(n-m)-}]_\infty$ (X = Cl, Br, I) have been identified in several crystal structures.[10] Silver complexes with mixed halide ligands have also been prepared, for example, discrete $[Ag_2Br_4Cl_2]^{4-}$ and polymeric $[(Ag_6X_2I_6)^{2-}]_\infty$ (X = Cl, Br).[11]

The related pseudohalides AgCN, AgNCO, and AgSCN all have infinite chain structures. The Ag^+ ion in AgN_3 is coordinated tetrahedrally by four azide groups, each being surrounded in turn by four Ag^+ ions in a pseudotetrahedral arrangement.

3.2 Phosphorus Donor Ligands

With monophosphines, the complexes are mainly of the type $[AgX(PR_3)_n]$ ($n = 1-4$). The 1:1 compounds are tetrameric, with either cubane or chair structures depending on the steric requirements of both X and PR_3. $[AgX(PPh_2Bu)]$ (X = Cl, Br, I) have been shown to possess a Ag_4X_4-cubane core.[12] By using $PR^1{}_2R^2$ ligands of intermediate size between Pcy_3 (which forms two-coordinate Ag^+ species) and PPh_3 (which forms four-coordinate species), several three-coordinate (R^1 = Ph; R^2 = Ph, cy, C_5H_9) or two-coordinate ($R^1 = C_5H_9$, cy; R^2 = Ph) complexes have been generated.[13]

Heterobimetallic complexes of platinum, rhodium, or group 6 metals and silver with bridged bis(diphenylphosphanyl) methane (dppm) have been obtained.[14] The reaction of $[CoCl_2(PR_3)_2]$ ($PR_3 = PPh_3$, PPh_2CH_2COPh) with $AgBF_4$ gives $[Ag(PR_3)_2]Cl$, but the triphenylphosphine cobalt complex in the presence of excess PPh_3 gives the heterotrimetallic complex $[Ag_2CoCl_4(PPh_3)_4]$.[15]

Silver complexes with bidentate diphosphines tend to be bridged dimers or tetramers (Figure 2). A common $[Ag_2(dppm)_2]^{2+}$ core occurs in $[Ag_2X_2(dppm)_2]$ (X = NO_3, O_2CH_2Ph, O_2CMe, CH_3COO). The complexes $[Ag_3Cl_2(dppm)_3]X$ (X = ClO_4, $SnPh_2(NO_3)Cl$), $[Ag_3I_2(dppm)_3]I$ and $[Ag_4(\mu\text{-dppm})_4(\mu_4\text{-E})](OTf)_2$ (E = S, Se, Te) contain tri- or tetranuclear species. Also, a series of hexanuclear and heptanuclear silver(I) chalcogenolate complexes with bridging dppm ligands, $[Ag_6(\mu\text{-dppm})_4(\mu_3\text{-EAr})_4](PF_6)_2$ (EAr = SPh, SC_6H_4Me-p, SePh, SeC_6H_4Cl-p)

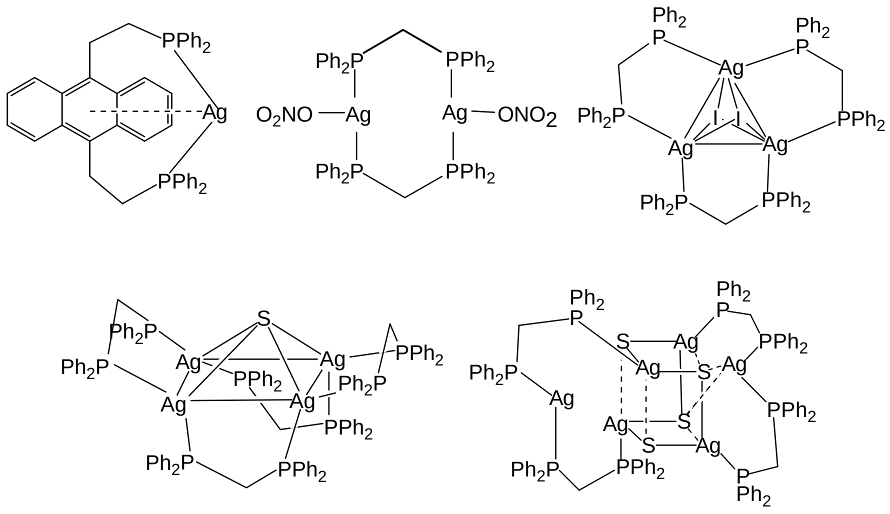

Figure 2 Structures of some silver(I) complexes with bridging bidentate diphosphines

and $[Ag_7(SPh)_7(dppm)_3]$, have been synthesized and characterized.[16] With some bulky diphosphines, such as 9,10-bis{(2-diphenylphosphanyl)ethyl}anthracene, mononuclear complexes can be obtained.[17]

3.3 Nitrogen Donor Ligands

There is considerable recent interest in the development of synthetic routes to supramolecular architecture from the self-assembly of silver(I) with multifunctional ligands under controlled reaction conditions.[18] Advances in this field have made use of nitrogen donors such as cyanide, thiocyanate, bipyridine, oligopyridines, aza-crowns, cryptands, tripodal imidazoles, and azide, leading to the rational synthesis of functional solid-state supramolecular silver(I) complexes with helical,[19] honeycomb channel,[20] interwoven diamondoid,[21] and other kinds of novel frameworks. The assembly process involves the interplay of various intermolecular interactions, which include hydrogen bonding, $\pi-\pi$ stacking, host-guest interaction, van der Waals forces, metallophilicity, and Coulombic attractions. Some examples of supramolecular silver(I) complexes consolidated by nitrogen donor ligands are shown in Figure 3.

3.4 Oxygen Donor Ligands

The most important classes of oxygen donor ligands for complexation of silver(I) are β-diketonates, carboxylates, crown ethers, and calixarenes.

Silver(I) β-diketonates are generally obtained by the reaction of Ag_2O with a β-diketonate in the presence of other ligands, or by treatment of $AgNO_3$ with the diketone in dry methanol and acetonitrile. They are of significant interest owing to the ease with which they can be reduced to the metal by metal-organic chemical vapor deposition (MOCVD), and volatility and stability problems have been overcome with new techniques such as supercritical fluid transport chemical vapor deposition (SFTCVD) and aerosol-assisted chemical vapor deposition (AACVD), as well as spray pyrolysis.[22]

Silver carboxylate compounds are light-sensitive and generally insoluble in most solvents, making it difficult for their structural characterization. In contrast, the zwitterionic betaine ligands $R_3N^+(CH_2)_nCO_2^-$ form stable silver complexes that are soluble in water and ethanol, and a variety of discrete dimers or polymeric chain/network structures constructed by the linkage of dimeric subunits have been obtained.[23]

Several silver(I) complexes with crown ethers and calixarenes have been synthesized. In the design of discrete molecules and infinite chains in silver acetylide chemistry, crown ethers function as blocking groups or protective cordons around a polyhedral $C_2@Ag_n$ cage so that the isolation of lower-dimensional supramolecular entities can be achieved.[24]

3.5 Chalcogen Donor Ligands

Silver(I) form numerous complexes with ligands containing soft S, Se, and Te donor atoms. The principal types of sulfur ligands are the thiolates, which give oligomers $(AgSR)_n$, dithiolates, thiocarbamates, dithiocarbamates, thiocyanate, thioureas, and thioethers. The complex $[Ag_4(SPh)_4(PPh_3)_4]$ takes the chair configuration. Silver(I) also binds to peptides and proteins, with a preference for –SR and imidazole nitrogen functionalities. Silver(I) thia-crown complexes have been used as templates for the synthesis of extended polyiodide networks, or as building blocks for the formation of coordination polymers.[25a–d] Silver(I) complexes with macrocyclic selenoethers are also known.[25e]

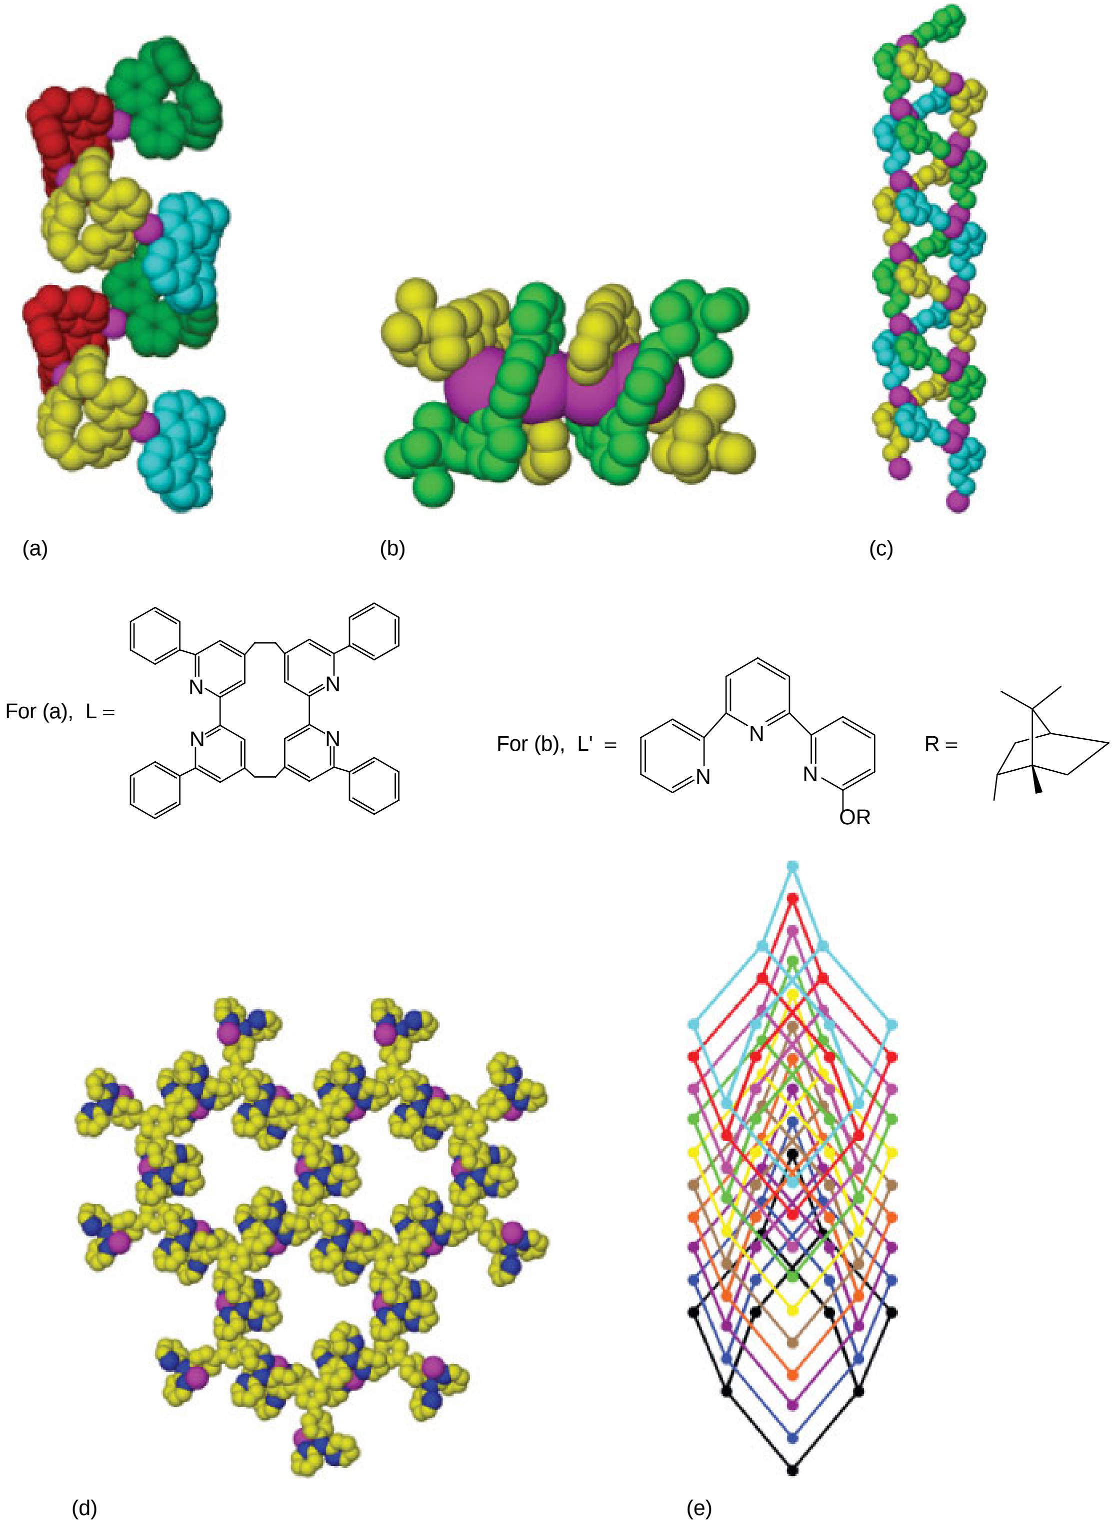

Figure 3 Structures of some supramolecular silver(I) coordination complexes with nitrogen donor ligands. (a) Helical polymeric cation in $[AgL]_n(PF_6)_n$. Different colors used for consecutive L ligands clearly reveal the pitch of the helix.[19a] (b) Tetranuclear M,M-$[\{Ag_2L'_2\}_2]^{4+}$ bis(double helices) in $[Ag_2(L')_2][PF_6]_2\cdot Me_2CO$.[19b] (c) Triple helical polymer in Ag(3-amp)ClO_4 (3-amp = 3-aminomethylpyridines) showing the pitch along the *b* axis.[19c] (d) Space-filling model of single honeycomb-shaped cavity in $[\{[Ag(CF_3SO_3)]_{1.5}(tdapb)\}_n]$ (tdapb = 1, 3, 5-tris(4-(2, 2′-dipyridylamino)-phenyl)benzene).[20a] Color code: silver, purple; nitrogen, dark blue; carbon, yellow. (e) Schematic view of the 10-fold interpenetration in the coordination network of $[Ag(ddn)_2]NO_3$ (ddn = 1,12-dodecanedinitrile)[21a]

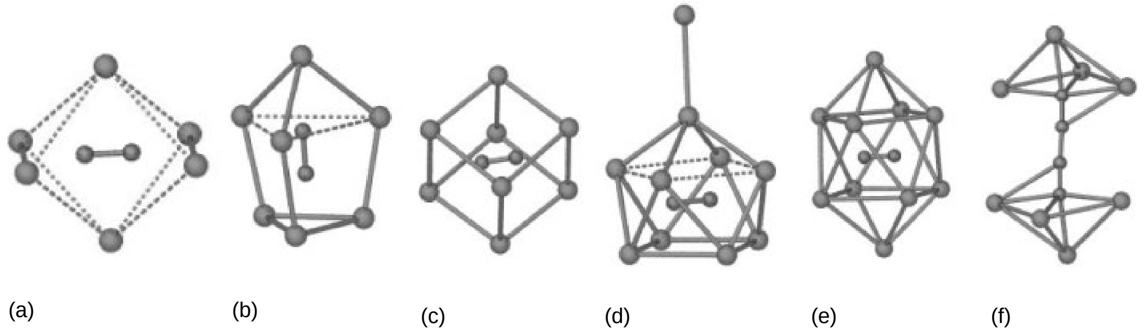

Figure 4 Silver polyhedra with embedded acetylenediide: (a) $C_2@Ag_6$ in $Ag_2C_2{\cdot}AgNO_3$.[27a] (b) $C_2@Ag_7$ in $2Ag_2C_2{\cdot}AgF{\cdot}4AgCF_3SO_3{\cdot}CH_3CN$.[27d] (c) $C_2@Ag_8$ in $[Ag_8(C_2)(CF_3CO_2)_6(L)_6]$ (L = 4-hydroxyquinoline).[27g] (d) $C_2@Ag_9$ in $Ag_2C_2{\cdot}8AgF$.[27b] (e) $C_2@Ag_{10}$ in $(L_2H)_4[Ag_{10}(C_2)(CF_3CO_2)_{12}(L)_2]{\cdot}5H_2O$ (L = 4-hydroxyquinoline).[27g] (f) $Ag_4C_4Ag_4$ aggregate in $Ag_2C_4{\cdot}6AgNO_3{\cdot}nH_2O$ (n = 2, 3)[27i]

3.6 Silver-rich Compounds

The significance of argentophilicity, that is, the $d^{10}-d^{10}$ closed-shell attraction that promotes the aggregation of silver(I) centers, has been substantiated by recent spectroscopic and structural evidence.[26]

3.6.1 *Complexes Containing Silver Acetylide or 1,3-Butadiynediide*

The general occurrence of $C_2@Ag_n$ polyhedra ($n = 6-10$; each with an embedded C_2^{2-} dianion) and fused double cages $(C_2)_2@Ag_{2n-m}$ (n vertexes, m shared atoms) has been established in a series of double, triple, and quadruple salts containing silver(I) acetylide (IUPAC name is acetylenediide), Ag_2C_2.[27a–e] The geometries of some $C_2@Ag_n$ polyhedra are illustrated in Figure 4. The exploration of $C_2@Ag_n$ polyhedra as building blocks for supramolecular assembly via functional linkages between the agglomerated components has led to the generation of a variety of new coordination frameworks.[27f–h] Replacement of C_2^{2-} by its higher homolog C_4^{2-} disrupts the convex $C_2@Ag_n$ cage, as found in two hydrated double salts $Ag_2C_4{\cdot}6AgNO_3{\cdot}nH_2O$ (n = 2, 3).[27i]

3.6.2 *Halide-centered Ag_n Cages*

The mixed-metal cluster $[Ni^{II}{}_6Ag^{I}{}_8(D\text{-pen})_{12}Cl]^{5-}$ (pen = penicillamine) has a central skeleton consisting of silver atoms at the corners of a cube with the chloride ion in its center.[28a] In the series of tetradecanuclear complexes $[Ag_{14}(C{\equiv}C^tBu)_{12}X]Y$ (X = F, Cl, Br; Y = OH, BF_4),[28b,c] the central cage is also a cubic array of silver atoms with an encapsulated halide ion, and the stabilization of these compounds is attributable to the argentophilic Ag···Ag interaction (Figure 5a). The halide-centered $Ag^I{}_8$ cubic cluster also occurs in $\{Ag_8(\mu_8\text{-X})\ [Se_2P(OR)_2]_6(PF_6)\}$ (R = Et, Pr, ^{i}Pr; X = Cl, Br).[28d,e] The isostructural silver(I) triple salts $AgCN{\cdot}AgF{\cdot}4AgCF_3CO_2{\cdot}2L$ (L = MeCN or H_2O) have a layer structure in which the fluoride-centered octahedral cage $F@Ag_6$ are interconnected by $\kappa C, \kappa C : \kappa N, \kappa N$-cyanide and $\mu\text{-}O, O{:}O'O'$-trifluoroacetato bridges.[28f]

3.6.3 *Silver–Chalcogenide Clusters*

Examples of silver-rich chalcogenide 'supercluster' complexes include $[NHEt_3]_4[Ag_{50}S_7(SC_6H_4tBu)_{40}]$,[29a] $[Ag_{70}S_{20}(SPh)_{28}(dppm)_{10}](CF_3CO_2)_2$ and $[Ag_{262}S_{100}(StBu)_{62}(dppb)_6]$,[29b] and $[Ag_{70}S_{16}(SPh)_{34}(PhCO_2)(triphos)_4]$ and $[Ag_{188}S_{94}(PR_3)_{30}]$ (R = nPr, nBu).[29c] Similar very large Ag–Se and Ag–Te clusters such as $[Ag_{172}Se_{40}(SenBu)_{92}(dppp)_4]$,[29d] $[Ag_{38}Te_{13}(TetBu)_{12}(dppe)_6]$[29e] and $[Ag_{124}Se_{57}(SePtBu_2)_4Cl_6(tBu_2P(CH_2)_3PtBu_2)_{12}]$[29f] have been reported (triphos = 1, 1, 1-tris(diphenylphosphanylmethyl)ethane, dppb = bis(diphenylphosphanyl)butane, dppp = 1, 3-bis(diphenylphosphanyl)propane, dppe = 1, 2-bis(diphenylphosphanyl)ethane).

3.6.4 *Silver–Gold Clusters*

Taking advantage of argentophilicity and aurophilicity, large ternary M–Ag–Au clusters have been prepared: for example, $[(Ph_3P)_{10}Au_{12}Ag_{12}PtCl_7]C1$[30a] (Figure 5b), $[(Ph_3P)_{10}Au_{12}Ag_{12}NiCl_7](SbF_6)$[30b] and $[(Ph_3P)_6Au_6Ag_6Pt(AgI_3)_2](THF)_2$.[30c]

4 SILVER(II) COMPOUNDS

The Ag^{2+} ion is produced as an orange transient species $[Ag(H_2O)_6]^{2+}$ via oxidation of silver(I) salts with ozone in strongly acidic solution. It readily oxidizes water to oxygen. Silver(II) fluoride, AgF_2, is formed by the highly exothermic reaction of fluorine with very finely divided silver. AgF_2 is antiferromagnetic, with a magnetic moment well below

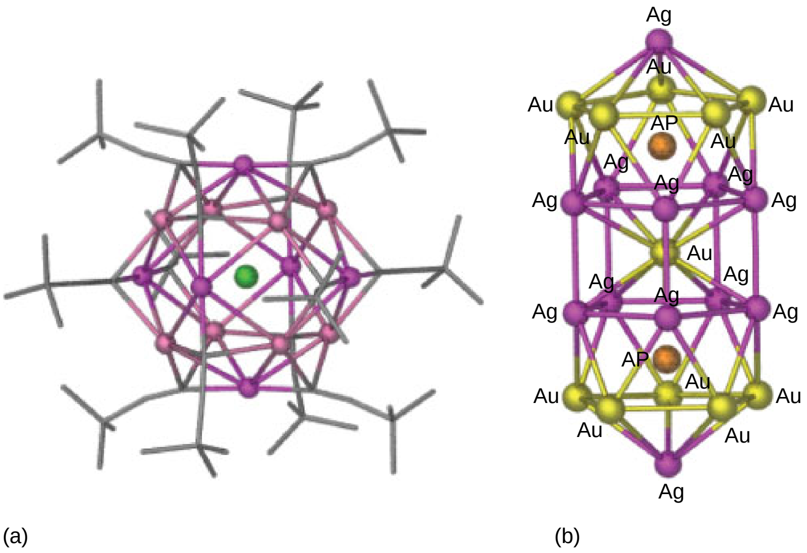

Figure 5 (a) Structure of silver cage complexes $[Ag_{14}(C{\equiv}C^tBu)_{12}X]OH$ (X = Cl, Br) showing the rhombic dodecahedron of silver atoms (solid bonds) and the encapsulation of a halide anion at the center of an octahedron of type 2 silver atoms. Silver atoms of types 1 and 3 cap the faces of this octahedron and define a cubic array.[28b] (b) Mixed-metal $Au_{12}Ag_{12}Pt$ core in $[(Ph_3P)_{10}Au_{12}Ag_{12}PtCl_7]Cl$; the Pt atom and one Au atom randomly occupy the pair of AP sites[30b]

that expected for one unpaired electron. It can conveniently be used as a good source of fluorine in chemical reactions. Silver has a remarkable catalytic effect on reactions of many gases with fluorine, owing to the formation of AgF_2 as an intermediate. Fluoride ions and AgF_2 form the fluoro-complexes AgF_3^-, blue-violet AgF_4^{2-} and AgF_6^{4-}; in each case the Ag^{2+} ion is octahedrally coordinated by F^- with some tetragonal distortion. The octahedra share either opposite faces (in AgF_3^-) or edges (in AgF_4^{2-}) to form an infinite chain, or exist as discrete species (in AgF_6^{4-}). Silver fluorosulfate $Ag(OSO_2F)_2$ is made by heating the metal with $S_2O_6F_2$ at 70 °C and is stable to 210 °C.

Silver(II) forms stable complexes with a variety of nitrogen donor ligands such as pyridine, substituted bipyridine, phenanthroline, or citrazinic acid. They are usually obtained by reaction of a silver(I) salt with peroxodisulfate in the presence of the ligand.[31]

Disproportionation of Ag(I) to silver metal and Ag(II) in the presence of tetraaza macrocyclic ligands depends upon the ring size of the macrocycle; thus while 14-, 15-, and 16-membered rings generally cause disproportionation, larger rings do not. Two mixed-valence complexes $[Ag^{II}(tmc)(BF_4)][Ag^{I}_6(C_2)(CF_3CO_2)_5(H_2O)]\cdot H_2O$ and $[Ag^{II}(tmc)][Ag^{II}(tmc)(H_2O)]_2[Ag^{I}_{11}(C_2)(CF_3CO_2)_{12}(H_2O)_4]_2$ (tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) have been prepared. In the former, a $[Ag^{II}(tmc)(BF_4)]^{+1}_{\infty}$ cationic column induces the assembly of an anionic zigzag chain constructed from edge-sharing of silver(I) triangulated dodecahedra each enclosing a C_2^{2-} species. As to the latter, $[Ag^{II}(tmc)]^{2+}$ and $[Ag^{II}(tmc)(H_2O)]^{2+}$ complex cations together induce the self-assembly of a centrosymmetric anionic cluster dimer from the Ag(I), C_2^{2-} and $CF_3CO_2^-$ species.[32]

The porphyrins constitute another class of nitrogen donor ligands which favor Ag(II) over Ag(I). Their macrocyclic structure provides strong in-plane ligand fields, which facilitate oxidation of the metal.[33] Phthalocyanine complexes of Ag(II) are very stable and can be oxidized electrochemically to Ag(III); further oxidation gives a Ag(III) phthalocyanine cation radical. The oxidation of Ag(I) complexes of sulfur macrocycles also leads reversibly to Ag(II) complexes.[34]

Silver(II) complexes in the gas phase have been prepared with several nitrogen- and oxygen-donor ligands including pyridine, tetrahydrofuran, benzene, and CO_2. The complexes are of the type $[AgL_n]^{2+}$, and the compound $[Ag(CO_2)_4]^{2+}$ is particularly stable.[35]

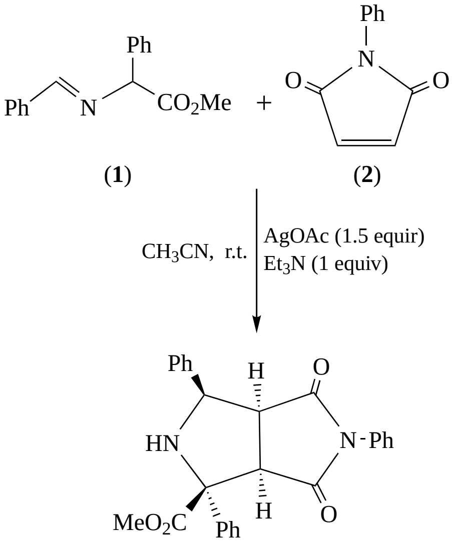
5 SILVER(III) AND SILVER(IV) COMPOUNDS

The anodic oxidation of neutral aqueous solutions of $AgClO_4$ or $AgBF_4$ yields black, metallic lustrous crystals of Ag_2O_3, which contain square-planar Ag(III). Oxidation at lower potentials leads to the black, semiconducting monoxide AgO, which is actually diamagnetic $Ag^{I}Ag^{III}O_2$; it can also be obtained by oxidation of Ag_2O with $S_2O_8^{2-}$ in alkaline solution. Trisilver tetroxide, Ag_3O_4, contains both divalent and trivalent silver, as indicated by the formula $Ag^{II}Ag^{III}{}_2O_4$.

Oxidation of Ag(I) by $S_2O_8^{2-}$ in a strong alkaline solution of periodate or tellurate yields a yellow, diamagnetic silver(III) complex, for example, $K_5[Ag(IO_6H)_2]$ and $Na_5[Ag(TeO_6H_2)_2]$.

Oxidation of a mixture of potassium and silver(I) halides with fluorine in alkaline solution produces yellow potassium tetrafluoroargentate, $KAgF_4$, which is very sensitive to moisture. The corresponding yellow sodium and cesium salts are also known. All contain the diamagnetic square-planar $[AgF_4]^-$ ion. There are mixed-metal salts such as KCs_2AgF_6, which contains the octahedral $[AgF_6]^{3-}$ ion. Fluorination of a mixture of CsCl and AgCl under pressure yields a complex salt of tetravalent silver $Cs_2[Ag^{IV}F_6]$.

A mixed-valence silver(I)-silver(III) cryptate complex has been synthesized by condensation of tris(3-aminopropyl)amine and terephthaldehyde in the presence of $AgNO_3$. Other pyridine silver(III) complexes have been obtained by oxidation of silver nitrate and ammonia with ammonium peroxydisulfate in aqueous ammonia solution. An air-stable diamagnetic silver(III) complex of a N-confused tetraphenylporphyrin, 5,10,15,20-tetraphenyl-2-aza-21-carboporphyrin argentate(III), has been described.[36]

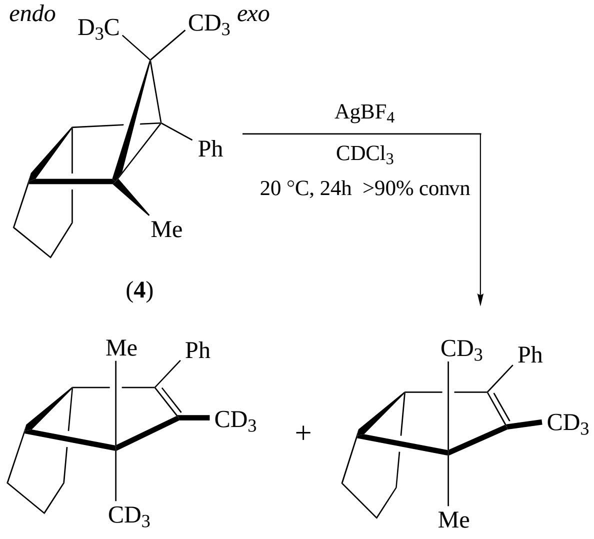


(1) (2) (3)

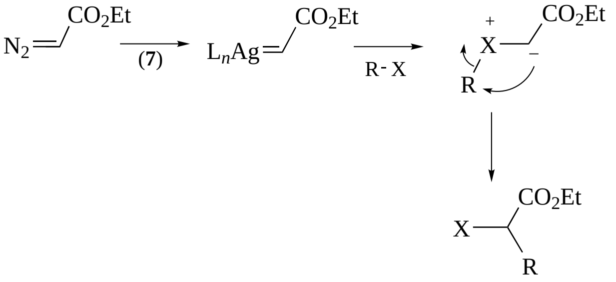
6 CATALYSIS

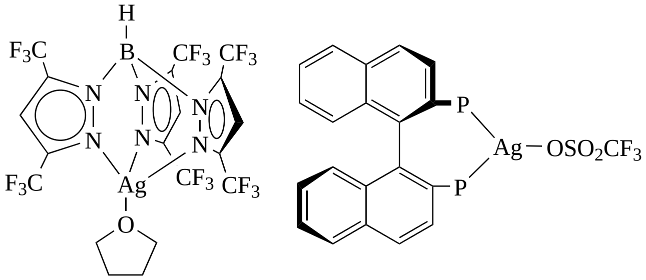
The metal is useful as a catalyst, particularly in the partial oxidation of ethylene to ethylene oxide. Silver(I) salts have mild Lewis acidity, rendering them useful as promoters and catalysts in organic synthesis.[37] Achiral silver(I) compounds, especially $AgBF_4$ and AgOTf, have been widely used in organic synthesis and numerous selective carbon–carbon bond-forming reactions, including cycloaddition, rearrangement, arylation and alkylation.[38] For example, AgOAc catalyzes the cycloaddition of (**1**), an arylidene imine of an α-amino acid ester, to dipolarophile (**2**), to give the proline derivative (**3**) in 71% yield.[39]

A catalytic amount of $AgBF_4$ promotes the rearrangement of housane (**4**) to the diastereomeric cyclopentenes (**5**) (*endo*-CD_3 group migration, 86% yield) and (**6**) (*exo*-CD_3 group migration, 14% yield).[40]



(4) (6) (5)





(**7**) (*R*)-BINAP·AgOTf (**8**)

The complex $[HB\{3,5\text{-}(CF_3)_2pz\}_3]Ag(THF)$ (**7**) has been employed in the silver-catalyzed activation of carbon-halogen bonds through a carbene insertion process that occurs at room temperature, resulting in formation of a new sp^3–sp^3 carbon–carbon bond.[41]

The remarkable affinity of the silver ion for halides can be conveniently applied to accelerate the chiral palladium-catalyzed Heck reaction and other reactions.[42] Enantioselectivity of these reactions is generally increased by addition of silver salts, and hence silver(I) compounds in combination with chiral ligands hold much promise as chiral Lewis acid catalysts for asymmetric synthesis. Employing the BINAP·silver(I) complex (**8**) as a chiral catalyst, the enantioselective aldol addition of tributyltin enolates (**9**) to aldehydes (**10**) has been developed.[43] This catalyst is also effective in the promotion of enantioselective allylation, Mannich, ene, and hetero Diels–Alder reactions.

1 INTRODUCTION

The synthesis of organometallic compounds of silver has long been rather limited owing to the low thermal stability of the resulting compounds, which are generally less stable than their copper analogs. Furthermore, organometallic silver compounds are generally photosensitive, a fact that further limits their synthesis. The first alkylsilver compounds were reported[1] in 1941, although π and acetylene complexes were known prior to this time.[2] Fluoroalkyls have been used to prepare much more stable alkyl silver complexes, although most of these compounds are also air, moisture, and light sensitive. Surprisingly high thermal stability has been realized with ylide (*see Ylide*) complexes of silver. However, even these compounds tend to be photosensitive and often deposit a silver mirror. Although this lack of thermal and photostability has hampered structural studies of organometallic silver complexes, some X-ray structural results have been obtained. A few organometallic clusters also have been characterized structurally. A thorough review of silver organometallic compounds appeared in 1995.[3] Perhaps, the single most active area of organometallic silver chemistry during the past decade has been the study of carbene complexes. Although they were first reported[4] in 1991 by Arduengo, considerable progress has been made in understanding the synthesis, reactivity, and bonding of these compounds. Arnold reviewed advances in this chemistry in 2002.[5]

The relatively small energy separation[6] (about one-half the value for Cd^{II}) between the filled d orbitals and the 5s orbital tends to cause the coordination about Ag^{I} to be linear with strongly donating ligands such as are found in organometallic species. Ag^{II} or Ag^{III} organometallic species are also much more difficult to obtain than similar copper and gold compounds. No organometallic compounds have been reported to date that have been crystallographically characterized which contain silver in one of these well-established higher oxidation states.

The $I = 1/2$ nuclear spins of ^{109}Ag and ^{107}Ag have made it possible to study organometallic silver complexes by NMR (a tool that has been less successfully used with similar copper complexes), although the sensitivity of the silver nuclei is rather low.

Organometallic silver complexes do not require special handling techniques aside from taking precautions regarding light, atmosphere, and thermal sensitivities typical of organometallic compounds. The well-known antibacterial properties of silver and its compounds suggest that new materials be handled cautiously. Contact with skin generally leads to brown–black stain deposits, which take a considerable time to vanish.

2 ALKYL AND ARYL COMPOUNDS

The use of organozinc compounds to prepare alkylsilver species was attempted as early as 1859. Success in synthesizing alkylsilver compounds, however, was not achieved until 1941 when Semerano and Riccoboni[1] found that tetraalkyllead could be used as a starting material (equation 1).

$$R_4Pb + AgNO_3 \xrightleftharpoons{-80\,^{\circ}C} RAg + R_3PbNO_3 \qquad (1)$$

The much more stable arylsilver compounds had been obtained by Krause and Schmitz[7] in 1919. Taking advantage of the thermodynamically favorable formation of Et_3PbONO_2, various unsymmetrical Et_3PbR compounds were used by Glocking[8] to prepare a number of different silver compounds, such as $PhCH_2Ag$, p-$CF_3C_6H_4Ag$, p-$Me_2NC_6H_4Ag$, and the more stable alkenyl compound PhCH=CHAg. Glocking noted that these reactions occurred by a single ligand transfer with exclusive transfer of the special ligand, and that the most stable organosilver compounds were those with R groups in which the radical, R•, has the least stability. At $-80\,^{\circ}C$, the alkylsilver(I) compounds were found to be stable for several hours. Higher temperatures lead to quick decomposition. A listing of a few alkylsilver compounds is presented in Table 1. The thermal stability decreases as the alkyl group becomes larger; at $-30\,^{\circ}C$, for example, CH_3Ag, a polymeric species, is stable for a short time while $CH_3CH_2CH_2Ag$ decomposes quickly at $-60\,^{\circ}C$.

Table 1 Representative alkyl and aryl silver(I) compounds

		Thermal stability[a]	
Compound	Appearance	Slow dec.	Fast dec.
MeAg[1,3]	Yellow	−80 to −50[b]	−30
$MeAg{\cdot}AgNO_3$[1,3]	Light yellow	[c]	–
EtAg[1,9]	Red-brown	−80[d]	−50
$PhCH_2Ag$[8]		−78[e]	–
PhAg[10–13]	Dark brown	25[f]	–
$2PhAg{\cdot}AgNO_3$[6]	Bright yellow[g]	50	80−100
2,5-$Me_2C_6H_4Ag$[10]	Rust	25	–

[a]Temperature in °C. [b]Half-life times for pure dry powder are 6 months at −50 °C but only 4 h at −30 °C. [c]Somewhat more stable than MeAg. [d]Half-life times in ethanol are 3 h at −40 °C and 19 min at −20 °C. [e]Only a transient existence. [f]Ether suspension. [g]Light sensitive.

Phenylsilver was made by Krause[10] and by Reich[11] from a Grignard reagent in the dark (equation 2).

$$AgCl + PhMgBr \xrightarrow{\text{dark}} PhAg + MgBrCl \quad (2)$$

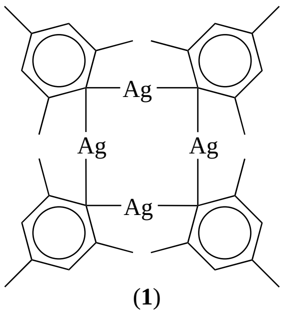
The dark brown phenylsilver compound exhibits slow decomposition at 25 °C. While the compound is sensitive to both air and nitrogen atmospheres, it is not particularly light sensitive. Hasimoto and Nanako[12] studied the decomposition and proposed a radical decomposition mechanism. The addition of *p*-benzoquinone decreased the formation of biaryl products in ether or pyridine.

Gilman *et al.*[13] found that the Grignard reaction with AgBr was considerably accelerated by light (equation 3).

$$AgBr + PhMgBr \xrightarrow[Et_2O]{h\nu,\ -18\,^\circ C} PhAg + MgBr_2 \quad (3)$$

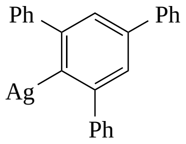
Phenylsilver was found to react readily with acetyl chloride, allyl bromide, and phenyl isocyanate to give MeCOPh, $CH_2{=}CHCH_2Ph$, and $(PhNCO)_3$ respectively, but better yields and cleaner reactions occur with phenylcopper. Although symmetrical tetraalkyllead and tin compounds do not react with $AgNO_3$, the unsymmetrical Ph_3EtM (M = Pb, Sn) species do react[6] to give $2PhAg{\cdot}AgNO_3$ and $EtPh_2MONO_2$, with Pb reacting more quickly than Sn. The silver compound is very light sensitive, decomposing in a few minutes in daylight. A few of the arylsilver compounds are listed in Table 1.

The first structural report of an arylsilver complex appeared in 1983. Floriani and coworkers[14] prepared (mesityl)Ag from the Grignard reagent MesMgBr and AgCl under N_2 in the absence of light. The product is a crystalline tetramer, $Ag_4(Mes)_4$ (**1**) with Ag…Ag distances of 3.97 and 3.79 Å, well outside bonding distances. The mesityl group sterically shields the Ag^I atoms, which are two coordinate. This ligand is not subject to orthometallation (*see Orthometalation*). The Cu^I and Au^I mesityl compounds have different structures from the Ag^I species.



(**1**)

Unfortunately, the compound thought to be an example of a mono-coordinate Ag(I) complex,[15] the species reported to be Ag[Triph], (**2**) (Triph = –C_6H_2-2,4,6-Ph_3) apparently is the bromide starting material, TriphBr.[16] In a very nice paper by Power,[17] the syntheses and structures of lithium organoargentate salts $[Li(THF)_4][Ag(Triph)_2]{\cdot}THF$ and $[Li(THF)_4][Ag(C_6H_3$-2,6-$Mes_2)_2]{\cdot}1/8OEt_2$ (Mes = C_6H_2-2,4,6-Me_3) have been reported. These structures show Ag−C distances, 2.05−2.11 Å, that are longer than those of the Cu(I) analogues, as expected, further supporting the conclusions of Haaland[16] regarding the supposed mono-coordinate Ag(I) (and Cu(I)) species.



(**2**)

3 ALKENYL AND ALKYNYL SILVER(I) COMPOUNDS

Alkenylsilver compounds have been prepared from more electropositive element organometals, such as tetraalkenyllead.[18,19] While these compounds are more stable thermally than the alkylsilver species, they are air and moisture sensitive (Table 2). Complete decomposition of styrenylsilver,[18] for example, takes several days at room temperature. Metallic silver and polystyrene are formed.

Silver acetylides are readily prepared from silver salts such as the nitrate or perchlorate and the alkyne in aqueous or methanolic ammonia. They have been known[22] since the mid-1800s. In neutral solutions, a mixed salt, $AgC{\equiv}CR{\cdot}nAgNO_3$, is obtained.[24] Acetylene gives[20] the silver carbide, Ag_2C_2, and

Table 2 Examples of alkynylsilver compounds

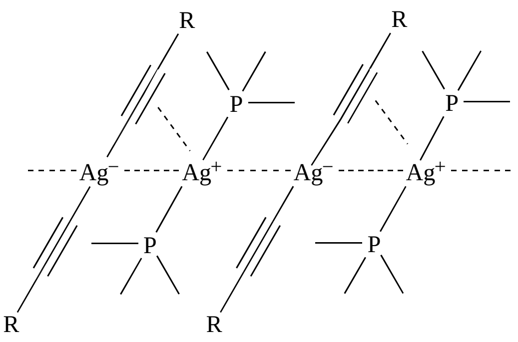
Compound	Appearance	Decomposition temp. (°C)
$AgC{\equiv}CAg$[20]	White, shock sens.	140–190
$AgC{\equiv}CAg{\cdot}AgNO_3$[20]	White needles	210–230
$[KC{\equiv}CAg]_n$[21]	Polymeric	–
$HC{\equiv}CAg$[21]	Intense yellow	0
$MeC{\equiv}CAg$[21,22]	White crystalline	70
$PhC{\equiv}CAg$[22]	White crystalline	100
$PhC{\equiv}CAg{\cdot}AgNO_3$[22]	White needles	–
$[PhC{\equiv}CAgPMe_3]_n$[23]	Polymeric cryst.	130–140

mixed salts such as $Ag_2C_2{\cdot}nAgNO_3$, depending upon specific reaction conditions.

Acetylene and its derivatives react with trialkyl or triaryl phosphite complexes of AgCl to produce[25] the corresponding alkynyl complexes (equation 4).

$$RC{\equiv}CH + ClAgP(OR')_3 \longrightarrow RC{\equiv}CAg + HPO(OR')_2 + R'Cl$$
$$R = H, Ph, PhO, p\text{-}BrC_6H_4O, Me_3Si;\ R' = Et, Ph \qquad (4)$$

The insolubility of alkynylsilver compounds indicates coordination polymerization. These acetylides are thermally rather stable, decomposing[24,26] between 100 and 200 °C. The lowering of the triple bond C≡C stretch frequency in the IR spectrum also suggests that the triple bond interacts directly with Ag through π-bonding in the solid state. Addition of strong donor ligands results in the breakdown of the polymer. The resulting solid product from phenylethynylsilver, R, and trimethylphosphine, L, is a linear chain of metal atoms with alternating $[L_2Ag]^+$ and $[R_2Ag]^-$ moieties. The crystal structure[23] reveals that the coordinated alkyne also residually π-bonds to an adjacent Ag atom in the cation (**3**). The Ag···Ag distance is 3.033 Å.



(**3**)

Silver tetranuclear clusters of luminescent silver(I) arylacetylides have been synthesized, characterized structurally, and studied for their photophysical properties.[27] Interesting rhombohedral silver-alkynyl cage compounds $[Ag_{14}(C{\equiv}C^tBu)_2(X)][BF_4]$ (X = F, Cl, Br) with O_h molecular symmetry, apparently form templates around the halide ions.[28] The silver...silver edge distances are about 2.9 Å, similar to the silver...silver distances observed in the tetranuclear clusters.

Complex anionic silver acetylides, $K[Ag(CCR)_2]$ (R = H, Me, Ph), are known and are prepared from the appropriate alkynylsilver and the potassium acetylide in a polar solvent.[21] They are colorless crystalline solids that are sensitive to light and that decompose in solution. They apparently are not explosive.

4 π-BONDED COMPOUNDS

Alkene interactions with Ag^I are well known, and chromatographic columns containing silver salts have long been used to separate alkenes. An early crystal structure[29] was that of 1,3,5,7-cyclooctatetraenesilver(I) nitrate, a pale yellow crystalline material that melts with decomposition at 173–174 °C. The structure of the benzenesilver(I) perchlorate was described by Rundle[30] in 1950 and again by Smith and Rundle[31] in 1958. The structure consists of chains of benzene and Ag^+, with Ag^+ also sitting above and below the benzene rings, giving a three-dimensional polymeric network. The syntheses of alkene(β-diketonato)silver(I) compounds are described[32] in *Inorganic Syntheses*. The compounds all lose the alkene when stored in air. The use of silver catalysts for the epoxidation of olefins[33] has been the primary focus of olefin–silver studies in recent years although separations of olefins using silver substrates on supports also has produced a number of patents and papers.[34]

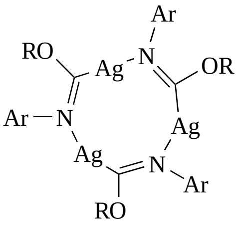
5 CYANIDES, ISOCYANATES, AND RELATED COMPOUNDS

Elsewhere in this encyclopedia, there is a general discussion of cyanide complexes of the transition metals (*see* ***Cyanide Complexes of the Transition Metals***). AgCN has a chain structure with a linear N–Ag–C coordination.[6] Addition of alkali metal cyanides to AgCN produces the stable, linear $[NC\text{–}Ag\text{–}CN]^-$ anion. Much work has been related to the photophysics of these species that show exciplex formation in solution.[35] Reaction of alkyl iodides with AgCN produces isocyanides, Ag(CN)(CNR), from which the RNC can be removed upon heating with KCN. The bis(isocyanide)Ag^I cationic complexes $[Ag(CNC_6H_4Me\text{-}p)_2]X$ ($X = ClO_4, NO_3$) were studied by IR spectroscopy and found to have a higher NC stretching frequency than the uncoordinated ligands.[36]

Isocyanides of the general formula $[AgC(OR){=}NR']_3$ can be prepared according[37] to equation (5).

$$(ArNC)AgCl + ROH + KOH \longrightarrow H_2O + KCl + \frac{1}{3}[AgC(OR){=}NAr']_3$$
$$Ar = p\text{-}MeC_6H_4 \ (R = Me, Et, n\text{-}Pr) \quad (5)$$

Unlike the analogous isocyanide Au^I complexes, which react with alcohols or amines to form carbenes, the Ag^I complexes rearrange to the formamidate (RN=CHOR′) or formamidine (RNHCH=NR′) species, which are all probably cyclic oligomers such as (**4**).



(**4**)

These trimers are sensitive to heat and light, but at the time they were first made they were some of the most stable nonfluorinated σ-bonded organometallic Ag^I compounds known. The ligand can be transferred to other metals by metathesis; hence, they are synthetically useful reagents.

6 STABILIZED ORGANOSILVER COMPOUNDS

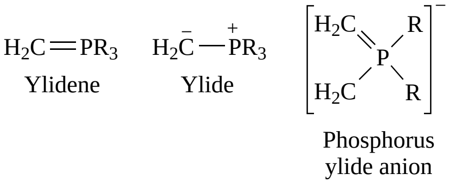
Several different approaches have been taken to form stabilized σ-bonded Ag^I organometallic compounds. One of the earliest was to use perfluoroalkyls. In 1968, it was shown[38] that AgF will react directly with a fluorinated alkene such as $CF_2{=}CFCF_3$ in MeCN at 25 °C to form $AgCF(CF_3)_2$, a product which darkens slowly upon standing at room temperature. The 1-chloroperfluoroisopropyl and perfluoro-1,1-dimethylbutyl derivatives were also synthesized in this manner. In general, perfluorocarbanions will react[39] with silver salts such as silver acetate to form the perfluorinated organometallic compound. The perfluoro carbanions are formed from alkali metal fluorides and fluoroalkenes. The perfluorinated organosilver compounds are air, moisture, and light sensitive. Reaction of $AgCF(CF_3)_2$ with O_2, for example, gives hexafluoroacetone. Thermal decomposition generally occurs at temperatures under 100 °C. It was reported that bis(trifluoromethyl)ketene reacts with AgF to produce the perfluoroaldehyde complex $AgC(CF_3)_2C(O)F$.[40] Excess alkali or alkaline earth halides can suppress thermal decomposition of organosilver compounds. Thus butylsilver, formed from AgBr·2LiBr using Grignard or alkyllithium reagents, decomposes at −10 °C compared with the −60 °C decomposition temperature of the nonstabilized species. The structure of (acetonitrile)perfluoroisopropylsilver(I) has been reported by Burch and Calabrese.[41]

Chelation has been used to stabilize organosilver compounds.[42] The compound {2-[(dimethylamino)methyl]-phenyl}silver, a chelate involving N and C coordination, melts at 180 °C. The adduct with AgBr is light and air stable for 10 days. The product from LiBr was the first example[43] to contain bridging phenyl groups. It decomposes at 180 °C but is air and moisture sensitive.

Whitesides and Casey[44] demonstrated that alkylsilver compounds could be stabilized by phosphine coordination to the Ag^I. The mechanism of decomposition of these complexes was investigated by Whitesides and his students over several years.[45] Radical processes generally are involved. Thus, thermal decomposition of n-BuAgP(n-Bu)$_3$ gives 93% C_8H_{18}, 5% C_4H_{10}, and lesser amounts of other products along with elemental silver and free phosphine. Photolysis gave a different product distribution. With s-butyl(tri-n-butylphosphine)silver(I), the product distribution suggested silver hydride formation; however, no general mechanism for decomposition was discernible.

Remarkable stability of the Ag^I–C σ-bond has been observed with a broad class of organic ligands called ylides (*see Ylide*) (**5**). These neutral or anionic ligands are believed to contribute stability[46] to the metal–carbon bond by delocalization of charge away from the metal atom to the ligand. The stability of the uncoordinated ligand itself accommodates metal–carbon bond rupture without radical formation. Schmidbaur and his coworkers[47] pioneered the use of these ligands to form stable organometallic species and were the first to synthesize organometallic ylide complexes of silver (6). Chlorinated hydrocarbon solvents used for syntheses only slowly attack the organometallics. Isolated compounds show remarkable thermal stability, melting without decomposition at 192–194 °C (R = H), 118–120 °C (R = Me), and 124–126 °C (R = i-Pr) and decomposing at temperatures above 200 °C. While air and moisture stable, they all appear to be photosensitive.

$$AgCl + 2CH(R)PR'_3 \longrightarrow [R'_3PC(R)H\text{-}Ag\text{-}CH(R)PR'_3]Cl \quad (6)$$
$$R = H, Me, i\text{-}Pr$$

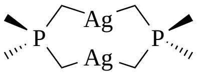


(**5**)

The ^1H NMR spectra of these ylide silver compounds showed coupling to ^{107}Ag and ^{109}Ag with ^2J(Ag–H) at

about 12 Hz. The $^{31}P\{^1H\}$ spectrum is a doublet with ^3J(P–Ag) = 9.1 Hz. Both silver isotopes (*see Isotopes & Isotope Labeling*) couple nearly equivalently, and hence only a doublet appears. The $^{13}C\{^1H\}$ spectra were the first to demonstrate $^{13}C-^{107,109}Ag$ spin–spin coupling. The neutral one-to-one adducts of CH_2PPh_3 with AgCl also were obtained by Schmidbaur and his coworkers[48] as monomeric species in solution, a result different from that obtained with the analogous copper(I) species that are polymeric. The pale yellow solid Ph_3PCH_2AgCl melts at 166–169 °C and is thermally stable up to 150 °C, although it is subject to decomposition in halocarbon solvents and in light.

At the same time, the synthesis of mononuclear silver ylide complexes were achieved, Schmidbaur and his colleagues[47] discovered that the ylide anions produced dinuclear species, $Ag_2[(CH_2)_2PMe_2]$. The remarkably stable methyl compound melts at 153–155 °C and can be sublimed at 150 °C and 0.1 atm. Mass spectral and ^1H and $^{31}P\{^1H\}$ NMR studies demonstrated the ring structure of the compound, although no structural analysis could be performed due to the photosensitivity of the compound. The synthesis of the dinuclear silver(I) ylide complex (**6**) is described[47] in *Inorganic Syntheses*, and although colorless crystals are obtained, no X-ray structure was possible due to sample decomposition in the X-ray beam.



(**6**)

The first structural report of a silver–ylide complex appeared[49] in 1988. This compound, C_6F_5–Ag–CH_2PPh_3, shows that the C–Ag–C geometry is linear with a Ag–CH_2 distance of about 2.2 Å. Additional structural reports have appeared.[50]

Five general types of silver(I) ylide complexes have been described (Table 3). They are all remarkably stable thermally but decompose in halohydrocarbon solvents and they are generally photosensitive. The intramolecular Ag···Ag distances in the dinuclear compounds are 2.9–3.0 Å and they generally range from colorless to yellow. The $[AgCH_2P(S)Ph_2]_2$ complex luminesces yellow at 77 K when subjected to UV radiation and is a linear chain polymer in the solid state with an intermolecular Ag···Ag distance of 3.1 Å. The compound also displays a dynamical NMR pattern (*see* ***Structure & Property Maps for Inorganic Solids***) in solution in which a ^2J(Ag–H) coupling is observed only at −60 °C. Rapid isomerism was suggested as the cause of the absence of $^{13}C-^{107,109}Ag$ coupling in $[Ag(CH_2)_2PMePh]_2$. A similar suggestion was made for the NMR pattern of $[AgCH_2P(S)Ph_2]_2$. Such an isomerization has been established for $[Au(CH_2)_2PMePh]_2$ where the trans isomer has been obtained by crystallization and studied crystallographically (*see* ***Gold: Organometallic Chemistry***). The mixed Cu, Ag dimer can be obtained by mixing the dinuclear copper(I) and silver(I) complexes in solution.

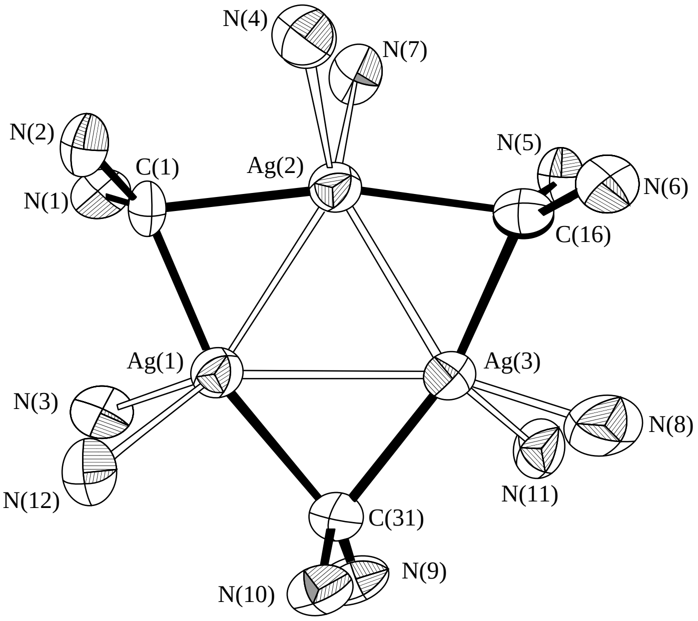
Table 3 Types of Ylide Complexes

	Type	Examples
I[46]	RAgY	Y = CH_2PPh_2, CH_2AsPh_2 R = C_6F_5
II[46]	[YAgY]X	Y = CH_2PPh_3, $CH_2S(O)Me_2$, $CHMePPh_3$, $Me_3PCH(SiMe_3)$, $Ph_3PCHCOR'$ (R′ = OMe, OEt, Me) X = NO_3^-, Cl^-
III[46,47]		E = P, As R = Me, Ph R′ = Me
IV[49]		R = Ph
V[49]		R′ = PPh_3

In addition to the phosphorus ylide complexes, arsenic and sulfur ylide complexes of silver have been obtained,[51] although no structural reports exist. While the arsenic derivatives match the phosphorus ylide complexes for stability of the Ag^I products, the sulfoxonium ylide complexes are somewhat less stable.

7 CARBENES

The 'bottleable' carbenes[5] formed by deprotonation of dialkyl imidazolium salts have produced a number of new compounds and clusters in which there is a Ag–C bond. There is good evidence that the singlet carbenes are dative-bonded[5] to silver through the C lone pair of electrons, with little, if any, metal-ligand π-bonding. Although discovered by Arduengo,[4] the synthesis from Ag_2O as developed by Lin[52] has proved to be sufficiently straightforward that a considerable new carbene chemistry has resulted.[5] An example of this is the work of Catalano,[53] who has found a new trinuclear cluster in which the carbenes bridge the silver atoms with the Ag_3 core seen here (**7**).



(**7**)

8 MISCELLANEOUS COMPOUNDS

A few interesting and unusual organometallic compounds of silver have been reported structurally that are categorized as miscellaneous. For example, a carbonyl complex has been obtained with a tetrakis(pentafluorotelluroxy)borate ligand.[43] Some unusual carbonyl clusters have been characterized, which contain bridging CO bonded to Ag with Os[44] and Ru[45] carbonyl components. Several cyano complexes also have been structurally characterized, such as bis(3,4;3′,4′-bis(ethylenedithio)-2,2′,5,5′-tetrathiofulvalenium)dicyanosilver(I) monohydrate, a compound of interest in studies of conducting materials.[46] In 2002, Mak reported[54] the structure of a silver cluster formed from Ag_2C_2 in which the C_2 unit is encapsulated within a Ag_8 square antiprism. These units are fused together into a polymeric column by edge-sharing of four of the Ag atoms of the Ag_7C_2 core structure. The dry starting material, Ag_2C_2, unfortunately detonates easily with thermal shock. Special silver(III) alkyl compounds such as $Ag(CF_3)_3L$, L = phosphine, and even $[Ag(CF_3)_4]^-$ have been reported. A detailed review of the synthesis of organometallic silver compounds appeared in 2004.[55]

1 INTRODUCTION

In 1845, M. Ebelmen, a French chemist, observed that tetraethyl orthosilicate reacts slowly with moisture to give a glassy solid. This was actually the first synthesis of an inorganic material (silica) from a metal–organic molecular precursor. It then took more than a century before this sol–gel synthesis began to attract academic and industrial interest. The first sol–gel products appeared on the market in 1953. Large-scale production by Schott Glaswerke started in 1959 with automotive rear-view mirrors and continued with antireflecting coatings in 1964. In the early 1960s, the sol–gel process was used for the production of ThO_2 and UO_2 microspheres in the nuclear industry. Since then, hundreds of scientists have become involved in this field and sol–gel science is now reaching its maturity.[1]

Glasses and ceramics are inorganic materials that have been produced for thousands of years (*see* ***Oxides: Solid-state Chemistry*** and ***Noncrystalline Solids***). Traditionally they are made from natural raw minerals such as clays or sand. Crystalline ceramics are shaped by adding water to clays in order to produce a plastic material and then heated in a furnace. Amorphous glasses are made from the melt and shaped by moulding near their softening temperature. In both cases, high temperatures are required.

In the sol–gel process, a solution of molecular precursors is converted by a chemical reaction into a sol or a gel which on drying and densification gives a solid material. This allows the production of single or multicomponent materials with high purity, novel compositions, tailored microstructures, and potentially greater chemical homogeneity at lower temperature. Moreover, films or fibres can be obtained directly from sols or gels by such techniques as dip-coating, spin-coating, spray, or drawing.[2]

The sol–gel process was first focused on silica glasses and then on multicomponent ceramics. The aim was to develop cheaper processing routes and to improve the properties of these materials. Nowadays, the major advance of sol–gel processes is undoubtedly the synthesis of hybrid organic–inorganic materials.[3]

This article describes the basic chemical reactions involved in the sol–gel synthesis of solid materials using molecular alkoxide precursors and reviews recent advances in hybrid materials preparation and properties.

2 BASIC PRINCIPLES OF SOL–GEL CHEMISTRY

2.1 Synthesis and Reactivity of Metal Alkoxides

Metal alkoxides $M(OR)_z$, where R is typically an alkyl group (R = Me, Et, etc.), have been known for a long time.[4,5] Many of them (M = Si, Al, Ti, etc.) are now commercially available. They can be synthesized via the reaction of metal chlorides with alcohol as follows:

$$MCl_z + h\ ROH \longrightarrow MCl_{z-h}(OR)_h + h\ HCl \quad (1)$$

Most transition metal chlorides undergo only partial alcoholysis leading to chloroalkoxides $MCl_{z-h}(OR)_h$. Therefore the reaction has to be driven to completion by adding a base such as ammonia or sodium alkoxide.

The reaction of metal chloride with alcohol is not the only way to synthesize alkoxides. Other inorganic compounds such as oxides can also be used as precursors for the synthesis of metal alkoxides:

$$P_2O_5 + 3EtOH \longrightarrow PO(OH)(OEt)_2 + PO(OH)_2(OEt) \quad (2)$$

Alkaline and alkaline-earth metals (*see* ***Alkali Metals: Inorganic Chemistry*** and ***Alkaline Earth Metals: Inorganic Chemistry***) are oxidized directly by alcohol:

$$Na + MeOH \longrightarrow NaOMe + \tfrac{1}{2}H_2 \quad (3)$$

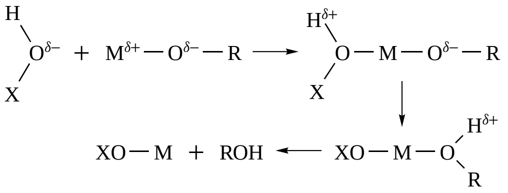
Alkoxy groups are rather hard π-donor ligands. They stabilize the highest oxidation number of the metal. Therefore alkoxides of main group elements and d^0 transition metals are well known, while those corresponding to soft d^n late transition metals have been much less studied. The number and stability of metal alkoxides decrease from left to right across the *periodic table*.

For coordinatively saturated metals the hydrolysis and condensation of metal alkoxides $M(OR)_z$ corresponds to the nucleophilic substitution of alkoxy ligands by hydroxylated species XOH:

$$M(OR)_z + x\ XOH \longrightarrow [M(OR)_{z-x}(OX)_x] + x\ ROH \quad (4)$$

where X stands for hydrogen (hydrolysis), a metal atom (condensation), or even an organic or inorganic *Ligand* (complexation).

These reactions can be described by a S_N2 mechanism, as follows:



(5)

The reaction starts with the nucleophilic addition of negatively charged $HO^{\delta-}$ groups on to the positively charged metal atom, $M^{\delta+}$, leading to an increase of the coordination number of the metal atom in the transition state. The positively charged proton is then transferred toward an alkoxy group and the positively charged protonated ROH ligand is finally removed.[6]

The chemical reactivity of metal alkoxides toward hydrolysis and condensation mainly depends on the positive charge of the metal atom δ_M, and its ability to increase its coordination number *N* (*see* ***Coordination Numbers & Geometries***). As a general rule, the *Electronegativity* of metal atoms decreases and their size increases when going from the top right of the *periodic table* to the bottom left. The corresponding alkoxides become progressively more reactive toward hydrolysis and condensation. Silicon alkoxides are rather stable while cerium alkoxides are very sensitive to moisture. Alkoxides of electropositive metals must be handled with care under a dry atmosphere, otherwise precipitation occurs as soon as water is present. Alkoxides of highly electronegative elements such as $PO(OEt)_3$ (*see* ***Phosphorus: Inorganic Chemistry***) cannot be hydrolyzed under ambient conditions, whereas the corresponding vanadium derivatives $VO(OEt)_3$ (*see* ***Vanadium: Inorganic & Coordination Chemistry***) are readily hydrolyzed into vanadium pentoxide gels.

2.2 Molecular Structure of Metal Alkoxides

All silicon alkoxides $Si(OR)_4$ are monomeric and tetrahedral, but the situation is completely different with other metal alkoxides $M(OR)_z$. The coordination number 'N' of metal ions in $MO_{z/2}$ oxides is usually larger than their oxidation state Z. Therefore most metal alkoxides are not coordinatively saturated and coordination expansion is a general tendency of the sol-gel chemistry of metal alkoxides $M(OR)_z$. This is currently achieved by oligomerization via the formation of alkoxy (OR) or oxo (O) bridges and metal alkoxides often exhibit oligomeric molecular structures $[M(OR)_z]_n$. The degree of oligomerization increases with the size of the metal atom, its electropositive character and the 'N–Z' difference. As a general rule, it increases with the atomic number and decreases with the oxidation state. Large electropositive metals are known to give oxo-alkoxides such as $Pb_4O(OEt)_6$ in which oxo bridges favor coordination expansion. Oxo-alkoxides are more stable than the corresponding alkoxides and, of course, are less reactive toward hydrolysis and condensation.[7]

Alkoxide precursors are usually dissolved in a solvent so that coordination expansion can also occur via solvation. Solvate formation is often observed when alkoxides are dissolved in their parent alcohol. The stability of such solvates increases with the size and the electropositive character of the metal, that is, when going down the *periodic table*. At room temperature monomeric $Ti(OPr^i)_4$ (**1**) is not solvated by isopropanol whereas solvated dimeric species $[Zr(OPr^i)_4(Pr^iOH)]_2$ (**2**) and $[Ce(OPr^i)_4,Pr^iOH]_2$ are formed in alcoholic solutions (*see* ***Titanium: Inorganic & Coordination Chemistry***; ***Zirconium & Hafnium: Inorganic & Coordination Chemistry***, and ***Actinides: Inorganic & Coordination Chemistry***). (Figure 1). The degree of oligomerization of metal alkoxides can be tailored by an appropriate choice of the solvent. $[Zr(OPr^n)_4]_n$ oligomers are formed ($n \leq 4$) in nonpolar solvents such as cyclohexane allowing slow hydrolysis rates and the formation of clear gels. Less condensed solvates are formed in propanol ($n = 2$), hydrolysis becomes much faster leading to precipitation rather than gelation.

The molecular structure of metal alkoxides also depends on the steric hindrance of alkoxy groups. Bulky secondary or tertiary alkoxy groups tend to prevent oligomerization whereas most methanolates $M(OCH_3)_z$ form insoluble high polymers. $Ti(OBu^n)_4$ is currently used as a commercial precursor for TiO_2. It does not react too fast with water and can be handled without too much care. Because *n*-Bu, with four carbon atoms, is the largest alkoxy group that does not prevent oligomerization. It gives mainly $[Ti(OBu^n)_4]_3$ trimers (**3**) in

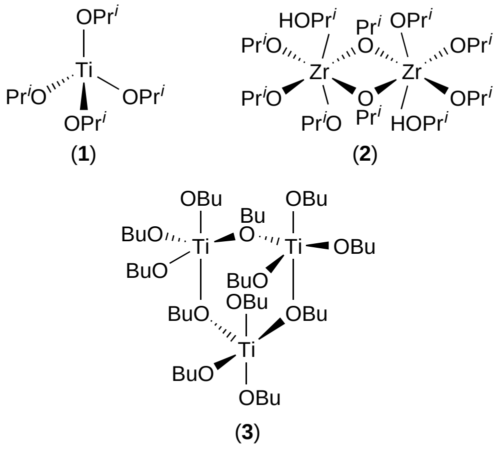


Figure 1 Molecular structure of some transition metal alkoxides: $Ti(OPr^i)_4$ monomer (**1**); $[Zr(OPr^i)_4(Pr^iOH)]_2$ dimer (**2**); $[Ti(OEt)_4]_3$ trimer (**3**)

benzene and $[Ti(OBu^n)_4,BuOH]_2$ dimers in its parent alcohol (Figure 1).

Hydrolysis and condensation rates depend on the molecular structure of metal alkoxides and alkoxide precursors have to be chosen as a function of the desired material final product. In the case of TiO_2, for instance, monomeric precursors such as $Ti(OPr^i)_4$, in which Ti is fourfold coordinated, react very quickly with water leading to the uncontrolled precipitation of polydispersed TiO_2. The reaction is much slower with oligomeric precursors such as $[Ti(OEt)_4]_n$ in which Ti has a higher coordination number. Spherical monodispersed TiO_2 powders can be produced via the controlled hydrolysis of diluted solutions of $Ti(OEt)_4$ in EtOH. On the contrary, monomeric precursors are more convenient for the sol-gel synthesis of multicomponent oxides. The perovskite phase $BaTiO_3$ is formed upon heating around 800 °C when $[Ti(OEt)_4]_n$ is used as a precursor. This temperature decreases down to 600 °C with the monomeric precursor $Ti(OPr^i)_4$ which favors the formation of Ti–O–Ba bonds.[8]

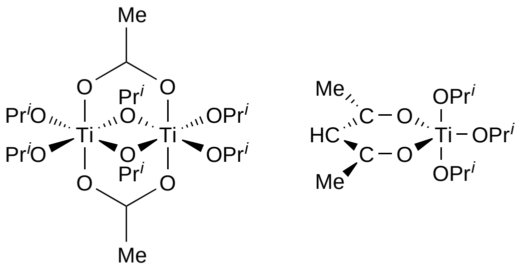
The tendency of metal ions to increase their coordination number via oligomerization depends on their oxidation state. Large monovalent (Li^+, Na^+, K^+) and divalent (Ba^{2+}, Ca^{2+}, Cu^{2+}, Zn^{2+}, etc.) metal ions give insoluble polymeric derivatives that can no longer be used as precursors for sol-gel syntheses. Oligomerization has then to be prevented by adding the metal powder directly in the alcoholic solution of another metal alkoxide. The alkaline alkoxide reacts readily with other precursors in the solution, giving rise to soluble heterometallic alkoxides rather than high polymers.[9]

Soluble low-valent metal alkoxides can also be synthesized by replacing small alkoxy group OR by bulky polydentate ligands such as 2-methoxyethanol $CH_3OC_2H_4OH$. This solvent is currently used to prevent polymerization and get soluble molecular precursors with low-valent metal cations such as Cu^{2+} in the sol–gel synthesis of advanced ceramics such as high T_c superconductors $YBa_2Cu_3O_{7-x}$ (*see* ***Sulfur: Organic Polysulfanes***).[10]

2.3 Chemical Control of Alkoxides Structure and Reactivity

Because of coordination expansion, most metal alkoxides, other than silicon, are highly reactive toward hydrolysis and condensation. Precipitation occurs as soon as water is added. Therefore their chemical reactivity has to be decreased in order to avoid uncontrolled precipitation. This can be performed via the chemical modification of the molecular precursor prior to hydrolysis.[11] Nucleophilic chemical additives are currently employed in order to stabilize highly reactive metal alkoxides and control the formation of condensed species.

Metal alkoxides react with hydroxylated compounds XOH such as carboxylic acids or β-diketones leading to the elimination of alkoxy groups, following equation (4). These complexing XOH species behave as bridging (acetate, AcO^-) (**4**) or chelating (acetylacetonate, acac) (**5**) bidentate



(**4**) (**5**)

Figure 2 Chemical modification of $Ti(OPr^i)_4$: with acetic acid $[Ti(OPr^i)_3(OAc)]_2$ (**4**); with acetylacetone $[Ti(OPr^i)_3(acac)]$ (**5**)

ligands (Figure 2). They increase the coordination number of the metal atom. The new precursor has a different molecular structure, a reduced functionality, and therefore a different chemical reactivity toward hydrolysis and condensation. Complexed alkoxides are usually much less sensitive toward hydrolysis and condensation. Complexing ligands such as β-diketones are currently added to the alkoxide solution prior to hydrolysis, allowing a better control over the formation of oxide particles.

TiO_2 powders can be readily obtained from the hydrolysis and condensation of titanium alkoxides. However such precursors are highly reactive, leading to the uncontrolled precipitation of polydispersed powders upon addition of water. The formation of TiO_2 can be controlled chemically by adding acetylacetone to the alkoxide $Ti(OBu^n)_4$. This leads to the formation of $Ti(OBu^n)_{3-x}(acac)_x$ species. This modified precursor can then be hydrolyzed by adding a given amount of water. The hydrolysis of alkoxy ligands gives reactive Ti–OH groups allowing condensation to proceed whereas acac groups act as polymerization lockers preventing condensation. The condensation of these molecular precursors can then be chemically controlled, by varying these two chemical parameters. Molecular clusters, colloidal particles, gels, or precipitates can be formed depending on the relative amount of hydrolysis ($h = H_2O/Ti$) and complexation ($x = acac/Ti$).

Fine powders can be obtained in the h/x range where colloidal sols are formed (*see* ***Semiconductor Nanocrystal Quantum Dots***). Amorphous colloidal particles are obtained when more water is added. Their mean diameter increases when h increases and x decreases. Monodispersed crystalline anatase TiO_2 particles are formed by heating the colloidal solution at 60 °C in the presence of an organic acid such as PTSA (ParaToluene Sulfonic Acid). Ti–acac bonds are then dissociated, allowing the formation of Ti–O–Ti bonds and the crystallization of the titanium oxide. Some organic groups (acac and PTSA) remain bonded to the surface of the colloids preventing their aggregation. Stable nonaggregated TiO_2 sols are then obtained. They can be dried to give nanopowders and even redispersed without aggregation in water–alcohol solutions at concentrations higher than 1 M, and deposited onto glass substrates in order to make antireflecting TiO_2

coatings. Crystalline zirconia nanoparticles synthesized from chemically modified zirconium alkoxides have been used for the production of microporous ceramic membranes.[12]

The sol–gel chemistry of silicon alkoxides is much simpler (*see* ***Silicon: Inorganic Chemistry***).[13] Si^{IV} is fourfold coordinated ($N = z = 4$) in the precursor as well as in the oxide so that coordination expansion does not occur. The electronegativity of Si is rather high compared to transition metals. Silicon alkoxides are therefore not very sensitive toward hydrolysis. Their reactivity decreases when the size of the alkoxy groups increases. This is mainly due to steric hindrance, which prevents the formation of hypervalent silicon intermediates (*see* ***Hypervalent Compounds***). Silicon alkoxides, $Si(OR)_4$, are always monomeric. Heterometallic alkoxides have never been obtained via the reaction of a silicon alkoxide with another alkoxide. Silicon alkoxides have to be prehydrolyzed before Si–O–M bonds can be formed.

Hydrolysis and condensation rates of silicon alkoxides have to be enhanced by acid or base *catalysis*, otherwise gelation would take several days (Table 1). Inorganic acids reversibly protonate negatively charged alkoxide ligands and increase the reaction kinetics by producing better leaving groups. Basic catalysis provides better nucleophilic OH^- groups for hydrolysis, whereas deprotonated silanol groups ($Si–O^-$) enhance condensation rates.

Catalysis not only enhances hydrolysis and condensation rates, but it also leads to polymeric species of different shapes. The negative charge of the OR groups increases as the electron-providing power of oxo and alkoxo ligands increases. The ease of protonation of OR groups, therefore, decreases as the connectivity of the adjacent Si atom increases. Acid-catalyzed condensation is directed preferentially toward the ends of oligomeric species, resulting in chain polymers. The positive partial charge δ_{Si} increases with its connectivity so that nucleophilic addition of $Si–O^-$ is directed preferentially toward the middles of oligomers, giving more compact, highly branched species that lead to the formation of monodispersed colloids.

The chemical reactivity of silicon alkoxides can also be increased by nucleophilic activation in the presence of chemical species, such as DMAP (dimethylaminopyridine), n-Bu_4 NF, or NaF, which behave as Lewis bases. A pentavalent intermediate is reversibly formed with F^- that stretches and weakens the surrounding Si–OR bonds. The positive charge δ_{Si} increases, rendering the silicon atom more prone to nucleophilic attack. This nucleophilic activation is efficient for both hydrolysis and condensation reactions.

Table 1 pH and gelation time Tg of a solution of $Si(OEt)_4$ (0.5 M) in the presence of various acid-base catalysts[6]

Catalyst	pH	Tg (h)
No catalyst	5	1000
HF	1.9	12
HCl	0.05	92
HNO_3	0.05	100
CH_3COOH	3.7	72
NH_4OH	9.9	107

2.4 Inorganic Precursors

Inorganic precursors are much cheaper and easier to handle than metal alkoxides. Therefore the industrial production of oxide powders for ceramics and catalysts is mainly based on the precipitation or coprecipitation of inorganic salts from aqueous solutions. Gibbsite, $Al(OH)_3$, (*see* ***Aluminum: Inorganic Chemistry***) is precipitated from aluminate solutions. TiO_2 powders are made via the controlled hydrolysis of titanium salts. Stabilized zirconia is coprecipitated from aqueous solutions of zirconium oxychloride, $ZrOCl_2$, and yttrium nitrate, $Y(NO_3)_3$.

Water, however, behaves both as a solvent of ionic compounds and a chemical reagent for the hydrolysis of molecular precursors (*see* ***Water & O-donor Ligands***). Hydrolysis and condensation reactions are therefore more difficult to control. Several monomeric or oligomeric solute species are often formed simultaneously when a metal salt is dissolved in water. These species are in rapid equilibrium and it is not easy to know which one is going to nucleate the solid phase. There are considerable data in the literature about the hydrolysis of metal cations in dilute solutions but very little is known about the formation of polynuclear species at concentrations greater than about 1 M, although these conditions are generally relevant to the synthesis of solid phases. Moreover, anions are known to play an important role even when they do not seem to be chemically involved in the hydrolysis and condensation of metal cations. As for the chemical modification of metal alkoxides by organic ligands, anions are able to form complexes with cationic precursors to provide a chemical control of the hydrolysis and condensation reactions.

The reactivity of inorganic precursors in aqueous solutions has been recently extensively described by Jolivet and will not be discussed in further detail here.[14] It is, however, worth mentioning that, in the presence of an excess of water, metal alkoxides lead to molecular or condensed species similar to those synthesized from aqueous precursors.

2.5 Recent Developments

The hydrolysis of trialkoxysilane $HSi(OR)_3$ under acidic conditions provides access to gels of composition $HSiO_{1.5}$. Because of Si–H bonds remaining at the gel surface, these compounds are hydrophobic, in contrast to silica gels bearing hydrophilic silanol groups. Thermal treatment of $HSiO_{1.5}$ under an NH_3 atmosphere leads to silicon oxynitrides $N(SiO_{1.5})_3$. Under oxidizing conditions, SiO_2 is obtained via the formation of silicon sesquioxide Si_2O_3 containing Si–Si bonds. Si_2O_3 can also be obtained from the hydrolysis of Si_2Cl_6.

Metal halides MX_n (M = Si, Al, Ti) can also be used in the formation of nonhydrolytic gels (NHG). When added to oxygen donors such as ethers, aldehydes or, for Al and Ti, parent metallic alkoxides in organic media, gels are formed. In the case of alumina, because no water is present in the reaction process, low-temperature hydrated crystalline phases, such as boehmite (AlO(OH)) cannot be formed so that gels remain amorphous over a larger range of temperature than for gels obtained via the hydrolytic process. Accordingly, the nature of the oxygen donor can control the high-temperature anatase-rutile transformation for titania NHG.[15]

3 HYBRID ORGANIC–INORGANIC MATERIALS

Sol-gel synthesis not only provides a new route to glasses and ceramics, but the 'chimie douce' conditions involved in the reaction process allow the incorporation of organic moieties into inorganic materials. These organic groups can be introduced in the precursor solution to control the sol–gel process and eliminated upon completion of solid formation. Alternatively, they can be retained within the inorganic framework, leading to hybrid organic-inorganic materials, also known as ORMOCERs (ORganically MOdified CERamics) or ORMOSILs (Organically MOdified SILicates)

3.1 Organic-templated Porous Materials

Organics can be used as catalysts, network modifiers or templating agents during the gel formation. Further washing, calcination or photodegradation treatments lead to purely inorganic solids. Recent developments in this field include the synthesis of meso-organized materials (*see* ***Porous Inorganic Materials***).[16] In contrast to microporous zeolites (*see* ***Zeolites***) obtained in hydrothermal conditions, these materials are obtained near room temperature using molecular or polymer surfactants as structure directing agents. Polymerization of inorganic precursors via the sol–gel process takes place at the interface with self-assembled templates (*see* ***Selenium Proteins Containing Selenocysteine***). Withdrawing the surfactants leaves empty pores in the inorganic network whose size, shape, and organization replicate the initial organic structure (Figure 3). Because surfactants can assemble as spherical or cylindrical micelles, which can aggregate as hexagonal, cubic, or lamellar liquid crystal phases, a wide range of pore size (2–50 nm) and organization can be obtained. Moreover, this self-assembly process is partially controlled by the interactions between the templating agent and the inorganic precursor. Therefore, the reactivity of the metal alkoxide is a key parameter for mesostructure formation, less stable transition metal precursors (Ti, V, etc.) lead to poorer organization than silicon alkoxides. Nevertheless, although this approach was pioneered for silica-based materials, numerous mesostructured oxides M_xO_y (M = Al, Ti, Zr, V, Nb, etc.) as well as nonoxides have been synthesized.[17] In addition to this chemical diversity, a wide range of shapes, such as powder, monoliths, fibres, films, and nanoparticles are now accessible, which should find applications in catalysis, optics, drug release (see Section 3.3). The most recent studies focus on hierarchically structured materials that would associate micro-, meso-, and macroporosity using micromoulding approaches, biotemplates (*see* ***Biomineralization***), and organogelators.[18]

3.2 Sol–Gel Approaches to Hybrid Nanocomposites

The sol-gel process allows the intimate mixing of inorganic and organic moieties at the molecular level. Based on the nature of the organomineral interface, hybrid organic-inorganic materials are conveniently divided in two classes.[19] Class I corresponds to systems in which organic components are simply embedded in an inorganic matrix. In contrast, Class II hybrids involve covalent or iono-covalent bonding between the organic and inorganic components.

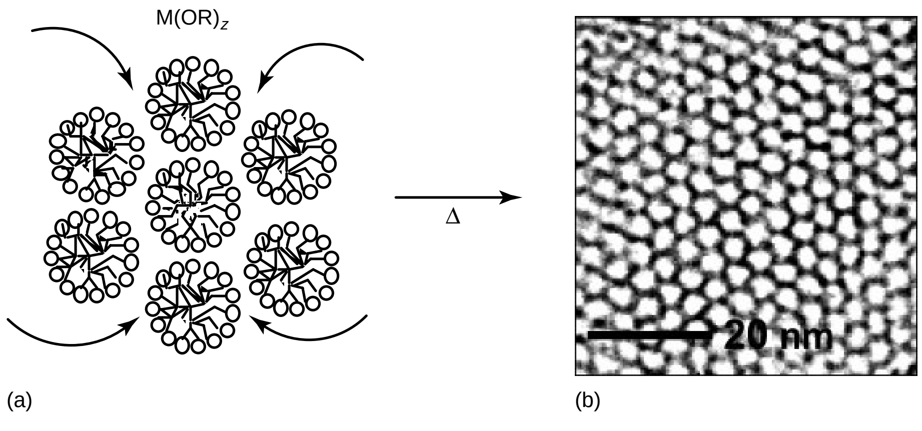


Figure 3 Synthesis of mesoporous metal oxides: (a) hexagonal assemblies of micellar systems are used as templates for the hydrolysis/condensation of $M(OR)_z$ alkoxides; (b) after calcination, the corresponding oxide exhibits an hexagonal array of mesopores

3.2.1 Class I Hybrid Materials

A wide variety of organic species can be dissolved with metal alkoxides in a common solvent. Hydrolysis and condensation reactions lead to the formation of an oxide network in which organic molecules remain trapped. However, the synthetic routes often have to be adapted to the properties of the immobilized species.

This is particularly true for biomolecules which are highly sensitive to pH and alcohol. The typical sol-gel procedure, which involves the homogenization of water and alkoxides mixtures by adding the parent alcohol as a cosolvent, as well as an acid-catalyzed hydrolysis step (HCl, pH $\approx$ 2.), is therefore not compatible with their entrapment. Actually, it was shown that the alcohol released during the alkoxide hydrolysis reaction was sufficient to rapidly homogenize the aqueous precursor solution. Moreover, the addition of a buffer to the hydrolyzed solution raises the pH above 5, allowing further mixing with the aqueous suspension of proteins. The pH buffer being close to 7, condensation occurs rapidly under basic conditions, embedding the biomolecules within the oxide network.[20]

In the case of polymer-oxide hybrids, a good homogeneity of the material is difficult to achieve unless weak interactions between both phases favor their mutual interpenetration at the molecular level. This can be achieved by taking advantage of the Brönsted acidity exhibited by M–OH hydroxyl groups produced via $M(OR)_n$ alkoxide hydrolysis. These groups can form hydrogen bonds with amide carbonyl groups of polyamides polymers. Based on this principle, polymers such as poly(*N*-vinyl pyrrolidone) (PVP) or poly(*N*,*N*-dimethylacrylamide) (PDMAAm) could be associated with silica forming colorless, homogeneous, and transparent gels (Figure 4a).[21]

Alternatively, a suitable polymer-silica blend can be obtained by in situ polymerization of organic monomers. This can be achieved either by impregnation of a preformed gel, or by adding these monomers to the alkoxide solution. In this case, the simultaneous polymerization of organic and inorganic precursors leads to IPN (Interpenetrating Polymer Network) hybrids where both cross-linked gels are associated at the molecular level, as demonstrated for PDMAAm- and polystyrene-silica materials (Figure 4b).[22]

3.2.2 Class II Hybrid Materials

Organic species can also be chemically bonded to the oxide network via Si–C bonds. Many organoalkoxysilane precursors, $R'_{4-x}Si(OR)_x$, are commercially available. They contain nonhydrolyzable Si–C bonds, so that organic moieties are not removed upon hydrolysis. Depending on the nature and amount of organic and inorganic components, it becomes possible to tailor the microstructure and even obtain multifunctional materials.

The sol–gel synthesis of hybrid organic–inorganic compounds usually involves a mixture of di- or trifunctional organosilanes, which introduce Si–C bonds, with metal alkoxides, mainly $Si(OR)_4$, as cross-linking reagents to build the inorganic network.[23,24]

- Trifunctional alkoxides, $R'Si(OR)_3$, are the usual precursors used to introduce organic groups within an inorganic network. Careful control of polymerization reactions can lead to a homogeneous distribution of organic R′ groups within the silica network. These precursors can be used as such to modify silica surface properties such as hydrophobicity using long chain alkyl groups $(RO)_3$–Si–C_nH_{2n+1}, or fluoroalkyl silanes, $(RO)_3$–Si–$(CH_2)_2(CF_2)_nCF_3$, finding application in water-repellent coatings on metals or glasses. R′ can also be a polymerizable organic group, such as vinyl, epoxy, or methacrylate, leading

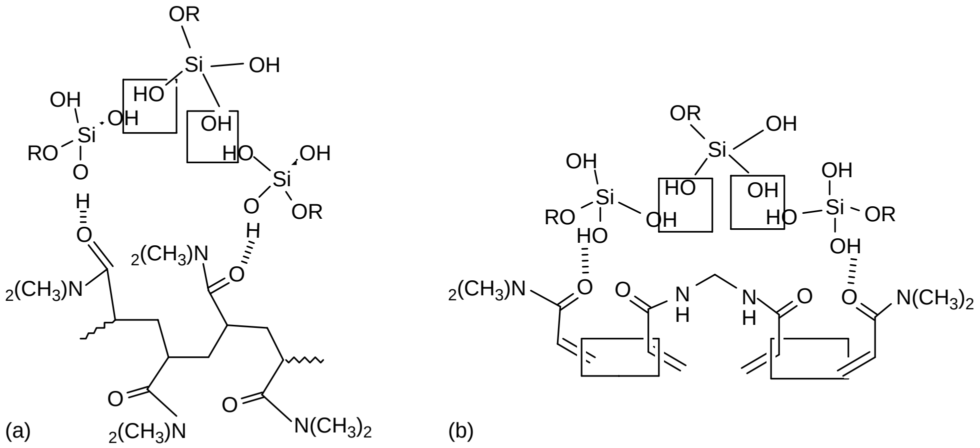

Figure 4 Polymer-silica hybrid materials: hydrogen bonding between silanol groups of hydrolyzed silicon alkoxides and carboxylate groups of preformed poly(*N*,*N*-dimethylacrylamide) (a) or in situ polymerized *N*,*N*-dimethylacrylamide/methylene bisacrylamide precursors (b) favors the formation of homogeneous organic–inorganic networks

to a polymer-silica hybrid. Starting from *N*-3-trimethoxy-silyl-propyl-pyrrole (**6**), polypyrrole-silica materials were obtained exhibiting high electrical conductivity (Figure 5). Alternatively, R′ can provide a reactive site for further binding of ions, organics, and biomolecules.

– Difunctional alkoxides, $R'_2Si(OR)_2$, such as diethoxy-dimethylsilane (DEDMS), cannot act as network formers. However, their tendency to form chains is currently used to impart some flexibility to the oxide network. Polydimethylsiloxane (PDMS) (**7**) with terminal hydroxyl groups has also been used in this role instead of DEDMS (Figure 5). Polymers of various molecular weights lead to a whole set of hybrid materials ranging from viscous liquids to brittle glasses (*see* ***Polysiloxanes & Polysilanes***).
– Metal alkoxides act as cross-linking agents between organosilicon units, increasing the hardness of the materials. Tetrafunctional silicon alkoxides are more commonly employed, but transition metal alkoxides $M(OR)_n$ (M = Ti, Zr, etc.) can also be used. They not only serve as cross-linking reagents, but can also increase the refractive index or catalyze condensation.

Polyfunctional precursors can also be used to design hybrid organic–inorganic materials. Monomers consisting of a variable organic bridging group and two or more trifunctional silyl groups can undergo hydrolysis and condensation reactions, leading to bridged polysilsequioxanes (**8**) (Figure 5). Because of the increased number of reactive functions, the gelation process is much faster than for tetraethoxysilane (TEOS) at equivalent concentration. Monitoring the size, shape, rigidity, and functionality of the spacer allows the control of the material porosity, optical properties, and thermal stability. Bridged polysilsequioxanes are used for surface modification and coating formulations, and could find application in catalysis and separation media.[25]

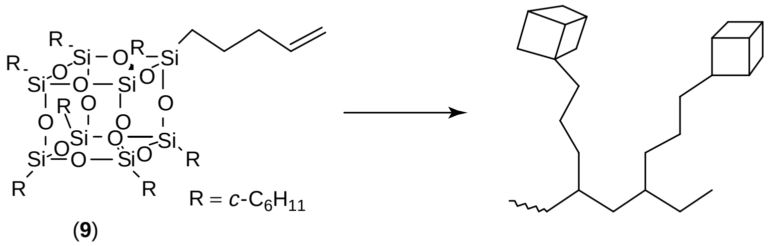
3.2.3 *The Nanobuilding Blocks Approach*

As an alternative to molecular precursors, the use of preformed objects, such as clusters (*see* ***Polynuclear Organometallic Cluster Complexes***) or nanoparticles (*see* ***Semiconductor Nanocrystal Quantum Dots***), that keep their integrity in the final material constitutes a convenient and fruitful method to control the organic-inorganic interface as well as the hybrid architecture. A wide range of Nano Building Blocks (NBBs), including polysilsesquioxane, organotin, polyoxometallates, and metal-oxo clusters, have been used, which can be functionalized with polymerizable ligands (vinyl, styryl, methacryl) or organic bridging spacers (telechelic molecules, polymers, dendrimers). Class I or II hybrids are obtained, depending on the anchoring interactions between the inorganic core and the organic moieties. The hybrid structure at the macromolecular scale is defined by the nature and number of functional groups. Using the monofunctional R–Si(c-C_6H_{11}Si)$_7O_{12}$ polyhedral oligosilsesquioxane, with R = styryl, 3-propylmethacrylate (**9**), or 2-ethylnorbornyl, linear polymeric backbones are obtained, exhibiting pendant silsequioxane cubes (Figure 6). In similar systems, the good dispersion of the NBB as well as its covalent anchoring to the organic network increase the polymer glass transition up to 200 °C. The oxo-hydroxo butyltin macrocation $(BuSn)_{12}O_{14}OH_{6}{}^{2+}$ can be functionalized with two polymerizable anions 2-acrylamido-2-methyl-1-propanesulfonate. Copolymerization of these NBB with methylacrylate in toluene leads to homogeneous gels, which can be redissolved in DMSO owing to the electrostatic interactions responsible



(**9**)

Figure 6 The nano building block approach to hybrid materials: polymerization of R–Si(c-C_6H_{11}Si)$_7O_{12}$ polyhedral oligosilsesquioxane, with R = 3-propylmethacrylate, (**9**), leads to linear polymeric backbones, exhibiting pendant silsequioxane cubes

for the cross-linking. Glassy transparent xerogels could be obtained by the association of $Ti_{16}O_{16}(OEt)_{32}$ oxo clusters with carboxylate- or alcoholate-functionalized dendrimers. Covalent bonds are formed, leading to a stable ordered dispersion of clusters at the 10 nm range. The cross-linking of water-soluble poly(acrylamide) with the $[\gamma\text{-SiW}_{10}O_{36}(RSiO)_4]^{4-}$ polyoxometalate, where $R = CH_2{=}C(Me)C(O)OPr^-$, allows the synthesis of hydrogels with swelling properties similar to those of super absorbent materials. Finally, silica, alumina, zirconia, and titania nanoparticles functionalized with alkylmethacrylate groups, are used to design reactive ceramic fillers for PMMA-based composites. The above-illustrated high versatility of this approach constitutes a promising tool for the future design of multiscale and/or multifunctional hybrid materials.[26]

3.3 Properties and Applications

The sol–gel process allows the synthesis of tailored-made inorganic or hybrid materials, with many different shapes and microstructures, while being compatible with a wide range of molecules, polymers, nano-objects as well as biospecies. These materials can be used as such, as filtration membranes or coatings, and constitute suitable hosts for organic/organometallic reactions, electrochemical process, photochemistry or bioactivity. It is therefore not surprising that the possible applications of organic–inorganic hybrids cover the whole field of materials science.[27]

3.3.1 Organic–Inorganic Hybrid Catalysts

Immobilization of organic (or organometallic) catalysts onto solids allows their easy recovery from reaction media and improves their recyclability. In case of preformed porous silica surfaces, direct grafting of the organic moiety can be achieved if an organosilane derivative incorporating the desirable functional groups can be synthesized. The commercially available aminopropyl-silanes have been widely used to design base catalysts for the Knoevenagel reaction. Alternatively, the support can be first functionalized with an appropriate reactive moiety that constitutes an anchoring site for further grafting. Imine-supported silicas could be prepared from amino-grafted supports and used for Michael addition *Catalysis*.

Nevertheless, the grafting approach presents several drawbacks, particularly: (1) the catalyst is linked to the silica surface via an external Si–O–Si bridging bond, whose stability can be incompatible with certain reaction conditions; (2) the accessibility of the pore surface to organosilane reagents in amorphous solids can be limited, leading to poor loading as well as heterogeneous distribution of the catalytic groups. The latter problem can be partially overcome if ordered porous materials are used. Although this approach was studied for microporous zeolites, its efficiency was more clearly revealed with mesoporous supports exhibiting larger surface area and pore size. In parallel, direct incorporation

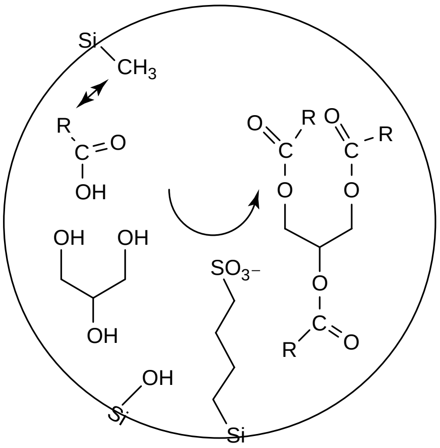


Figure 7 Mesoporous silica grafting for catalysis: enhanced activity towards glycerol esterification is obtained when a hydrophobic methyl chain is cografted with the sulfonate function, providing favorable interactions with fatty acid reagents

of the catalyst by cocondensation of the corresponding organosilane with network-forming tetrafunctional silicon alkoxides allows the elimination of the former limitation. Thus, a large variety of functional groups (amine, epoxide, thiol, etc.) can be introduced that remain accessible for further reaction. Incorporated in mesoporous materials, vinyl and methacrylate moieties can be postbrominated in situ whereas cyclodextrins maintain their chelating properties. Bifunctional materials are also obtained when a mixture of organosilanes is used. Sulfonic acid moieties act as catalysts for monoglyceride synthesis from glycerol and fatty acids. The cocondensation of the corresponding organosilane with hydrophobic methyltrimethoxysilane increases the catalytic activity of the bifunctionalized mesoporous materials by three when compared to the monofunctionalized support (Figure 7).[28]

Two recent approaches open up new possibilities to design more stable and efficient hybrid catalysts. The first one relies on the incorporation of the organic moiety within the walls of the mesoporous materials rather than into the network voids, using bridged bis(trialkoxysilyl)-organosilanes.[29] As far as catalyst selectivity is concerned, the molecular imprinting approach, already widely used in organic polymers, has also been applied to silica gels. In this case, the sol-gel process is performed in the presence of suitable substrates that control the three-dimensional organization of the functional groups during the porous network formation. Removing the substrate leaves an optimized configuration for following catalytic reactions, mimicking the high selectivity of enzyme active sites.[30]

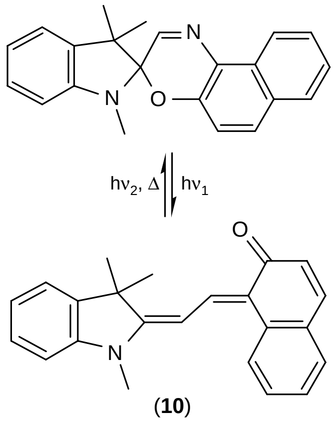
3.3.2 'Sol–Gel Optics'

Incorporation of photoactive species within sol–gel matrices has been extensively studied for dye laser materials,

rare-earth ion-doped glass devices, nonlinear optics (NLO), photochemical hole burning (PHB) as well as photochromism and electroluminescence.[31] Because the sol–gel process allows the optimization of host-guest interactions by the fine tuning of the dye environment, some of these materials have been commercialized as television screen coatings (Toshiba) or colored glassware.

Optimization of photochromic devices provides a nice illustration of the flexibility of the sol–gel approach. Spirooxazine (SO) dyes (**10**) can undertake a reversible color change by absorption of a photon associated with large structural changes (Figure 8). The efficiency and rate of the photochromic response as well as the thermal stability of the open form are highly dependent on the host flexibility, pore size, and hydrophobicity. Thus, even though Class I hybrid materials obtained by SO-doping of pure silica matrices were shown to exhibit photochromic properties, slow thermal fading was observed because of the stabilization of the polar open form by hydrogen bonding with Si–OH silanol surface groups of the host. Moreover, at high concentration, these dyes tend to aggregate, interfering with the photochromic reaction. The use of hydrophobic matrices, synthesized from cocondensation of $MeHSi(OR)_2$ and $HSi(OR)_3$, increases the thermal fading kinetics by two orders of magnitude. Incorporating aromatic groups on the matrix surface using $C_6H_5HSi(OR)_2$ precursors, allows a higher SO loading while avoiding its aggregation. Alternatively, the photochromic dyes can be grafted on the silica surface via an organic spacer whose length controls the rate of the photochromic response.

Apart from the tuning of the host-guest interactions, the elaboration of efficient optical devices also relies on the optimization of the matrix mechanical properties and thermal stability. This is clearly demonstrated in the development of hybrid materials for NLO, and especially second harmonic generation (SHG). These properties rely on their noncentrosymetric organization of organic chromophores in the condensed phase. Because incorporation in a silica matrix leads to a random distribution of dyes, electrical field poling technics are needed to align the organic molecules. Nevertheless, upon aging, orientational relaxation occurs, leading to the loss of chromophore alignment and therefore of SHG efficiency. There is therefore a need for matrices with improved rigidity, which can be achieved by improving the silica network cross-linking by increasing the sol aging time, using prepolymerized precursors, or by adding thermally stable polymers such as polyimides. In addition, similar to photochromic materials, Class II hybrids involving the covalent linking of the chromophore to the silica surface via functionalized trialkoxysilane lead to better time and thermal stability and allow higher loadings of photoactive molecules. Thus, organic-inorganic composites incorporating high polarizable diazobenzene chromophores such as Red17 or DR1 can be made with high thermal stability (80–100 °C) as well as nonlinearities comparable to those reported for inorganic solids and organic polymeric materials.



(**10**)

3.3.3 Bioencapsulation in Silica Gels

The ability to form hybrid silica glasses under aqueous, room-temperature conditions (at which proteins and cells are active) opens up the possibility to extend sol-gel processing to the encapsulation of biologicals.[32] However, as mentioned earlier, the traditional sol–gel route using silicon alkoxides has to be adapted to avoid excess alcohol as well as low pH conditions (see section 3.2.1). Moreover, because biospecies could be denatured by covalent bonding, most bioorganic–inorganic composites are Class I hybrids.

Enzymes retain their biological activity when encapsulated within porous sol-gel glasses and can be used for the realization of biocatalysts or biosensors.[33] Glucose oxidase (GOD) is by far the most studied enzyme for applications in the field of medicine and food industry. GOD is capable of catalyzing the oxidation of D-glucose by molecular oxygen into D-gluconolactone and D-gluconic acid as follows:

$$\text{Glucose} + O_2 \xrightarrow{\text{GOD}} H_2O_2 + \text{Gluconic acid} \tag{6}$$

The flexibility of the sol–gel process allows multiple approaches to enzymatic activity monitoring. The formation of hydrogen peroxide can be followed by optical measurements using another enzymatic reaction in which the oxidation of an organic dye is catalyzed by a peroxidase (HorseRadish Peroxidase HRP), coentrapped with GOD. The presence of glucose in the solution can also be detected via electrochemical means by following the redox reactions at the active site of GOD. However, because of the steric hindrance of the protein molecule, a ferrocene mediator has to be used in order to transfer electrons from the hidden active site to the electrode. Alternatively, oxygen consumption can be measured with a Clark electrode. The hybrid gel is deposited on a Pt cathode

from a GOD and hydrolyzed tetramethoxysilane (TMOS) mixture. After d-glucose addition, oxygen concentration is measured by amperometric titration at imposed potential. All these experiments show that the catalytic activity of GOD is preserved within the gel and that their active sites remain accessible to the substrate. Moreover, upon encapsulation, the decrease of GOD catalytic activity with time is slowed up, suggesting that the silica matrix protects the enzyme against denaturation.

Sol–gel matrices can also provide a chemical surrounding that favors enzymatic reactions. Lipases act on ester bonds and are able to hydrolyze fats and oils into fatty acids and glycerol. These are interphase-active enzymes with lipophilic domains and the catalytic times reaction occurs at the water-lipid interface. Entrapped lipases can be almost 100 times more active when a chemically modified silica matrix is used. The cohydrolysis of $Si(OMe)_4$ and $RSi(OMe)_3$ precursors provides alkyl groups that offer a lipophilic environment that can interact with the active site of lipases and increase their catalytic activity. Such entrapped lipases are now commercially available and offer new possibilities for organic syntheses, food industry, and oil processing.[34]

Antigen-antibody reactions have also been performed within sol–gel matrices extending the field of sol–gel chemistry toward immunosensors. Specific haptens are used for the biodetection of chemicals such as atrazine, a widely used herbicide. Antiatrazine antibodies are trapped within the sol–gel matrix and nanograms of atrazine are applied on SiO_2 sol–gel columns doped with this antibody. Titration of eluted solutions shows that high amounts of atrazine remain bound to antiatrazine antibodies inside the silica gel. For medical applications, whole cell parasitic protozoa (*Leishmania donovani infantum*) have been trapped within sol–gel matrices and used as antigens for blood tests with human sera. Antigen–antibody interactions were followed by the so-called Enzyme-Linked Immunosorbent Assays (ELISA) and the presence of antibodies in the blood detected via a colored reaction, showing a clear-cut difference between negative and positive sera.[35]

The sol–gel encapsulation of whole cell bacteria *Escherichia coli* was first reported using the modified silicon alkoxide process. However, the release of alcohol during the hydrolysis step induces bacteria lysis. Using genetically engineered *E. coli* exhibiting stress-dependent luminescence properties, it was possible to optimize the sol–gel procedure (pH, water/TMOS ratio, drying time) for cell entrapment in silica thin films (*see* ***Thin Film Synthesis of Solids***). Moreover, the possibility to entrap simultaneously cells from two different strains was demonstrated, opening new possibilities for dual or multiple sensing. Alternatively, aqueous routes using a mixture of sodium silicate and colloidal, in the presence of organic additives, such as glycerol, allowed entrapped *E. coli* survival over one month (Figure 9). These studies also demonstrated that generic tests to assess bacteria viability in solution, such as culturability or glucose incorporation, could be transposed to cells entrapped in silica gels.

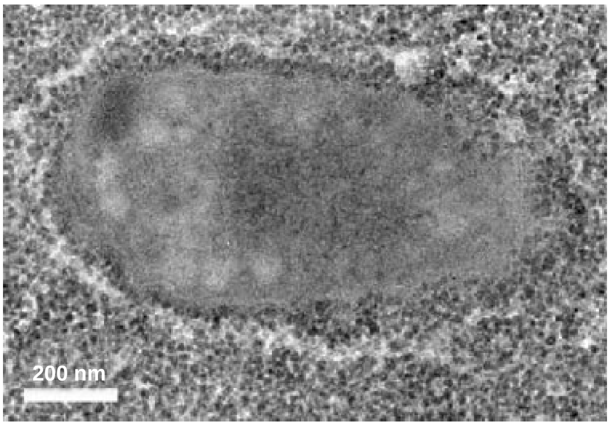

Figure 9 Transmission electron micrograph of an *E. coli* bacteria encapsulated in a silica gel

Mammalian tissues such as the pancreatic islets of Langerhans are known to produce insulin in response to glucose challenge. After encapsulation, they have been transplanted into a diabetic mouse where they retain their activity. The fine porosity of the gel protects transplanted islets against antibody aggression but permits nutrients to reach the cell and by-products to escape. Urinary excretion of glucose fell to almost zero within a few days of transplantation and remained close to zero for almost three months. In addition, both blood sugar and blood insulin concentrations were normal. After one month of transplantation, the surgically removed transplant showed no evidence of fibrosis. Such transplants, if viable for extended lengths of time, could emerge as a viable treatment for diabetes.[36]

4 CONCLUSION

Sol-gel chemistry has been extensively studied during the past decade. The basic reactions, hydrolysis, condensation, and complexation, involved in the formation of oxide networks from molecular precursors are now quite well described. The sol-gel process brings new opportunities in the field of materials science. It allows a powderless processing of glasses and ceramics. Coatings can be easily deposited directly from the solution onto a wide variety of substrates. Many patents have been taken and several products are now on the market. Other industrial applications will undoubtedly be developed during the next few years.

However, one of the main advantages of sol-gel chemistry will be to lead to new materials that cannot be obtained from the usual processing routes. At least three new fields are being

explored taking advantage of soft chemistry to mix fragile organic molecules with hard oxide materials:

1. Mesoporous materials have been extensively studied since the discovery of mesoporous silica. The great progresses made in sol-gel chemistry open the way to the synthesis of hierarchically nanostructured porous materials.
2. New fields such as 'sol–gel optics' are based on the synthesis of hybrid organic-inorganic materials. They offer a new kind of materials ranging from polymers to glasses.
3. A new field is now emerging in which biomolecules or cells are trapped within sol-gel matrices. Silica gels offer many advantages and could compete in the near future with usual polymeric matrices. Rather few laboratories are involved in this field. More work is still required to make reproducible experiments, but some applications have already been developed.

1 INTRODUCTION

The driving force behind the rapid development of powder diffraction methods over the past 10 years is the increasing need for structural characterization of materials that are only available as powders. Examples are zeolite catalysts, magnets, metal hydrides, ceramics, battery and fuel cell electrodes, piezo- and ferroelectrics, and more recently pharmaceuticals and organic and molecular materials as well as biominerals. The emergence of nanoscience as an interdisciplinary research area will further increase the need for powder diffraction. pair-distribution function (PDF) analysis of powder diffraction pattern allows the refinement of structural models regardless of the crystalline quality of the sample and is therefore a very powerful structural characterization tool for nanomaterials and disordered complex materials.

Shortly after the discovery of X-ray diffraction by von Laue and von Knipping in 1910, Debye and Scherrer[1] (1916) in Germany and Hull[2] (1917) in the United States independently pioneered X-ray powder diffraction. Zachariasen[3,4] (1949) determined the first structures solely from powder diffraction data by using an intuition-based trial-and-error approach. The structures of UCl_3 as well as α- and β-UF_5 were solved this way. More than a decade later Zachariasen and Ellinger[5] (1963) used direct method procedures to solve the monoclinic structure of β-Pu. In direct methods, the crystallographic phase problem is solved using only the observed intensities by applying phase sum relationships. The first structure solved from powder data using Patterson methods was UO_2Cl_2 in 1968.[6] In the Patterson technique, an interatomic vector map ('autocorrelation function') is used to assign 'heavy atoms' that dominate the map and thereby determine atomic positions. These were however isolated one-off studies. The majority of structures were still being solved using single-crystal diffraction methods. Today, structure solution and refinements are no longer the exclusive domain of single-crystal diffraction. This shift towards using powder diffraction methods was triggered by (1) the advent of the application of least-squares fitting to powder diffraction pattern (Rietveld refinement method), (2) instrumental improvements of laboratory-based X-ray powder diffractometers, (3) the availability of user-friendly and dedicated high-resolution powder diffractometers at research reactors, neutron spallation sources and synchrotron radiation sources and (4) the increase of computing power. In recent years, the gap between laboratory and facility-based high-resolution diffractometers has closed and an increasing number of structures are now being solved using laboratory-based X-ray powder diffractometers. This has in turn led to a change in the use of facility-operated powder diffractometers, where 'parametric studies' of a sample as a function of sample environment such as temperature, pressure, and magnetic and electric fields are nowadays called for. Furthermore, powder diffraction studies are now increasingly used to probe mesoscopic structures beyond the atomic level such as texture, particle size, strain, and stacking faults. It has also come to the attention of the solid-state community that phase coexistence might be a necessary prerequisite for certain functionalities, that is, in giant magentoresistant oxides, magnetocaloric materials, and multifunctional catalysts. Therefore, the study of phase mixtures and their mesoscopic interplay will continue to challenge powder diffraction. Modern powder diffraction methods have developed from a mostly qualitative to a quantitative tool used to detect new phases and determine the atomic, magnetic, and mesoscopic structures. Langford and Louer wrote a substantial recent review of state-of-the-art powder diffraction techniques.[7]

Powder diffraction makes use of elastic scattering where the probe (neutron or X-ray photon) is deflected without energy transfer and located on a Debye-Scherrer cone at an angle θ according to Bragg's law $n\lambda = 2d\sin\theta$. Scattering processes are often described using scattering triangles, where a scattering vector Q is defined by the vector relationship $Q=k-k'$, k and k' being the incident and diffracted spherical wavefronts. Simple trigonometric arguments show that in the case of elastic scattering $Q = 4\pi\ \sin\theta/\lambda$. If the probing particles interact with the scattering centers in such a way that the scattered waves have a phase relationship with each other, one speaks of coherent scattering. Diffraction or Bragg scattering is the simplest form of coherent

scattering. In an incoherent scattering process, no interference is possible. The intensities therefore simply add up. In neutron scattering, the large incoherent scattering of hydrogen adds up to an effective absorption. Therefore hydrogen-containing samples need to be deuterated for neutron scattering experiments.

2 NEUTRON POWDER DIFFRACTION

Neutrons can be described by de Broglie's wave-particle formalism and a wavelength λ can be determined according to $\lambda = h/mv$ with h being Planck's constants and m and v being the mass and velocity respectively. The neutron's mean energy can be expressed as:

$$E(\text{eV}) = 0.08617T(\text{K}) = 5.227\, v^2(\text{kms}^{-1}) = \frac{81.81}{\lambda^2(\text{Å})} \tag{1}$$

Neutrons used for research are made either in a fission or spallation process. Both processes create neutrons that need to be slowed down via a moderation process, that is, the neutrons adjust to the temperature of a hydrogen-containing moderator via inelastic neutron-proton collisions. In a research reactor, this moderation creates a distribution of neutrons between 1 and 3 Å. Using equation (1), one obtains a wavelength of 1.78 Å for a moderator temperature of 300 K, which is ideally suited for diffraction experiments. Neutrons interact with the atomic nucleus and not as X-rays do with the electrons. Nuclear forces have a very short range and the size of the nuclear scattering centers are about 10^5 times smaller than the probed interatomic distances. The nucleus is referred to as a 'point scatterer' and as a consequence the neutron is scattered isotropically. The neutron scattering length, b, which has dimensions of a length (given in fm) scatters independent of the scattering angle leading to strong nuclear Bragg intensities at high Q-values. This is in marked contrast to X-ray scattering, where the atomic form factor monotonically decreases the further one increases Q. Furthermore, the neutron scattering length does not, as in the case of X-rays, vary systematically with the atomic number Z, which leads to one of the attractive features of neutron scattering: light elements such as deuterium ($b = 6.671$ fm) or oxygen ($b[^{16}O] = 5.80$ fm) can scatter stronger than heavy elements such as W ($b = 4.86$ fm) or Ba ($b = 5.07$ fm). This is of tremendous advantage for the study of metal oxides and hydrides, where the scattering contribution of oxygen and hydrogen/deuterium is in general larger than in the corresponding X-ray scattering experiment and as mentioned above does not 'fall off' at high scattering angles. Neutron diffraction experiments in particular powder diffraction experiments with hydrogen-containing materials will be done using deuterium owing to the large incoherent scattering of hydrogen, which leads to a large neutron absorption. Another consequence of the nucleus-neutron interaction is that neighboring elements such as Mn ($Z = 25$), Fe ($Z = 26$) and Co ($Z = 27$) can have significantly different scattering lengths, namely, $b_{Mn} = -3.73$ fm, $b_{Fe} = 9.45$ fm and $b_{Co} = 2.5$ fm respectively. To distinguish Mn^{2+} from Fe^{3+} with X-rays, one needs to perform anomalous scattering experiments, whereas with neutrons a straightforward distinction is possible. Another useful property of the neutron-nucleus interaction is that the neutron scattering length is isotope dependent and can have negative values. The latter is due to a phase shift of the neutron during the interaction with the nucleus. The best-known example is hydrogen ($b = -3.74$ fm) and deuterium ($b = 6.674$ fm). Varying the ration of H_2O:D_2O can therefore make water 'invisible' in neutron scattering experiments. Similar 'zero-scattering isotope alloys' can be made for Ni ($b(^{58}Ni) = 14.4$ fm, $b(^{60}Ni) = 2.8$ fm, $b(^{61}Ni) = 7.60$ fm and $b(^{62}Ni) = -8.7$ fm) and Ti ($b(^{48}Ti) = -6.08$ fm and $b(^{50}Ti) = 6.18$ fm). In neutron high-pressure scattering experiments, a Ti–Zr zero-scattering alloy, which has an appreciable mechanical strength is used. The isotope specific neutron scattering length can be exploited in experiments to locate an atomic species, which is disordered over more than one site. Using four separate samples containing ^{nat}Ni, ^{58}Ni, ^{60}Ni and ^{62}Ni Henry *et al.* were able to determine the distribution of Ni^{2+} and Fe^{2+} over two metal sites in $Fe_2Ni(PO_4)_2$ using neutron powder diffraction.[8] A critical comparison of isotope substitution neutron powder diffraction and anomalous X-ray powder diffraction shows that the first is superior for distinguishing between Ni and Fe. Thus the unique neutron-nucleus interactions offer an investigative route for site-disordered solids provided the right isotopes are available.[9] However, the neutron-nucleus interaction is very weak compared to the X-ray-electron or electron–electron interaction. The energy of a 1 Å neutron is 82 meV whereas that of a 1 Å X-ray photon is 12 keV. Therefore, neutrons can penetrate deep into matter. A flux of neutrons with a wavelength of 1.78 Å is only attenuated to one half after 50 cm of Al, whereas half of the X-rays with 1.78 Å are already absorbed after 0.003 cm. As a consequence, it is very easy to penetrate sample environments (heat shields, pressure cells) using neutrons. However, the typical neutron fluxes are in the order of 10^8 neutrons/s. A standard sealed-tube X-ray diffractometer provides a flux of $\sim 2 \times 10^9$ photons/s and at a synchrotron 10^{12} photons/s can be routinely accessed for diffraction experiments. Another application of paramount importance is magnetic neutron scattering. Neutrons have a magnetic moment of $1.9132\,\mu_B$, which can interact via dipole–dipole interactions with the magnetic moments of unpaired electrons. Magnetic neutron scattering is the best method for the characterization of long-range-ordered spin structures. Nuclear and magnetic scattering have similar magnitudes, however, now that the neutron is interacting with an unpaired electron, which can no longer be approximated as a 'point scatterer' magnetic scattering – like X-ray scattering is not isotropic and therefore also has a Q-dependent form factor.

3 X-RAY AND SYNCHROTRON RADIATION POWDER DIFFRACTION

Synchrotron radiation is radiation emanating from charged particles (i.e. electrons or positrons) traveling at relativistic speeds in applied magnetic fields, which force them to travel along curved paths. Bending magnets keep the particles in a closed orbit. The two main insertion devices are wigglers and undulators in which an alternating magnetic field forces the electrons to oscillate and thereby produce synchrotron radiation.[10] The main advantages powder diffraction experiments using synchrotron radiation have over conventional X-rays is the high intensity, its narrow collimation and availability as a continuous spectrum. Many K- and L-absorption edges are accessible with synchrotron sources. This is exploited when performing anomalous powder diffraction experiments. This technique makes use of the modification of the atomic scattering amplitude occurring near an absorption edge. The atomic scattering factor f_i is dependent on the scattering vector Q and the incident photon energy E and can be written as: $f_i(Q,E) = f_i^\circ(Q) + f_i'(E) + if_i''(E)$.The nonresonant scattering factor $f_i^\circ(Q)$ is energy independent and neglects the electronic bonding effects and falls off with Q as mentioned above. The resonant part $f_i'(Q)$ and $if_i''(E)$ originates mainly from the core electrons and for the same arguments as made above for neutron scattering does not vary with Q and is strongly dependent on the chemical bonding and becomes significant only near absorption edges. Its value reaches a few electrons, that is, at its K edge $f_i''(\text{Fe})$ is increased by 5 electrons. This can be used to enhance the contrast between atoms.[11–13]

For the ab initio determination of structures, high Q-resolution is important to reduce the peak-overlap of Bragg reflections and be able to deconvolute their individual intensities. Using a so-called crystal-analyzer configuration pioneered by Hastings *et al.*,[14] an angular resolution of less than 0.01° full-width-at-half-maximum (FWHM) of Bragg reflections can be achieved. ($\Delta d/d \sim 5 \times 10^{-4}$). Using a linear position-sensitive detector,[15] angular resolutions of ∼0.03° FWHM can be reached ($\Delta d/d \sim 10^{-3}$). Alternatively image plates can be used and the spatial resolution of 100 μm leads to an angular resolution between 0.05 and 0.1°.

There are two principal experimental setups for diffraction experiments:

1. In the angle-dispersive or constant wavelength mode, one measures with a monochromatic beam obtained by making use of a single-crystal monochromator, which selects a narrow wavelength band $\Delta\lambda/\lambda$ via a Bragg condition. By varying the scattering angle horizontally or vertically, one then collects a section of the Debye-Scherrer cone as a diffraction pattern. In synchrotron X-ray powder diffraction, $\Delta\lambda/\lambda$ in the vertical is much smaller than in the horizontal and one therefore measures in the vertical direction to maximize resolution. A lot of commercial diffractometers employ the so-called Bragg-Brentano geometry (see Figure 1), where a divergent beam of X-rays coming from the line of focus of the X-ray tube passes through collimators and irradiates the flat surface of a specimen. All of the diffracted X-rays, which must fulfill the Bragg condition, converge to a line at a receiving slit and are then detected.
2. If one leaves the scattering angle constant and uses a white beam with a very broad $\Delta\lambda/\lambda$ distribution, one is measuring in an energy-dispersive setup. In neutron scattering, this is also referred to as the time-of-flight technique since the time it takes a particle to travel from the source to the detector allows the separation of the Bragg peaks corresponding to their different d-spacings as follows: Combining de Broglie's law $\lambda = h/mv = ht/mL$ with Bragg's law one obtains: $d = ht/(2mL\sin\theta)$ [3]. If detectors are placed on locations defined by $L\sin\theta = \text{constant}$, then the neutron scattered at different angles from one d-spacing will all be detected at the same time-of-flight. Neutron diffraction at spallation sources relies heavily on the time-of-flight mode.

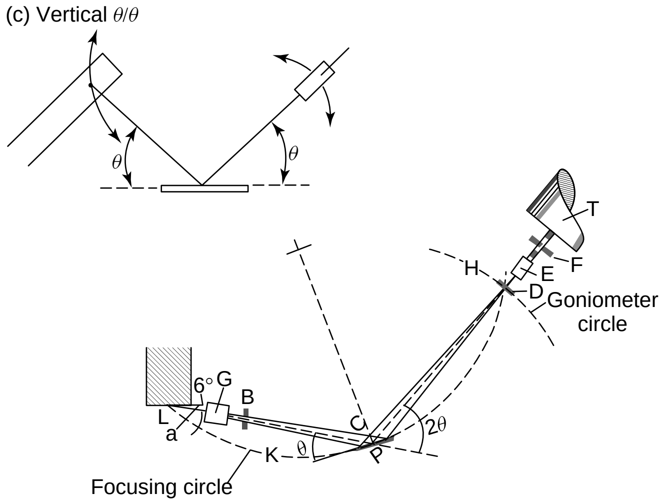

Figure 1 Bragg-Brentano geometry

What information can one obtain from a powder diffraction experiment?

1. **Position of the Bragg Reflections:** For constant wavelength diffractometers, the d-spacings can be obtained by measuring the angular position in 2θ corrected for the zero-point shift and then applying Bragg's law $d = \lambda/2\sin\theta$. In the case of a neutron time-of-flight experiment, $d = ht/2mL\sin\theta$ when the detectors are located on a functional so that $L\sin\theta$ is constant. Indexing unknown structures is the first hurdle that needs to be overcome in a

successful ab initio structure determination from powder diffraction data alone. Up to now the majority of indexing strategies rely on the above-mentioned extracting of peak positions. The most widely used indexing programs are ITO,[16] TREOR[17] and DIVCOL.[18] Recently, Kariuki *et al.* forwarded a new approach based on a full-profile fitting and global optimization using a genetic algorithm.[19] The genetic algorithm is used to explore a hypersurface of the reliability factor Rwp, which is a function of the unit-cell dimensions {a,b,c,α,β,γ}. Other modern search strategies such as Monte Carlo and simulated annealing might also be employed. An efficient way to extract lattice parameters and d-spacings from powder diffraction data is to perform a cell-constrained full-profile refinement in which the individual Bragg intensities are treated as variables together with a zero-point shift in 2θ, various peak shape parameters and 'machine parameters', which determine the 2θ dependency of the FWHM. One thereby refines unit-cell parameters without reference to a structural model. The so obtained individual intensities of all Bragg reflections can then be used for structural solution attempts similar to intensities obtained from single-crystal diffraction experiments. Pawley pioneered these full-profile refinements.[20] LeBail[21] implemented a computationally more robust algorithm by iteratively adjusting the intensities. The correct assignments of errors to the intensities and the problem of completely overlapping reflections were addressed by David.[22] This method can also be used for data obtained from energy-dispersive diffraction.[23] The experimentally determined d-spacings of a material with unknown structure allow (1) the determination of unit-cell parameters using auto-indexing programs, (2) the calculation of precise lattice parameters as a function of temperature, pressure, electric, and magnetic fields, as well as (3) the residual stress in materials[24] to name just the most prominent uses. As an example, Figure 2 shows the temperature dependence of the unit-cell volume, the orthorhombic distortion, and individual cell parameters of $NdBaFe_2O_5$. This double perovskite undergoes a Fe^{2+} /Fe^{3+} charge-ordering transition at 216 K and a premonitory transition at 286 K, which is related to an orthorhombic deformation where a partial charge ordering into $Fe^{2.5+\delta}$ and $Fe^{2.5-\delta}$ takes place.[25] A very small enthalpy change and minute lattice distortion is associated with the latter. High-resolution synchrotron radiation powder diffraction data with a resolution of $\sim 10^{-3}$ in Δ d/d and closely stepped temperature intervals are required to detect such subtle unit-cell volume variations.

2. **Modification of the Peak Shape:[26]** The intrinsic peak shape (i.e. gaussian, lorentzian, and convolutions thereof) and FWHM after subtraction of the instrumental contribution by using a standard[27] such as LaB_6 or silicon permits:

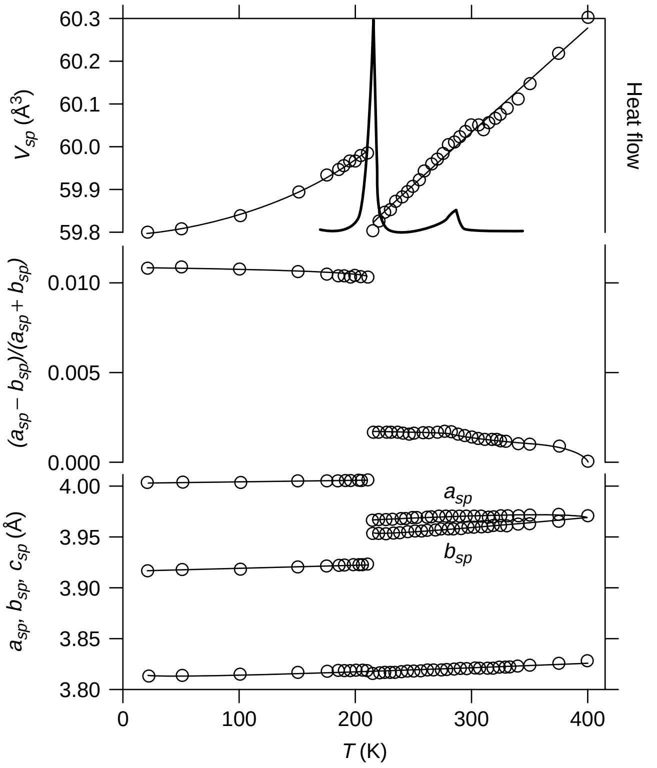

Figure 2 The variation of the unit-cell parameters of $NdBaFe_2O_5$ as a function of temperature revealing a very subtle phase transition near 286 K

- The determination of particle sizes using the Scherrer equation $\Delta(2\theta) = K\lambda/A\cos\theta$ [4] where A is the diameter of the coherently diffracting domain, K, a constant close to unit and $\Delta(2\theta)$ represents the broadening of the FWHM of the Bragg reflection in 2θ.
- The determination of stacking faults, which can lead to diffraction line broadening (i.e. twinning) and peak shifts as well.[28] Recent examples using X-rays are the examination of stacking faults in $Ni(OH)_2$, which can be related to the electrochemical behavior of this material[29] and neutron diffraction work by Berliner and Werner[30] on the 9R structure of lithium below 20 K.
- The local variation Δ d/d (microstrain) due to anisotropic strain in crystallites, lattice defects, and/or local compositional variations $\Delta(2\theta) = -2\Delta$ d/d $\tan\theta$ [5]. Figure 3 shows the comparison of the temperature-dependent behavior of two samples of $Nd_{0.5}Sr_{0.5}MnO_3$ with nominally the same composition. This material shows giant-magnetoresistive behavior.[31] The first sample phase separates into three coexisting macroscopic phases at low temperatures: a ferromagnetic phase that is orthorhombic and exists at high temperatures (HTO),

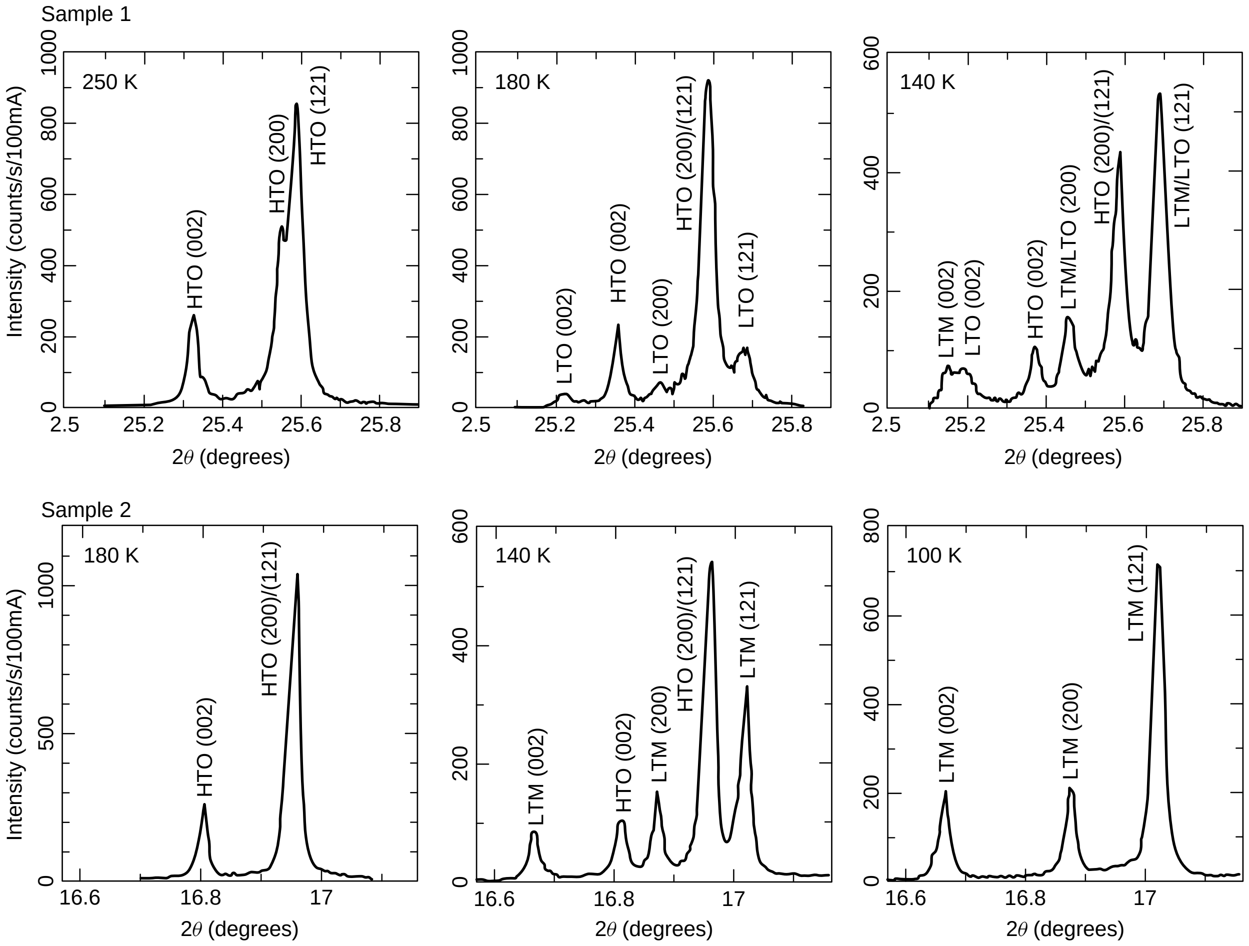

Figure 3 Temperature-dependent diffraction pattern of two samples of $Nd_{0.5}S\ r_{0.5}MnO_3$. The first sample was made using Mn_3O_4 as a starting material and phase separates at low temperatures into three coexisting phases owing to compositional variations. The second sample was made using MnO has a smaller compositional variation and shows only one phase at low temperature

an orthorhombic orbitally ordered antiferromagnetic low-temperature phase (LTO) and a monoclinic low-temperature phase, which is charge, orbital, and antiferromagnetically ordered (LTM). The second sample shows a clean transition from the HTO phase into the LTM phase with a small region of phase coexistence near 140 K. The first phase was made using Mn_3O_4 as starting material, the second using MnO.

The unusual behavior of the first sample is due to a slight excess of Mn^{4+} since Mn_3O_4 is a nonstoichiometric compound. As a result, a wider compositional range–range exists in this compound. At Mn^{4+}: Mn^{3+} ratios close to unity both electron delocalization and charge ordering occurs. This conclusion was obtained by analyzing a Williamson-Hall plot.[32] Combining the Scherrer equation with the above equation for microstrain broadening (equation 2) results in the following equality:

$$\mathrm{FWHM_{corr}}\frac{\cos\theta}{\lambda} = \frac{1}{\mathrm{A}} + \frac{\mathrm{K}\Delta d/d\sin\theta}{\lambda} \qquad (2)$$

$\mathrm{FWHM_{corr}}$ is corrected for the instrumental resolution and K varies with $\Delta d/d$ and the FWHM. Setting the Scherrer constant K to unity one then plots $\mathrm{FWHM_{corr}}\cos\theta$ against $\sin\theta$ as abscissa. One can then extract the scattering domain radius A from the intercept with the ordinate and $\Delta d/d$ from the slope (see Figure 4).

An explanation for this extrinsic phase separation is thus to imagine each crystallite having its unit-cell parameters and stoichiometry controlled by its Mn^{4+}: Mn^{3+} ratio, which ultimately determines whether the HTO phase transforms into to orbitally ordered LTO phase or the charge-ordered LTM one, or not at all (see Figure 5).

In another example, Muller *et al.* have revealed a correlation between the mesoscopic structure and the dielectric

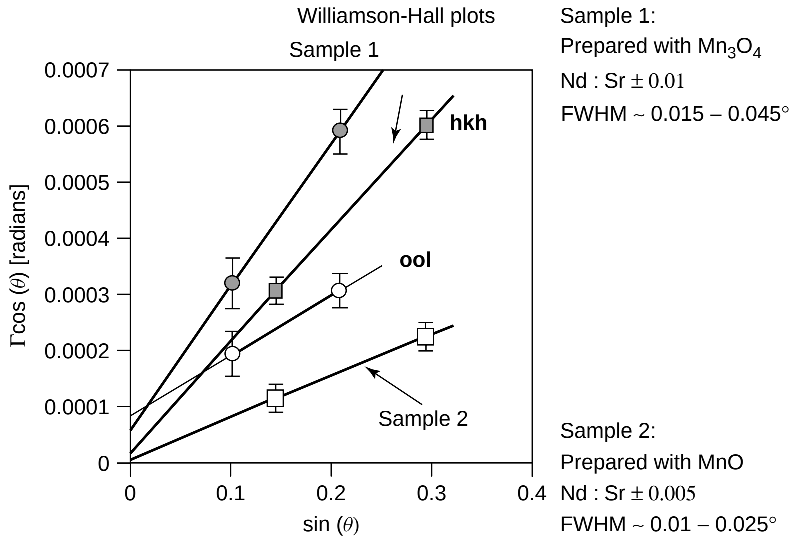

Figure 4 Williamson-Hall plot of the two samples of $Nd_{0.5}Sr_{0.5}MnO_3$ indicating a larger compositional variation of sample 1

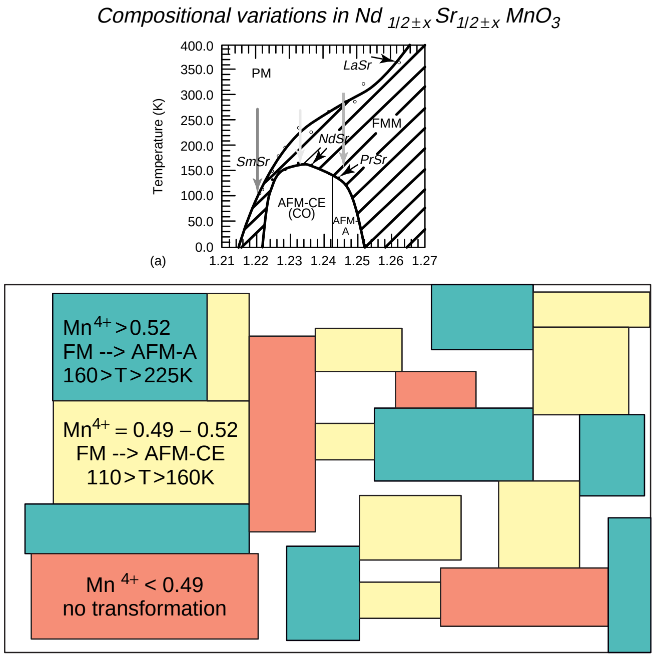

Figure 5 Phase diagram of $Nd_{0.5}Sr_{0.5}MnO_3$ as a function of average A cation radius revealing how the Mn^{4+} concentration influences the phase transformation of each individual crystallite class. At Mn^{4+}:Mn^{3+} ratios close to unity, both electron delocalization and charge- ordering occurs

response of ferroelectric $SrBi_2Ta_2O_9$ (SBT) ceramics.[33] Using again high-resolution synchrotron X-ray powder diffraction data and evaluating the Williamson-Hall plot they showed that a mechanically ground sample has a three times larger strain $\Delta d/d$ than one that was ground manually. As shown below, the shape as well as the position of the dielectric anomaly depends on the stoichiometry as well as the synthesis route used (see Figure 6). The mechanically ground sample was prepared by solid-state reaction between Bi_2O_3, Ta_2O_5 and $SrCO_3$ precursors, whereas the second sample was made by mechanically grinding the precursors in a ball-mill.

3. **Intensities of the Bragg Reflections:** The Rietveld method[34] of refining crystallographic models against the measured intensities of a powder diffraction pattern is based on the premise that the peak shape of Bragg reflections can be described analytically and their variation with the scattering vector Q can be expressed as a convolution of instrumental and sample related effects as described above. Modern powder methods[35] allow not only the refinement but also the determination of crystallographic structures.[36] For this the highest Q-resolution possible is needed to determine the unit cell of an unknown material and then apply structure solution methods (i.e. Patterson, direct methods) adapted to powder diffraction data and solve the phase problem. In recent years, more and more structures of molecular materials are being solved from powder diffraction data owing to the unavailability of good quality single crystals.[37] Innovative structure solution approaches are nowadays based on generalized Monte Carlo Methods,[38,39] simulated annealing,[40–42] and genetic algorithms.[43–45] Harris presents an overview of these recent developments in the structure determination of molecular materials. The program DASH written by David *et al.* uses modern simulated annealing techniques.[46] Recent highlights in molecular crystallography are the structure determination of lithium benzilate hemihydrate using DASH.[47] This monoclinic structure has 221 parameters and was refined using high-resolution synchrotron X-ray data.

4 COMBINED NEUTRON AND X-RAY HIGH-RESOLUTION POWDER DIFFRACTION STUDIES OF CATALYSTS

4.1 Structural Characterization of the M1 phase in the MoVNbTeO Propane Ammoxidation Catalyst

Of all catalytical reactions, the ammoxidation of propylene (C_3H_5) to acrylonitrile (C_2H_3CN) is one of the most important ones. The yearly worldwide production is above 10 billion pounds using the SOHIO/BP process. Current efforts in industrial research are focused on replacing propylene by the cheaper and more abundant propane. Propane (C_3H_8) ammoxidation catalysts for the production of acrylonitrile are mixed metal-oxide molybdenum systems. The best one is patented by Mitsubishi Chem. Ind. and composed of MoVNbTe-oxides. It provides a yield 59% yield with 63% selectivity. The catalytical reaction proceeds by first a hydrogen abstraction followed by an oxygen or NH insertion. V^{5+} has been identified as the important paraffin-activating element in paraffin oxidation and ammoxidation catalysts. To activate paraffins, the V^{5+} cations need to be in proximity to less electronegative metal cations such as Mo^{5+} or V^{4+}, so that the bridging oxygen is nucleophilic enough to abstract hydrogen. The hydrogen-abstracting element is Te^{4+} and the oxygen and/or NH insertion requires the presence of $(Mo^{6+})_2$. The latter two sites require close proximity and comprise the multifunctional catalytic moiety. To function properly, these catalytic centers need to be isolated. However, to achieve optimum activity they should be adjacent to reoxidation sites, so that they can communicate with each other over short distances.[48] This is achieved by four Nb^{5+} centers, each surrounded by five MoO_6 octahedra (see Figure 7). It was found when using the MoVNbTe-oxides that the active catalyst forms only under mildly reducing conditions and is made up of two prominent phases denoted M1 and M2. Recently, in a 'tour de force' the structures of both the M1 and M2 phase were determined by using a combination of transmission electron microscopy (TEM), high-resolution synchrotron, and neutron powder diffraction.[49,50] Predominantly single phase samples of M1 and M2 were synthesized. Initial models were obtained from TEM, in particular, selected area electron diffraction (SAED) and energy-dispersive spectroscopy (EDS). Then synchrotron X-ray powder diffraction data and neutron powder diffraction data were refined simultaneously. For the M1 phase, a total of 173 variables were refined against 2703 reflection in the neutron and 2441 reflections in the synchrotron powder diffraction data. The atomic structure of the M1 phase of this catalyst with the approximated stoichiometry of $Mo_{7.5}V_{1.5}NbTeO_{29}$ is shown in Figure 7. The unit cell of M1 is a = 21.134(2) Å, b = 26.658(2) Å and c = 4.0146(3) Å (space group Pba2, Z = 4). The M2-phase has the approximate stoichiometry $Mo_{4.31}V_{1.36}Te_{1.81}Nb_{0.33}O_{19.81}$ and a unit cell with a = 12.6294(6) Å, b = 7.29156(30) Å and c = 4.02010(7) Å (space group Pmm2, Z = 4).

The oxidation states of vanadium and its neighboring metals have been identified as critical factors in controlling the activity of the bridging oxygen. Bond valence calculations using the coordinates of the refined model suggest that this is the case in the M1 phase but not for the M2 phase. M1 fulfills all the requirements for a selective oxidation catalyst, whereas the M2 phase provides a catalytic moiety for propylene ammoxidation. Bond valence sum calculations are obtained using the relation $V_{ij} = \exp[(Ro - d_{ij})/0.37]$ with Ro being the ideal bond length between two atoms i and j and d_{ij} the actual distance between them.[51] In the M1 phase, the oxygen associated with the catalytic center for propane ammoxidation show significantly different Madelung site potentials when bound to V^{4+} and V^{5+} rather than Mo^{5+} and Mo^{6+}. The potential Φ_i of an ion I located on a site can be

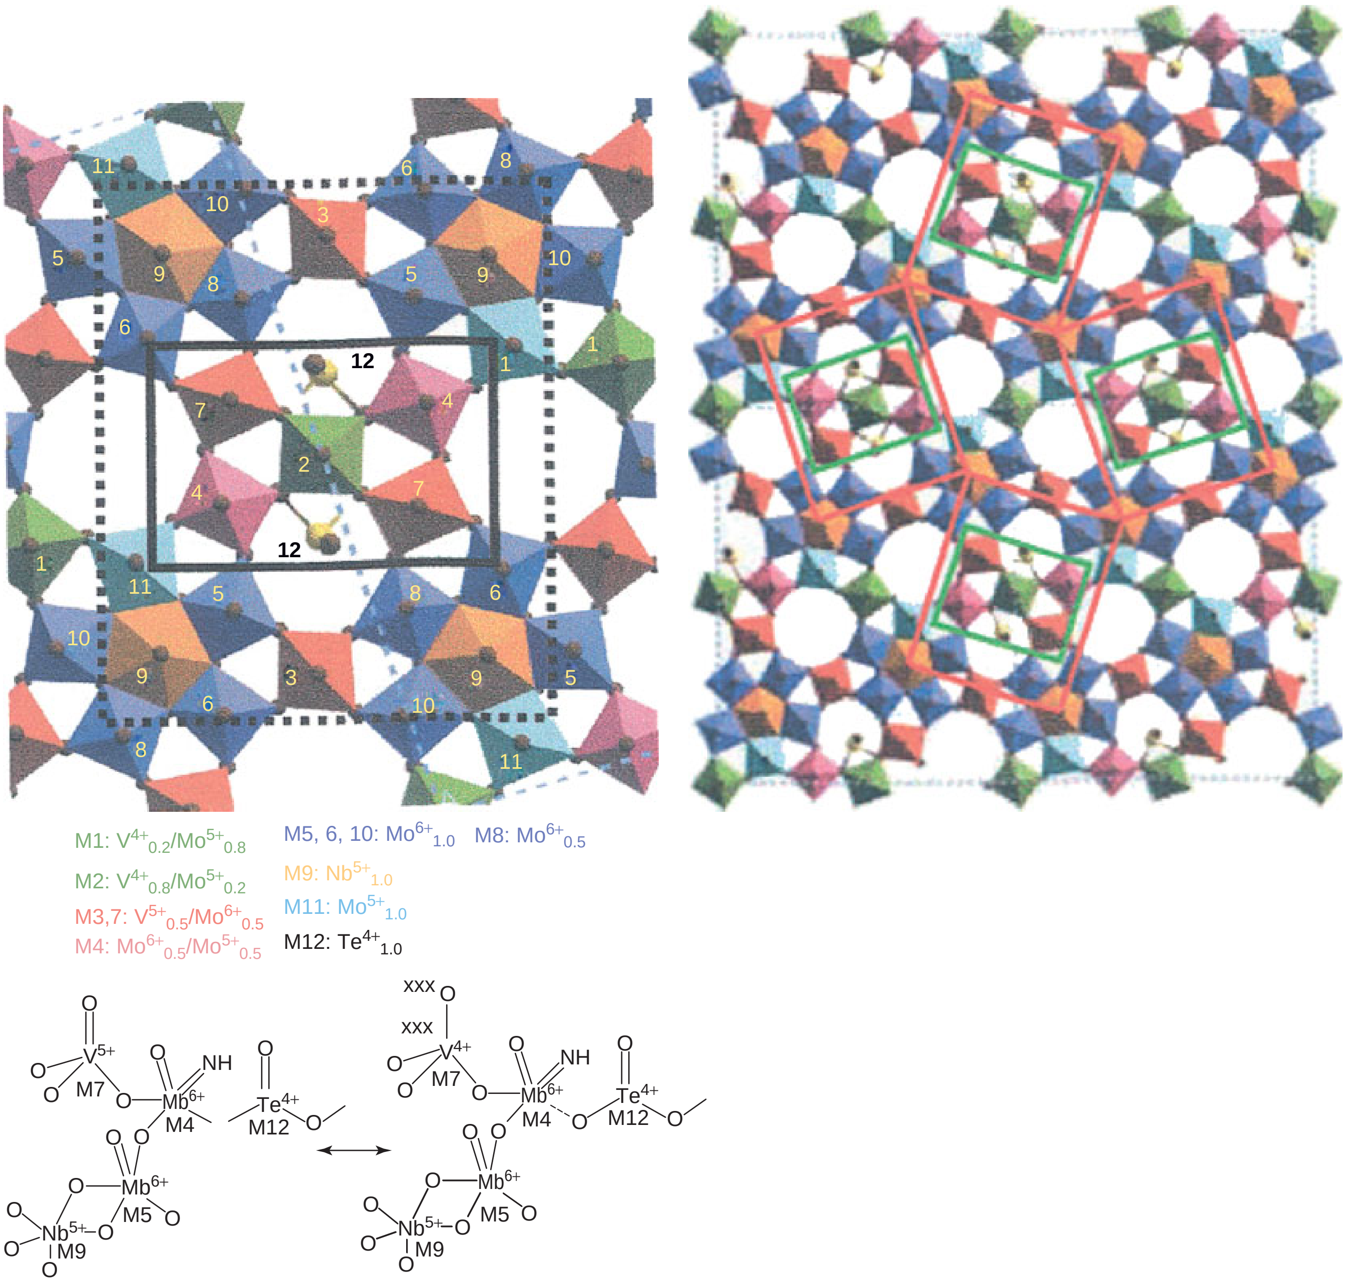

Figure 7 The average structure of $Mo_{7.5}V_{1.5}NbTeO_{29}$ in [001] projection and depictions of the active catalytic moiety. The right side shows how these active centers are isolated within the crystal structure

calculated from the Coulomb interactions between this ion and its neighbors using the charge obtained from bond valence sum calculations. In particular the apical oxygen O2 and O7 have much lower site potentials when vanadium partially occupies the Mo2 and Mo7 sites.

This structure reveals that the sites partially occupied by V^{5+} (red), V^{4+} (green), and Te^{4+} (light blue) cations are isolated providing sites for the propane amooxidation catalysis to occur on terminal [001] planes. In particular the ionicity of the metal–oxygen bonds in corner-sharing octahedra with a V^{5+} and V^{4+} /Mo^{4+} center provides a particularly nucleophilic bridging oxygen critical for propane activation. The Mo^{6+} sites have been shown to act as propane adsorption and nitrogen insertion sites in bismuth molybdates, which are also used for propane ammoxidation.

This structural characterization demonstrates how the multifunctionality required for an efficient and selective catalyst is based on the multielemental distribution within such complex oxide catalysts. Neutron powder diffraction is absolutely essential to be able to refine the oxygen

positions in such large structures in the presence of high-Z metals. High-resolution synchrotron powder diffraction on the other hand provides unique information about the phase composition of such multicomponent catalysts. By providing even higher flux and smaller beams, it is conceivable that in the future one can isolate diffraction contributions from different phases originating from different grains and unravel the complex structure of the individual grains as well as the strain and texture effects that might be beneficial for catalytic processes. Furthermore, it is conceivable that in situ and time-resolved powder diffraction of ‘real’ catalytic processes provide an unprecedented wealth of understanding and lead to new approaches when designing novel multifunctional catalysts. Structural investigations of catalysts in particular zeolites have in the past been a prime motivation for instrumental developments in high-resolution powder diffraction.

4.2 The Location of Bronsted Acid Sites in Zeolites

Acidic zeolites are used in the chemical and oil industry as catalysts owing to their outstanding reaction selectivity as well as their outstanding chemical and thermal stability in processes such as the isomerization of xylenes, catalytical cracking, and paraffin hydroisomerization. Their functionality is based on the donation of Brønsted acid protons from bridging framework hydroxyls. These acid protons balance the negative framework charge, which is created by the substitution of Si^{4+} by Al^{3+} cations. In general zeolites are converted to their acidic form by ion exchanging with an NH_4^+ salt and subsequent calcinations to remove NH_3. The proton bonds covalently to one of the oxygen neighboring an Al^{3+} ion. The location of these acidic sites is a very difficult task using X-ray diffraction since one relies on indirect information, that is, the distortion of the average T–O distances (T = Si,Al), which are expected to increase upon protonation. On the basis of a comparison with T–O distances occurring in other acidic faujasites, Olson and Dempsey[52] suggested that the O1 and O3 sites in zeolite Y were protonated. This was experimentally shown to be correct by Czjzek *et al.*[53] in a high-resolution neutron powder diffraction experiment using both hydrogen and deuterium containing samples and taking advantage of the negative and positive scattering length for hydrogen and deuterium respectively. Cheetham *et al.*[54] performed neutron powder diffraction studies on the hydrated La containing form of zeolite Y and observed a Brønsted acid site as well as the hydrolyzed cation responsible for its formation. Neutron powder diffraction studies of the deuterated form of zeolite RHO revealed that the O1 site was preferentially protonated.[55] The same two acidic sites were found in the high silica zeolite CHA (SSZ-13)[56] as well as in the deuterated silico-alumino-phosphate analogue SAPO-34.[57] Martucci and coworkers reported two acidic sites in ferrierite (FER)[58] and 4 preferential sites in mordenite (MOR).[59] The highly complex zeolite ERS-7 (ESV) with 6 unique T sites, 14 unique oxygen, and altogether 56 independent positional parameters allowed the location of three acidic sites.[60] In this case, again a combined neutron and X-ray powder diffraction study took advantage of the scattering power of deuterium with neutrons and the high-resolution of synchrotron X-ray powder diffraction. In addition to the Bronsted acid sites, both X-ray and neutron powder difference Fourier maps identified a disordered oxygen site owing to varying local geometries of the Al in the neighboring site. Powder diffraction studies of zeolites will continue to be important in the future. The complexity of the structures will increase. To date, SSZ-58 is the most complex zeolites in terms of the number of atoms in the crystallographic asymmetric unit to be solved from powder diffraction data. It contains 38 individual atomic sites in an orthorhombic unit cell with a = 25.1106 Å, b = 12.4972 Å and c = 12.8596 Å.[61]

5 HIGH-RESOLUTION X-RAY AND NEUTRON DIFFRACTION IN MAGNETIC FIELDS

The interaction of a magnetic field with matter and in particular, the electronic properties are of fundamental and technological importance. Magnetic field–induced structural phase transitions can be probed using field-dependent measurements of the electrical resistance (magnetoresistance), magnetization, heat capacity (magnetocaloric effect) and strain (magnetostriction) and provide valuable macroscopic information. However, only the atomistic details will reveal the mechanism driving the phase transition.

5.1 Neutron Powder Diffraction in Magnetic Fields – Breaking Bonds in Magnetoresistive Materials

MnAs is a ferromagnet with a Curie temperature near 313 K[62] where simultaneously a metal-insulator transition occurs.[63] Above 313 K the structure is orthorhombic, below hexagonal. Mira *et al.*[64] have shown using neutron powder diffraction in magnetic fields that when heating and equilibrating MnAs at 321 K and then applying a magnetic field above 3.5 T one can fully restore the hexagonal phase (see Figure 8). Both field- and temperature induced phase transitions show a small region of phase coexistence. The field-induced phase transition is also accompanied by an enhanced magnetoresistance of ∼17% at 310 K. In the region of phase coexistence, the hexagonal ferromagnetic phase that is derived from the orthorhombic paramagnetic phase by a cooperative displacement of pairs of [1, −1,0] rows grows at the expense of the latter. It forms strong Mn–Mn bonds across octahedral-site edges, which run in zigzag chains within the basal planes while weakening the Mn–Mn bonds between planes. The orbitals of the Mn atoms in the basal planes are half-filled. As these spins are aligned according

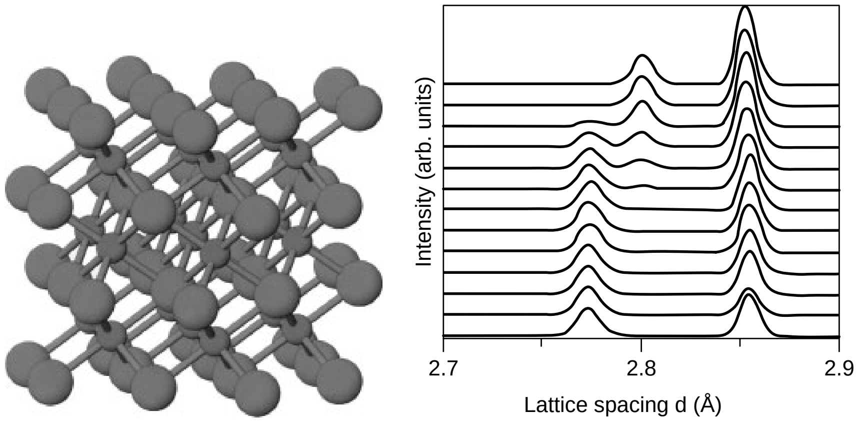

Figure 8 MnAs structure and the evolution from the orthogonal to hexagonal form as a function of increasing magnetic field strength along the y axis

to the Goodenough-Kanamori rules,[65] no bonding can occur between half-filled orbitals with parallel spins and therefore the high-spin ferromagnetic hexagonal phase is stabilized. Thus, this magnetic field–induced transition involves breaking of metal–metal bonds.

5.2 X-ray Powder Diffraction in Magnetic Fields – Strengthening Bonds in Magnetocaloric Materials

The inherent higher Q-resolution of X-ray powder diffraction allows the extraction of crystallographic details from highly complex magnetic structures. An example is Gd_5Ge_4 a giant magnetocaloric material,[66] which crystallizes in an orthorhombic structure with a primitive unit-cell volume above 800 Å^3. Magnetocaloric materials heat up when magnetized and cool down when demagnetized. They have the potential to be an alternative to cooling via the vapor-compression mechanism and would reduce the need for ozone depleting greenhouse chemicals. Gd_5Ge_4 orders antiferromagnetic below 130 K and the appearance of both magnetic and structural Bragg reflections would add further complexity to an already challenging neutron powder diffraction pattern. Furthermore, the prohibitive high absorption cross-section of natural Gd ($\sigma_{abs} = 49700$ barn for 0.0253 eV neutrons) and the exorbitant cost of the low absorbing isotopes ^{156}Gd ^{158}Gd and ^{160}Gd make neutron scattering experiments on this material unworkable. Pecharsky recently accomplished measuring X-ray powder diffraction pattern of Gd5Ge4 as a function of magnetic fields. His experimental setup is comprised of a standard Rigaku TTRAX system operating in Bragg-Brentano geometry with a theta/theta wide-angle goniometer and an 18 kW rotating anode X-ray generator providing monochromatic Mo Ka radiation. A custom-designed optical split-coil superconducting magnet allows the sample to be positioned at the center of the diffractometer and magnet, which gives uniform fields up to 35 kOe. Diffraction data up to a 2θ angle of 78 degrees enables the measurement of d-spacings larger than 0.564 Å. The samples are mixed with a nonreactive binder to prevent particle alignment with the easy magnetization axis parallel to the magnetic field, which would lead to preferred orientation.

Both the low-field(LF) and high-field (HF) structures of Gd_5Ge_4 have the same orthorhombic space group (Pnma) but slightly different structures (see Figure 9). The most prominent difference occurs in the interlayer Ge–Ge bonds. On transforming from the LF to the HF structure, a field-induced contraction and a concomitant strengthening of the Ge–Ge bonds between the layers occur. The intralayer distances vary up to a maximum of 5%, whereas the interlayer distances change as much as 27.6% (~1Å). The layers themselves undergo very little structural changes under field. The magnetic field thus induces a 'martensitic-like' phase transition.[67] It was also discovered that even in a magnetically saturated sample a small amount (7%) of LF-phase is still present. This inhomogeneity of the sample is due to the balance between the works performed by the magnetic field to overcome the strain created by the 1.1% volume change of the unit cell. Magnetic work becomes insignificant near saturation but the strain remains extensive.

6 ATOMIC PAIR-DISTRIBUTION FUNCTIONS AND NANOCRYSTALLOGRAPHY

With a new generation of synchrotron sources being in various stages of planning and commissioning, it can be projected that the field of nanocrystallography using pair-distribution function analysis will be extended to smaller amounts of samples as well as smaller regions within complex

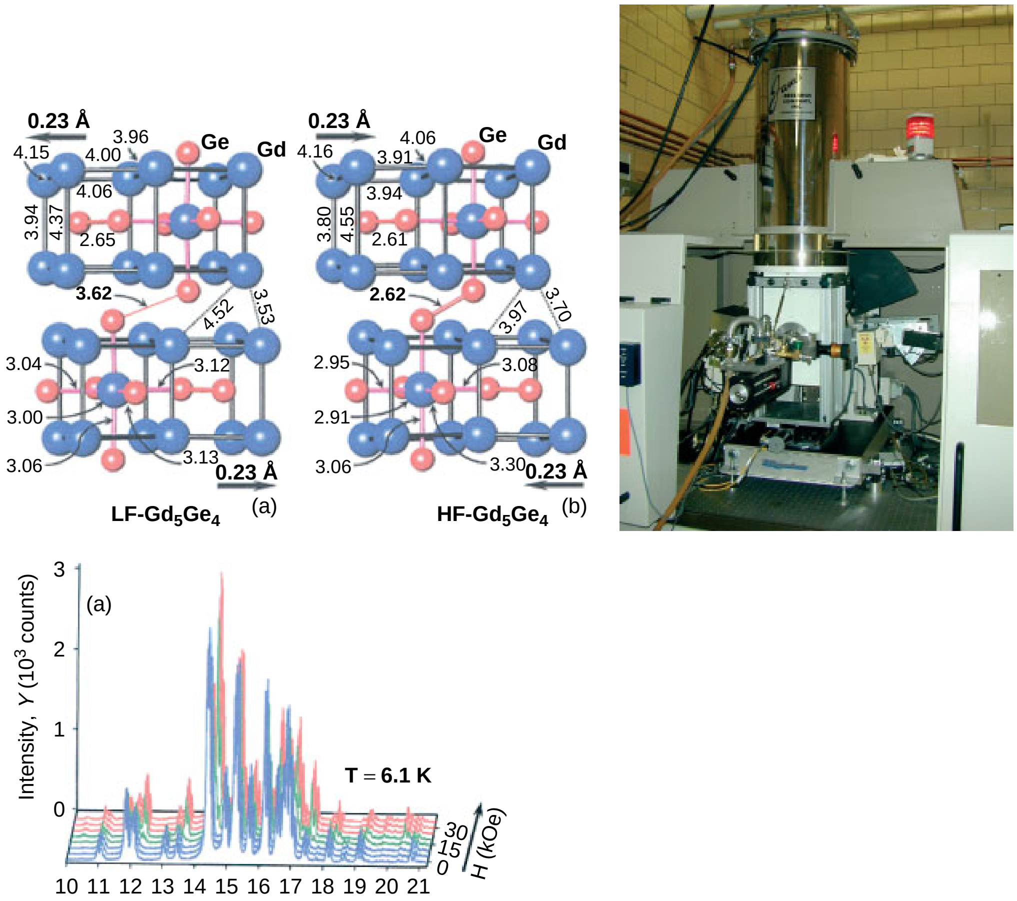

Figure 9 The antiferromagnetic low-field (LF) and ferromagnetic high-field (HF) Gd_5Ge_4 structures viewed along [001]. Under the influence of a magnetic field, the main changes occur in the interlayer distances. Below it is shown how the X-ray powder diffraction pattern changes at 6.1k as one increases the magnetic field. Blue indicates the LF, red the HF-Gd_5Ge_4 structure, and green the region of phase coexistence. On the right, the powder diffractometer (Bragg-Brentano geometry) equipped with an optical split-coil superconducting magnet is shown

materials. The focus of scientific attention on crystalline matter, and the use of symmetry to describe what are perforce only average structures do not adequately take into account the fact that real crystals are imperfect. Conventional crystallography encourages the view that atoms are to be placed within the context of symmetry elements even though they only react locally to physical forces. The advent of nanoscience and nanotechnology reminds us that structures are assembled locally. Recently, it has been realized that in complex materials there are conflicting forces, which compete locally *despite* the presence of a long-range-ordered structure. An adequate structural description of complex matter therefore has to go beyond classical crystallography and characterize both the local *and* average structure. Classical crystallography does also not take into account the fact that it is at the same time bulk and surface science. Nanoclusters comprised of fifty close-packed spheres have about 80% surface atoms and even a close-packed two thousand-atom grain still has about 20% surface atoms. The structural chemistry of nanomaterials as well as nanostructured complex materials often depends on the crystallography of internal surfaces in particular grains. Using atomic pair-distribution functions provides a means to obtain both the local *and* long-range atomic structure directly. In the PDF technique, both Bragg and diffuse scattering is Fourier transformed into real space. It therefore bridges the average crystallographic long-range structure generally obtained by standard Rietveld refinement and the local lattice distortions observable in TEM images and offers a stringent test for the validity of complex structure models.

6.1 The Pair-distribution Function

The diffraction experiments to collect pair-distribution functions (PDF) are typically done at synchrotrons or neutron spallation sources since high quality data at large momentum transfers $Q = 4\pi \sin\theta/\lambda > 20\,\text{Å}^{-1}$ are required to reduce termination errors at low real-space distances. The atomic PDF G(r) is defined as

$$G(r) = 4\pi r[\rho(r) - \rho_0] \tag{3}$$

where ρ_0 is the average atomic number density, $\rho(r)$ is the atomic pair-density and r is a radial distance. This function thus provides information about the number of atoms contained in a spherical section of a shell of unit thickness at distance r from a reference atom. The PDF is experimentally accessible since it is related to the total X-ray or neutron scattering S(Q) via its Fourier transform:

$$G(r) = \frac{2}{\pi}\int Q[S(Q) - 1]\sin(Qr)\,dQ \qquad (4)$$

The quantity Q[S(Q) – 1] is referred to as the reduced structure function. The total scattering structure function is related to the coherent part of the total diffracted intensity by:

$$S(Q) = \left[\frac{\left(I_{coh}(Q) - \sum c_i \left| f_i(Q)2\right)\right.}{\left|\sum c_i f_i(Q)\right|}\right] + 1 \qquad (5)$$

with Icoh(Q) being the total scattered intensity corrected for background and other experimental effects (i.e. absorption, multiple scattering) and normalized to the flux and number of atoms in the sample. Errors in these corrections result in peaks at unphysical low r values.[68] The atomic concentrations c_i and the individual atomic form factors f_i (or neutron scattering lengths b_i) of the individual species i are summed and in neutron scattering the different contributions of all isotopes and spin states (in neutron scattering) must also be included. The PDF is modeled by using the distance distribution via

$$G(r) + 4\pi\rho 0 = \frac{1}{r}\sum\sum \frac{(f_{0_i} f_{0_k})}{\langle f_0\rangle^2 \delta(r\text{-}r_{ik})} \qquad (6)$$

The form factors f_0 at Q = 0 are an approximation of the number of electrons Z of an atom. When modeling neutron PDFs, the appropriate nuclear scattering lengths or magnetic form factors replace these atomic form factors. In equation (6), r_{ik} is the distance between atoms i and k summed over all the atoms in the sample.

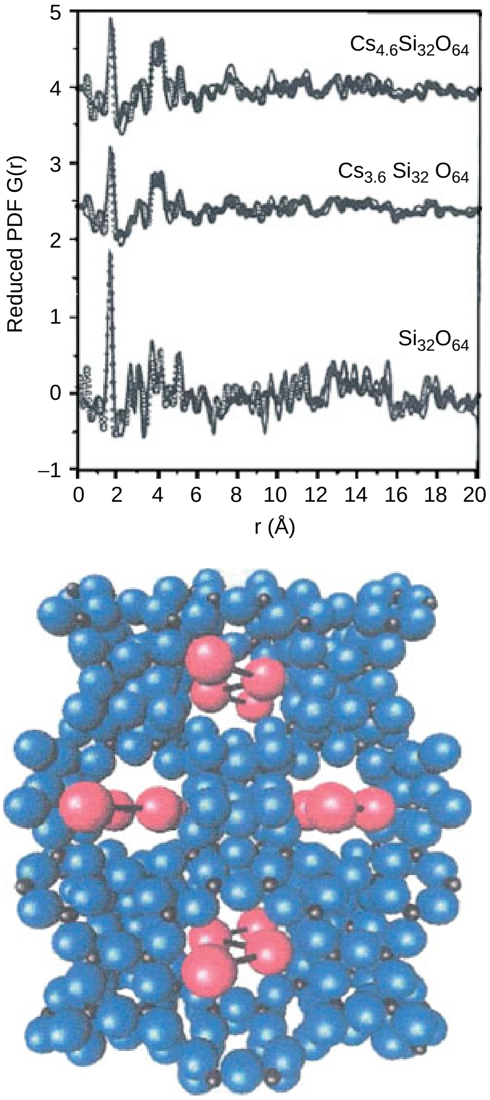

Figure 10 (a) Experimental (circles) and model (line) PDFs for $Cs_xSi_{32}O_{64}$ (x = 0, 3.6 and 4.6) (2) Fragment of the nanoscale structure of $Cs_xSi_{32}O_{64}$ where Cs^+ ions (red circles) in the nanopores are assembled in zigzag chains. Oxygen atoms are blue, silicon atoms black

6.2 Unique States of Matter – Room Temperature Electride

In electrides, electrons behave as anions. In a typical organic electride Cs^+ (15-crown-5)$_2$ e^-, the electrons occupy cavities connected by narrow channels. The first electride stable at room temperature was made by ionizing Cs into Cs^+ and e^- within the channels of an all-silica zeolite.[69] Petkov *et al.*[70] confirmed that Cs^+ and a low-density electron gas are present in the one-dimensional nanopores of the siliceous zeolite ITQ-4 ($Si_{32}O_{64}$). The PDF technique provided direct structural evidence that Cs intercalated in the form of Cs^+ ions arranged in short zigzag chains (see Figure 10). This structural model is now being used in electronic structure calculations to gain insight into this new nanoscale low-dimensional correlated electron material.

7 HIGH-PRESSURE NEUTRON AND SYNCHROTRON X-RAY POWDER DIFFRACTION

Pressure is a basic thermodynamic variable transforming matter from one state to another; when pressure is applied, atoms are brought closer together, ultimately altering a

material's structural, electronic, and mechanical properties in radical and often unexpected ways. However, our knowledge of pressure-induced phase transformations is still very limited compared to the vast number of temperature-dependent phases we have characterized over the past decades. This is largely due to the experimental difficulties involved in both the need for specialized equipment and the development of expertise in the use of high-pressure cells. These limitations, coupled with the obvious interest in matter under numerous pressure-temperature conditions within planets, have led to the dominance of the field of high-pressure research by the Earth Sciences community. As an example, Loveday *et al*.[71] undertook a combined synchrotron X-ray and neutron powder diffraction of methane hydrate under high-pressure conditions up to 10 GPa. Structural phase transitions at about 1 and 2 GPa to new hydrate phases were discovered that remain stable to about 10 GPa. This explains how methane in the core of Titan remained in a stable phase throughout differentiation without being lost into the atmosphere, where photochemical processes would rapidly have destroyed it. Equally interesting phenomena occur in the more general areas of condensed matter physics, chemistry, and biology: pressure causes proteins to unfold, insulators to become metals or superconductors, materials to reach their yield strength and phase transitions to occur. The wider community of solid-state scientists now benefits from the technology and expertise developed by Earth Scientists. This opens up more unconventional conduits of research. Furthermore, pressure experiments provide one of the most fundamental properties of matter, the equation of state, which reveals how the unit-cell volume of a sample changes with pressure. This is predicted and used in various physical theories.

7.1 First Observation of Superhydration in a Zeolite

Upon hydrostatic pressure increase in a water-containing medium, the zeolite natrolite shows an abrupt volume expansion (ca. 2.5%) between 0.8–1.5 GPa. Rietveld refinements and subsequent Fourier difference maps using synchrotron X-ray powder diffraction data showed that this anomalous swelling is due to the selective sorption of water from the alcohol-based pressure-transmitting media into the expanded channels, giving rise to a 'superhydrated' phase of natrolite, $Na_{16}Al_{16}Si_{24}O_{80}\cdot 32H_2O$, which is distinct from natrolite at ambient conditions,[72] $Na_{16}Al_{16}Si_{24}O_{80}\cdot 16H_2O$ containing twice the amount of water.

Powdered samples were loaded into a diamond-anvil cell (DAC) at ambient pressure and room temperature along with a few small ruby chips (see Figure 11). The DAC employs two diamonds with 0.5 mm diameter culets mounted on tungsten-carbide supports. The X-rays are admitted by a 0.5 mm diameter circular aperture, and the exit beam leaves via a 0.5×3.0 mm rectangular tapered slit, oriented perpendicular to the horizontal plane of the diffractometer. The sample chamber is provided by a 200 or 350 µm hole formed in the center of a 300 µm thick stainless steel gasket, preindented to 100 µm thickness before spark-erosion drilling. A mixture of 16:3:1 by volume of methanol:ethanol:water is used as a pore-penetrating hydrostatic pressure transmission fluid, which is known to remain hydrostatic up to ∼10 GPa.[73] The pressure is measured ex situ by detecting the shift in the R1 emission line of the included ruby chips.[74] The structural evolution under pressure is analyzed using the Rietveld method.

The evolution of the unit-cell parameters of natrolite is shown as a function of the pressure in Figure 12. Between 0.8 and 1.5 GPa, the pressure-induced swelling is caused

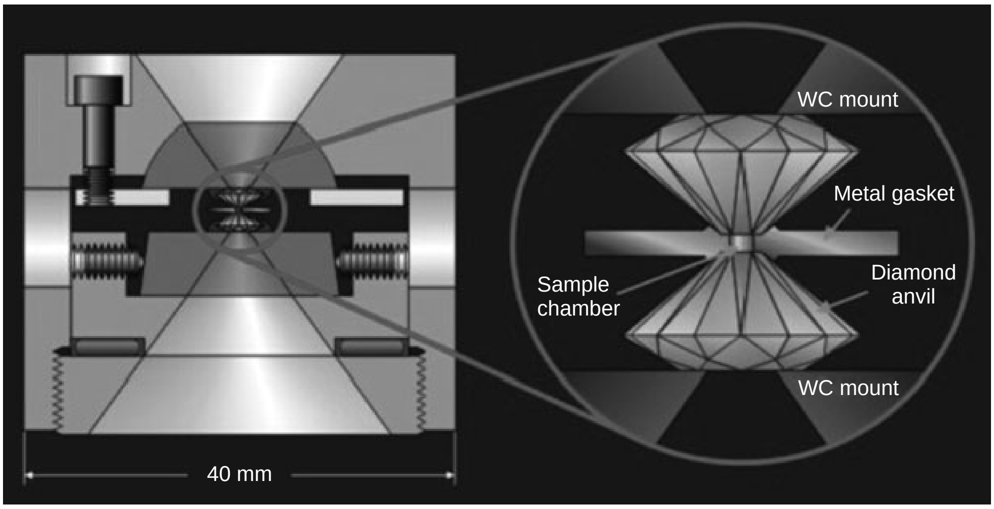

Figure 11 The diamond-anvil cell has emerged as the dominant and most versatile tool for achieving high pressures (up to millions times of the atmospheric pressure). It uses two diamond anvils, which exert pressure and serve as windows on the sample. A metal gasket confines the sample and supports the anvils. Because diamond is the strongest material known and is transparent over a wide range of the electromagnetic spectrum, various high-pressure experiments are performed using synchrotron radiation

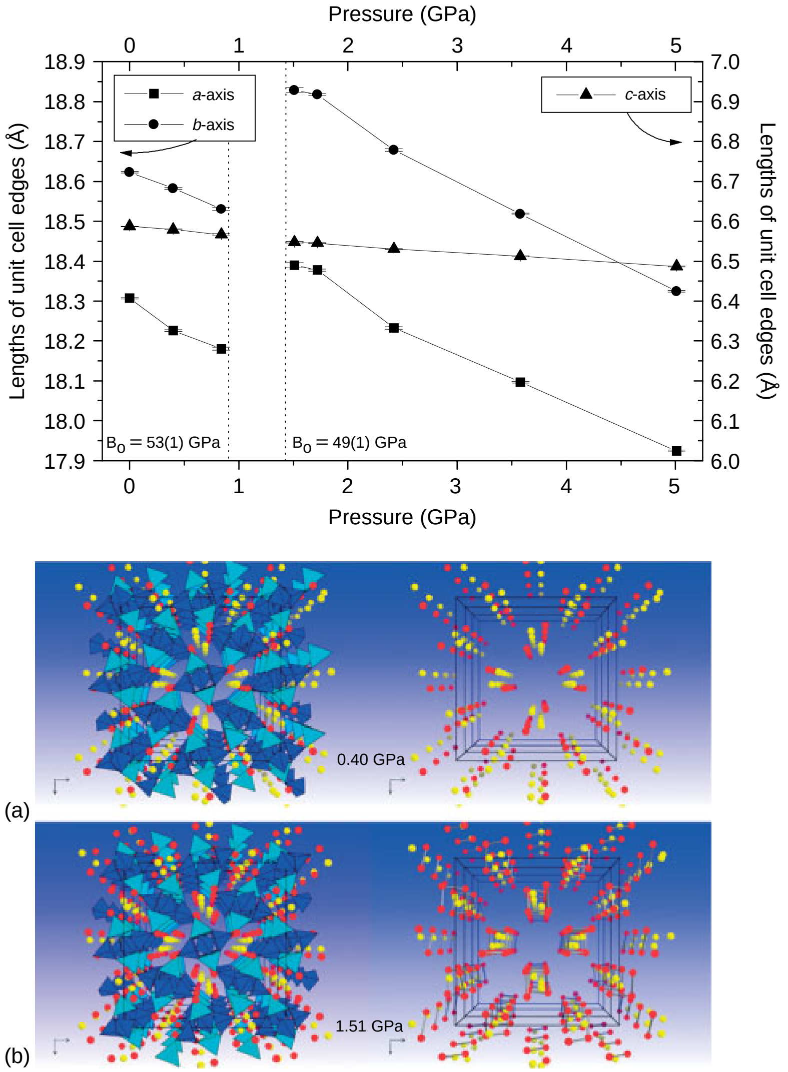

Figure 12 Changes in the unit-cell edge lengths (Å) of sodium aluminosilicate natrolite as a function of pressure. Polyhedral representations of natrolite at (a) 0.40 GPa and (b) 1.51 GPa viewed along [001], the chain/channel axis. Each representation is repeated on the right without the framework component to emphasize the channel contents. Note the formation of the hydrogen-bonded water nanotubes at 1.51 GPa. Red circles represent the oxygen of the water molecules; yellow ones sodium cations. Blue (azure) tetrahedra illustrate an ordered distribution of Si (Al) atoms in the framework

by the expansion of the unit cell along the *a*- and *b*-axes, whereas the *c*-axis shows the expected contraction throughout the volume expansion period. This anisotropic swelling suggests that the rotation of the tetrahedral chains along the *c*-axis and subsequent expansion of the channels in the (001) plane is responsible for the observed volume increase. The bulk modulus of the large-volume natrolite ($B_0 = 49(1)$ GPa) is slightly smaller than that of the normal natrolite ($B_0 = 53(1)$ GPa), illustrating an increased compressibility for the 'superhydrated' phase. The superhydration in sodium aluminosilicate natrolite is reversible. However, a synthetic analogue, potassium gallosilicate exhibits irreversible superhydration with retention of the high-pressure phase at ambient conditions.[75]

The two structural models for the phases before and after the volume expansion are shown below. After the volume expansion at 1.5 GPa, an additional fully occupied water site (OW2) appears along the channel, leading to 32 H_2O per unit cell. Unlike the chain of sodium and water in the low-pressure phase below 0.8 GPa, the superhydration at the OW2 site generates an infinite chain of hydrogen-bonded water nanotubes along the *c*-axis with O–O distances between 2.80(4) and 3.09(4) Å. The position of the sodium cation does not show any appreciable changes throughout the superhydration region. The ordered water nanotube in natrolite should be seen in light of theoretical water nanostructures proposed by Koga *et al.*[76] The presence of Na-ions within the water nanotubes should provide an incentive

to study ion transport under pressure. Furthermore, these observations will also draw attention to a possible geophysical implication: superhydration conditions resemble regions of the cold lithosphere during subduction[77] implying a new possible mechanism for the storage and transport of water in framework structures in the Earth's upper mantle.

7.2 High-pressure Neutron Powder Diffraction Studies of Cristobalite

The high-pressure phase of cristobalite, one of the SiO_2 modifications, was studied with neutron time-of-flight powder diffraction using the PEARL beamline at the neutron spallation source ISIS at the Rutheford Appleton Laboratory (UK).[78] The high-pressure data were obtained using a Paris–Edinburgh-cell. This cell weighs about 50 kg and uses a 200 ton ram and fits into a 30 cm cube (Figure 13).[79] With a modified encapsulated gasket, it is now possible to measure under hydrostatic conditions up to 9 GPa.[80] The sample was mixed with Fluorinert™ as the pressure-transmitting medium and loaded in a circular gasket made of a Ti–Zr alloy, which has a zero coherent scattering length. This was then mounted between tungsten-carbide anvils and subsequently pressurized.

The diffraction pattern was collected in the time-of-flight mode. The starting model for the Rietveld refinement was obtained from ab initio density-functional theory (DFT) calculations. The crystal structure of the high-pressure form of cristobalite was found to be a monoclinic distortion of the cubic SiO_2 phase. As shown below, the structure is composed of puckered 6-membered rings composed of corner-sharing SiO_4 tetrahedra (see Figure 14). In the cubic phase these rings are perfect hexagons. The puckering is the result of relatively large rotations of the tetrahedra. The cubic structure is an average structure in which dynamic reorientations of the SiO_4 tetrahedra take place. The ambient phase is tetragonal. The question arose if the monoclinic phase is due to a distortion of the tetragonal or cubic parent phase. Using a theoretical approach referred to as 'rigid unit model',[81] a displacive

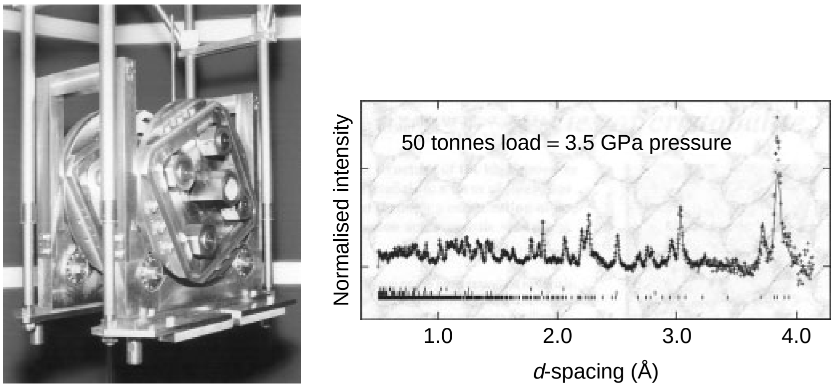

Figure 13 Paris–Edinburgh cell used for high-pressure neutron powder diffraction experiments. On the right neutron time-of-flight data of the high-pressure monoclinic form of cristobalite are shown

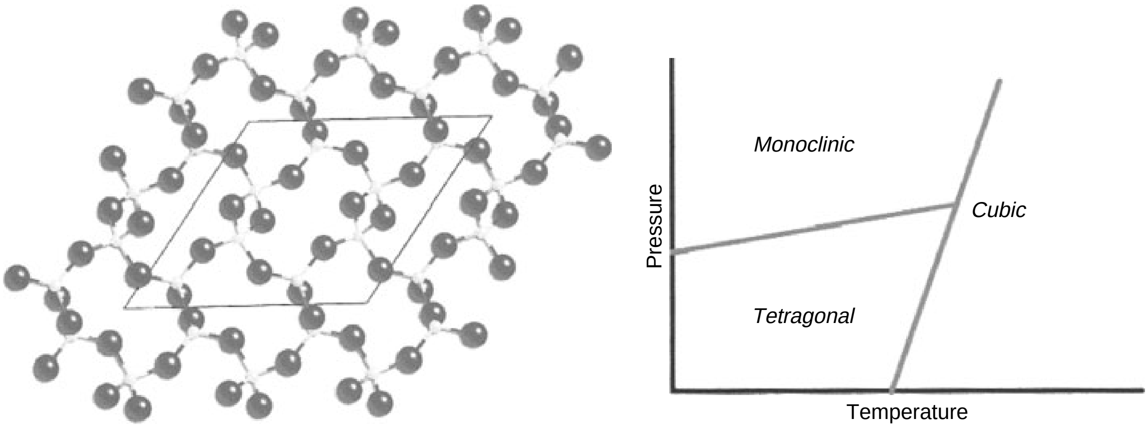

Figure 14 Structure of the monoclinic phase of cristobalite viewed down [010] revealing the puckered six-member rings of SiO_4 tetrahedra. On the right, a schematic pressure-temperature phase diagram

transition from the tetragonal phase seems unlikely. Rather, the monoclinic structure takes place owing to a so-called soft-mode in the cubic phase of cristobalite, which exists at high temperatures and pressures. This can also be inferred from the fact that the monoclinic space group $P2_1/c$ is not a subgroup of the tetragonal phase but of the cubic phase and therefore a displacive instability from the tetragonal phase is not possible.[82] This shows that high-pressure phase transitions can have more complex group-subgroup relationships than found in transitions caused by changing temperature.

8 OUTLOOK

New challenges and opportunities for powder diffraction are emerging. Powder diffraction is a very active field. As in the past, progress will benefit from advances in instrumentation and computing Examples are:

- The implementation of novel instrumental concepts and here, in particular, a new generation of neutron time-of-flight powder diffractometers. The General Materials Diffractometer (GEM) at ISIS is such a novel high-intensity, high-resolution neutron powder diffractometer ($\Delta d/d \sim 2 \times 10^{-3}$). When GEM is completed, it will have 7290 detector elements grouped in more than 98 modules. These detectors will cover scattering angles from 1.1° to 169.3°. The GEM scintillator detector system will contain 660,000 individual optic fibers, whose total length will be about 350 km.[83] The Spallation Neutron Source(SNS) currently being built at Oakridge National Laboratory will also provide access to a high-resolution GEM-type powder diffractometer.
- Another very active area of research is ultrafast time-resolved powder diffraction. Recent work at the European Synchrotron Radiation Facility (ESRF) by Teichert *et al.*[84] reported the direct observation of a photoinduced paraelectric-to-ferroelectric phase transition in a charge-transfer molecular material using a monochromatic 100 picosecond synchrotron pulse. The short-lived metastabile ionic state with long-range ferroelectric ordering was created by near-infrared light and more than 800 unique Bragg reflections were collected. With the start-up, the Sub-picosecond X-ray Pulse Source and the Linear Coherent Light Source (LCLS) at Stanford new horizons in single-shot diffraction and ultrafast time-resolved powder diffraction studies open up.
- A third area of research, which has the potential to revolutionize powder diffraction, is the focusing of X-rays into very small beams ('nanobeams'). Nanoscience and modern synchrotron diffraction are engaged in a synergetic relationship in which on the one hand nanoscience requires nanoscale X-ray beams to probe nanometer size regions of matter and on the other hand, nanolithography tools such as electron beam writers are needed to pattern and manufacture optical devices such as zone plates, refractive lenses, and waveguides.
- With respect to developments in computing power and modeling capabilities, it can be taken for granted that both will continue to proliferate and increase at the current growth rate. This opens up new possibilities in real-space modeling and on-line data analysis for parametric studies. Parallel computing of Rietveld refinements has been already been demonstrated in the very popular General Structure Analysis Systems (GSAS) code. Using a modest cluster with seven processors reduced the time it takes to complete least-squares refinements between 2.5 and 5 times.[85] Remote-instrument control at user facilities is already being put into operation. Nanocrystallography requires both automated direct Fourier transformations in contrast to 'manual' processing as well as 'smart' interactive modeling tools to deal with future increases in the data acquisition rate. New methods and tools are emerging that will take advantage of unprecedented computational capabilities. Powder diffraction techniques will be able to investigate structures of a complexity deemed impossible just a few years ago.

1 INTRODUCTION

Computational methods have had a major impact on almost all areas of science in recent years. The range of applications is now very broad, encompassing molecular biology, materials and surface science, mineralogy, and small molecule chemistry. This article focuses on the application of atomistic computer modeling techniques to materials science. We present a brief survey of the aims and scope of the field and short introduction to the main methodologies. We illustrate the current state of the art of computer modeling studies of materials by recent applications to bulk and surface properties of topical systems.

1.1 Range and Scope

Computer modeling is a distinct type of scientific technique that bridges fundamental theory with experimental observation on complex systems. Its success rests first on the fact that the basic physics controlling the behavior of matter at the atomic level has been established for over seventy years; secondly on the development over the last twenty years of approximate but effective methods for implementing this physics in complex systems; and thirdly on the ability of modern computers to handle the enormous demands regarding both processing power and memory required for realistic modeling of complex systems.

Computer simulation studies aim to provide reliable models at the atomistic level, which fulfill three main roles: first they can provide general insight and understanding of the systems simulated; secondly they can provide models, which can directly assist the interpretation of experimental data; and thirdly they can provide accurate numerical data on important parameters, which may be either difficult to measure or entirely inaccessible to experiment. As an example of the first role, we may cite the application of modeling techniques to the study of microporous materials[1] where they have given extensive insights into the structural and catalytic properties of these complex materials. The second role is illustrated by many applications in the science of defects and solids, where simulation tools have been used together with experiment to construct models of complex defect structures.[2] An excellent illustration of the third role is found in the field of high-pressure science, where computer modeling has enabled the accurate calculation of physical properties of materials under the enormous pressures present in the Earth's mantle and core.[3] The main characteristic of the present status of the field is its increasingly predictive nature and the growing complexity and realism of contemporary simulations, as will be illustrated in Section 3 of this chapter.

2 METHODOLOGIES

Two broad classes of technique are available for modeling matter at the atomic level. The first avoids the explicit solution of the Schrödinger equation by using *interatomic potentials* (*IP*), which express the energy of the system as a function of nuclear coordinates. Such methods are fast and effective within their domain of applicability and good interatomic potential functions are available for many materials. They are, however, limited as they cannot describe any properties and processes, which depend explicitly on the electronic structure of the material. In contrast, *electronic structure* calculations solve the Schrödinger equation at some level of approximation allowing direct simulation of, for example, spectroscopic properties and reaction mechanisms. We now present an introduction to interatomic potential-based methods (often referred to as atomistic simulations).

2.1 Atomistic Simulations

2.1.1 Potential Functions and Their Evaluation

The potential energy function $U(\mathbf{r}_1 \cdots \mathbf{r}_N)$ expresses the energy of an assembly of N atoms or ions as a function of the nuclear coordinates $\mathbf{r}_1 \cdots \mathbf{r}_N$. The Born-Oppenheimer approximation is, of course, implicit in the use of such functions but there is no explicit inclusion of the effects of the electronic structure of the system: such effects are subsumed into the potential function. The energy zero for such functions is normally taken to be that of the component atoms (or ions) at rest at infinity, that is, the self energies (electron-nuclear) of the atoms (or ions) are not included in U.

The potential function is commonly expanded as follows:

$$U = \frac{1}{2}\sum_i^N \sum_j^N{}' \varphi_{ij}(\mathbf{r}_i, \mathbf{r}_j) + \frac{1}{3}\sum_i^N \sum_j^\infty \sum_k^\infty{}' \varphi_{ijk}(\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k) + \cdots \tag{1}$$

and the prime indicates that we only include terms $i \neq j$; where the φ_{ij} are 'two-body' functions that depend only on the positions of pairs of atoms i and j; φ_{ijk} are the 'three-body' terms depending explicitly on the positions of atoms i, j, and k and where the prime symbol again indicates that we only include terms $i \neq j \neq k$. The expansion extends to four-body terms φ_{ijkl} and higher order terms, which are, however, rarely included. Indeed it has been common to approximate U by including only the two-body component φ_{ij}, which may be usefully decomposed into Coulombic and non-Coulombic terms:

$$\varphi_{ij}(\mathbf{r}_i, \mathbf{r}_j) = \frac{q_i q_j}{\mathbf{r}_{ij}} + V_{ij}(\mathbf{r}_{ij}) \tag{2}$$

where r_{ij} is the distance between i and j and q_i is the charge on the atom or ion (and is normally treated as a point entity). The Coulombic term, which is purely two-body in nature, is handled by the procedures discussed after. The non-Coulombic, V_{ij}, is then usually approximated by analytical functions that generally include both attractive and repulsive components; the latter describes the Pauli repulsion arising from overlap of closed shell electron configurations, and the former attractive terms from dispersion (i.e. induced dipole-induced dipole) and covalence effects. Several such functions are available, notably the Lennard-Jones potential:

$$V(\mathbf{r}) = \mathrm{A}r^{-12} - \mathrm{B}\mathbf{r}^{-6}, \tag{3}$$

the Morse potential:

$$V(\mathbf{r}) = D\{1 - \exp[-\beta(\mathbf{r} - \mathbf{r}_\mathrm{e})]\}^2 \tag{4}$$

and the Buckingham potential:

$$V(\mathbf{r}) = \mathrm{A}\exp\left(\frac{-\mathbf{r}}{\rho}\right) - C\mathbf{r}^{-6}. \tag{5}$$

Lennard-Jones potentials have been used widely in modeling rare gas and molecular crystals. Morse potentials become more appropriate when covalent systems are being studied; D may then be interpreted as the covalent bond-dissociation energy and $\mathbf{r}_\mathrm{e}$ the equilibrium bond length. Buckingham potentials have been very widely used in the study of ionic and semi-ionic solids.[4]

Inclusion of many-body effects may be achieved by the use of angle dependent forces. For example, Sanders *et al.*[5] employed simple 'bond-bending' terms of the type,

$$E(\theta) = \tfrac{1}{2}k_\mathrm{B}(\theta - \theta_0)^2 \tag{6}$$

where θ is the angle subtended by three atoms and θ_0 is an equilibrium value; k_B is the appropriate force constant. The use of such terms is most appropriate in systems with directional covalent bonding, for example, silicates, where θ_0 will correspond to the tetrahedral angle subtended by O–Si–O bonds in the tetrahedral SiO_4 groups.

Alternative, three-body functions are provided by the 'triple-dipole' formalism of Axilrod and Teller,[6] which takes the form:

$$V_{ijk} = \frac{k_\mathrm{T}(1 + 3\cos\theta_1\cos\theta_2\cos\theta_3)}{\mathbf{r}_{ij}^3\mathbf{r}_{jk}^3\mathbf{r}_{ik}^3} \tag{7}$$

where the angles and distances relate to the triangle defined by the three atoms i, j, and k. Such functions describe the three-body contributions to the induced dipole attractive forces, and have been shown by Meath and coworkers[7] to make important contributions to the cohesive energies of rare gas crystals. Work of Baetzold *et al.*[8] has shown that such terms may be of value in constructing potential models for the silver halide crystals.

Finally, we note that atomic and ionic polarization in solids is essentially a many-body effect. Moreover, in ionic materials polarization energies may be large, especially in the vicinity of charged defects and surfaces. Omission of polarization, while obviously leading to the failure to describe high frequency dielectric properties, also results in marked inadequacies in calculated phonon dispersion curves. The simplest way of modeling polarizability is to use the point polarizable ion (PPI) model, which assigns a linear constant of proportionality, that is, the polarizability, α, between the dipole moment μ and the field E acting on the atoms, that is:

$$\mu = \alpha E. \tag{8}$$

However, as the dipole is a point entity, it cannot describe the physical basis of polarizability, which is the displacement of the valence shell electron density in response to the applied field. Consequently, important physical effects, in particular, the coupling of polarizability and short-range repulsion, are omitted by these models, which fail badly in describing both dielectric and lattice dynamical properties of crystals, as discussed in greater detail in Reference 9. These deficiencies are largely overcome by the shell model originally proposed by Dick and Overhauser,[10] which describes the development of a dipole moment in terms of the displacement of a massless shell of charge Y (representing the valence shell electrons) from a core (representing the nucleus and core electrons). The core and the shell are connected by an harmonic restoring force for which the spring constant is k. The free atom polarizability, α, is then given by $\alpha = \mathrm{Y}^2/k$. Shell model potentials have been very widely used in studies of lattice dynamical and defect properties of ionic solids. Further discussion is given in Reference 9.

Having established the framework of the potential model to be used, it is next necessary to fix the variable parameters, that is, those used in the description of the short-range potential, $V(r)$, the shell model constants Y and k and the effective atomic charges q (although we note that in many modeling

studies of ionic oxides, halides, and even silicates, these have been fixed at integral fully ionic values).

2.1.2 Parameterization

This is undertaken by two procedures: first, *empirical methods*, in which variable parameters are adjusted, generally *via* a least squares fitting procedure to observed crystal properties. The latter must include the crystal structure (and the procedure of 'fitting' to the structure has normally been achieved by minimizing the calculated forces acting on the atoms at their observed positions in the unit cell). Elastic constants should, where available, be included; and dielectric properties are required to parameterize the shell model constants. Phonon dispersion curves provide valuable information on interatomic forces; and *force constant* models (in which the variable parameters are first and second derivatives of the potential) are commonly fitted to lattice dynamical data. This has been less common in the fitting of parameters in *potential models*, which are our present concern as they are required for subsequent use in simulations. However, empirically derived potential models should always be tested against phonon dispersion curves when the latter are available.

An important aspect of empirical potential parameterization is the question of transferability. Are, for example, models derived in the study of binary oxides, transferable to ternary oxides? Considerable attention has been paid to this problem by Cormack *et al*.,[11] who have examined the use of potentials in spinel oxides, for example, $MgAl_2O_4$, $NiCr_2O_4$, and so on; in addition Parker and Price[12,13] have made a very careful study of silicates especially Mg_2SiO_4. These studies conclude that transferability works well in many cases. However, systematic modifications are needed when potentials are transferred to compounds with different coordination numbers. For example, the correct modeling of $MgAl_2O_4$ requires that the potential developed for MgO, in which the magnesium has octahedral coordination, be modified in view of the tetrahedral coordination of Mg in the ternary oxide. The correction factor is based on the difference $\Delta\mathbf{r}^{c}$ between the effective ionic radii for the different coordination numbers. If an exponential, Born-Mayer, repulsive term is used, the preexponential factor is modified as follows:

$$A' = A \exp\left(\frac{\Delta\mathbf{r}^{C}}{\rho}\right) \tag{9}$$

where the unprimed and primed preexponential factors refer to original and modified coordination numbers. Cormack *et al.*[11] have shown that such procedures yield potentials that are successful in modeling spinels.

There are now several sets of empirical potential parameters for a range of solids. Parameter sets are available for organic, molecular solids (see, for example, the work of Williams[14] and of Kiselev[15]). Ionic solids have been widely studied in the last twenty years, and parameters are available for ionic halides,[16] oxides,[17,18] and silicates.[12,13]

Empirical procedures are still extensively used in developing potential parameters. They do, however, have obvious inadequacies: firstly, it is necessary to have a good range of accurate empirical data, which may not be possible when new systems are being studied; secondly, there is no guarantee of the validity of the potential function when used outside the range of interatomic spacings employed in the parameterization. For this reason there has been considerable incentive in recent years for the development of reliable theoretical procedures for calculating parameters. To date, such efforts have been directed largely towards parameterization of effective charges and of the short-range potential, V, and in a restricted number of cases, the three-body components of the potential. However it is still very difficult to calculate shell model parameters. Calculations of interatomic potentials have been of two types.

2.1.3 Electron Gas Methods

These methods are based on the electron gas description of the atom, which is used to calculate the interaction energies of pairs or in principle larger numbers of atoms (or ions) as a function of their nuclear coordinates. The method was established by Wedepohl[19] and by Gordon and Kim[20] and wide ranging and successful studies of ionic halides and oxides are reported by Mackrodt and coworkers (see, for example, References 21 and 22) (note also the compilation of parameters given in Reference 23). More recently, modified electron gas procedures developed by Cohen and coworkers[24] have enjoyed considerable success when applied to oxides and silicates.

As the electron gas method is now very standard and has been reviewed by the present author and others (References 9, 19, and 20), a more detailed discussion is not presented here; a summary of the essential features of the methodology is described in Reference 25.

2.1.4 Explicit Quantum Mechanical Methods

These are methods in which the Schrödinger equation is solved approximately for a cluster or periodic array of atoms in a variety of internuclear geometries; the resulting variation in the total energy is then fitted to an interatomic potential function. Ab initio Hartree-Fock (HF) methods are being increasingly used in such studies; examples are the early work of Mackrodt and coworkers,[26] and the more recent studies of Gale *et al.*[27] and Harrison *et al.*[28] The study of silicate systems has been particularly active, with calculation on clusters ranging from $Si(OH)_4$ to $Si_{15}O_{16}H_{12}$.[29–31]

In using such methods, care must be taken in the choice of basis sets (i.e. the atomic centred functions from which the LCAO-MOs are constructed). Unless good sets are used, then the resulting interatomic potential function will be

inadequate owing to basis-set superposition errors. This subtle effect arises from the use by each atom in the many-atom calculation of basis functions on *other* atoms to reduce its own energy – an effect that invariably arises when incomplete sets are used. Correction procedures are available;[32] but, in general, high quality potentials need high quality basis sets. Secondly, it is important to note that wave functions in crystals differ from those of free ions. It is necessary therefore to include in such calculations a representation of the effects of the surrounding ions on the interacting atoms. A simple procedure commonly used in ionic solids is to employ point charges to reproduce the Madelung potential of the surrounding lattice. Thirdly, it should be recalled that the HF method does not include effects arising from electron correlation. More sophisticated and computationally expensive configurational interaction or perturbation methods are needed to describe correlation effects. Since, however, correlation is responsible for dispersive interactions, other methods are needed to calculate these terms. Alternative ab initio methods based on Density Functional Theory (DFT) discussed in Section 2.2 include directly certain of the effects of electron correlation, although they are still unable to model dispersive effects accurately. Perturbation theories following the original work of Mayer[33] may be used; but empirical methods may be needed for some time to come.

Ab initio techniques are generally far more expensive computationally than the electron gas techniques, and the cpu and disk requirements increase rapidly with the total number of electrons in the calculation. The former methods are, however, preferable, if high quality basis sets may be used, as they allow a more accurate description of atomic interactions, in particular the redistribution of electron densities consequent upon interaction. Electron gas methods clearly, however, provide a cheap, useful, and generally applicable technique for deriving short- range potential parameters, and as such they will have a continuing role in this field.

Finally we should note a valuable approach developed by Pyper and coworkers[34] for ionic solids in which HF methods are used first to obtain a set of crystal orbitals, the interactions between which are calculated as a function of distance including a full explicit evaluation of the exchange term (unlike the local density approximation used in the electron gas method). Estimates of the dispersive energy are then added to the resulting interaction energy. This approach is particularly successful for strongly ionic halides and oxides.

Having developed and parameterized potential models, the final stage before their use in a simulation study should be their *evaluation.* Nonempirically derived potentials should be evaluated by reference to their ability to predict empirical crystal properties. For empirical potentials, it is clearly necessary to use data outside the range employed in the parameterization. We have already referred to the use of lattice dynamical data. Comparison with the results of high-pressure studies, in particular the variation of structural and elastic properties with pressure, is also of great value; and in this context we should note the work of Harding and Stoneham,[35] who examined several potentials for simple ionic materials by comparison with 'Hugoniots', that is, pressure-volume trajectories obtained from shock wave studies. A further useful and demanding test is provided by the ability of potential models to predict crystal structures of polymorphs of a compound other than that used in the potential parameterization.

The development of improved potential models will continue to be a central feature of simulation studies. Progress will require the increased availability of accurate crystal data and refinements in theoretical procedures for calculating potentials.

2.1.5 Simulation Methodologies: Static Lattice Techniques

The characteristic features of these methods is that they do not include any explicit representation of thermal motions. Energies and entropies are calculated for the static lattice; the entropy calculations normally assume the harmonic approximation. High temperature properties can be calculated using the quasi-harmonic approximation, which simply evaluates energies and force constants for the high temperature lattice parameters. Within this framework, it is possible to predict lattice expansivity by calculating the free energy minimum as a function of lattice parameter for a series of temperatures. Calculations may be performed on both perfect and defective lattice configurations; both will now be reviewed.

2.1.6 Perfect Lattice Calculations

The most basic quantity open to calculation is the lattice energy. If we omit the zero-point vibrational energy (and four-body) and higher order terms, this may be written as:

$$E = U_{\mathrm{C}} + \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{\infty}{}' V_{ij}\mathbf{r}_{ij} + \frac{1}{3}\sum_{i=1}^{N}\sum_{j=1}^{\infty}\sum_{k=1}^{\infty}{}' \varphi_{ijk}(\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k) \quad (10)$$

where U_{c} is the electrostatic energy which is obtained by summation of the coulomb term (see equation 2); this summation must not be truncated, and is usually handled by the Ewald procedure which involves a partial transformation into reciprocal space, as discussed, for example, in Reference 25. The summation conventions are as in equations (1) and the terms V_{ij} and φ_{ijk} are as defined in equations (1) and (2). We note that the great majority of lattice energy calculations only include the two-body contribution to the short-range energy. One important matter of definition is that the lattice energy gives the *energy of the crystal with respect to component ions at infinity.* If it is desired to express the energy with respect to atoms at infinity (for which the more appropriate term is then the *cohesive* energy), then the appropriate ionization energies and electron affinities will be added.

Lattice energy calculations are now routine, and may be carried out for very large unit cells containing several hundred atoms. The codes METAPOCS,[36] THBREL[37] and GULP[38] undertake lattice energy calculations including both two- and three-body terms, using both bond-bending and triple–dipole formalisms.

Lattice energy calculations provide valuable insight into the structure and stabilities of ionic and semi-ionic solids. The technique is most powerful when combined with energy minimization procedures, which generate the structure of minimum energy. These are discussed below after the calculation of entropies have been described. Good illustrations of the value of lattice energy studies are given in studies of the studies of the stabilities of microporous materials, discussed later in this chapter and in References 39 and 40.

In addition to calculating energies, it is also possible to calculate routinely a range of crystal properties, including the lattice stability, the elastic and dielectric and piezoelectric constants, and the phonon dispersion curves. The techniques used, which are quite standard, require knowledge of both first and second derivatives of the energy with respect to the atomic coordinates. Indeed it is useful to describe two quantities: first the vector, **g**, whose components $\mathbf{g}_i^{\alpha}$ are defined as:

$$\mathbf{g}_i^{\alpha} = \left[\frac{\partial E}{\partial x_i^{\alpha}}\right], \tag{11}$$

that is, the first derivative of the lattice energy with respect to a given Cartesian coordinate (α) of the ith atom. The second derivative matrix **W** has components $\mathbf{W}_{ij}^{\alpha\beta}$; defined by:

$$\mathbf{W}_{ij}^{\alpha\beta} = \left[\frac{\partial^2 E}{\partial x_i^{\alpha}\partial x_j^{\beta}}\right]. \tag{12}$$

The expressions used in calculating the properties referred to above from these derivatives are discussed in greater detail in Reference 9. For more detailed discussions of the calculation of phonon dispersion curves from the second derivative or 'dynamical' matrix W, the reader should consult References 41 and 42. Finally, we note that by the term 'lattice stability' we refer to the equilibrium conditions both for the atoms within the unit cell, and for the unit cell as a whole. The former are available from the gradient vector g, while the latter are described in terms of the six components $\varepsilon_1 \cdots \varepsilon_6$, which define the strain matrix ε, where

$$\varepsilon = \begin{bmatrix} \varepsilon_1 & \frac{1}{2}\varepsilon_4 & \frac{1}{2}\varepsilon_5 \\ \frac{1}{2}\varepsilon_4 & \varepsilon_2 & \frac{1}{2}\varepsilon_6 \\ \frac{1}{2}\varepsilon_5 & \frac{1}{2}\varepsilon_6 & \varepsilon_3 \end{bmatrix} \tag{13}$$

So when the unit cell as a whole is strained, we describe the modification of an arbitrary vector $\underline{\mathbf{r}}$ in the unstrained matrix to a vector $\underline{\mathbf{r}}'$ in the strained matrix, using the equation:

$$\mathbf{r}' = (1 + \varepsilon)\mathbf{r} \tag{14}$$

where 1 is the unit matrix. The six derivatives of energy with respect to strain, $[\partial E/\partial \varepsilon_i]$, therefore measure the forces acting on the unit cell. The equilibrium condition for the crystal therefore requires that $\mathbf{g} = 0$ and $[\partial E/\partial \varepsilon_i] = 0$ for all i.

2.1.7 *Entropy Calculations*

The entropy in a solid arises first from configurational terms that for a perfect solid are zero. However, for a solid showing orientational or translational disorder, configurational expressions based on the Boltzmann expression $S = k\ln(W)$ may be used. In this section, we shall pay more attention to the second term, which is arises from the population of the vibrational degrees of freedom of the solid. Thus the entropy of a solid may be written as:

$$S_{\text{vib}} = k\int_0^Q \mathrm{d}Q \sum_i \left\{\frac{h\nu_i}{kT}\left[\exp\left[\frac{h\nu_i}{kT}\right] - 1\right]^{-1} - \ln\left[1 - \exp\left[\frac{-h\nu_i}{kT}\right]\right]\right\} \tag{15}$$

where the sum is overall phonon frequencies and the integral is over the Brillouin zone. In practice, the integral is normally evaluated by sampling over the zone for which a variety of techniques are available.[43] Vibrational terms also give a contribution to the lattice energy of the crystal:

$$E_{\text{vib}} = kT\int_0^Q \mathrm{d}Q \sum_i \left\{\frac{h\nu_i}{2kT} + \frac{h\nu_i}{kT}\left[\exp\left[\frac{h\nu_i}{kT}\right] - 1\right]^{-1}\right\} \tag{16}$$

which results in the following expression for the crystal free energy with respect to ions at rest of infinity:

$$F = E + kT\int_0^Q \mathrm{d}Q \sum_i \left\{\frac{h\nu_i}{2kT} + \ln\left[1 - \exp\left[\frac{h\nu_i}{kT}\right]\right]\right\} \tag{17}$$

where E is the lattice energy (omitting vibrational terms) given by equation (10).

2.1.8 *Energy Minimization*

Having evaluated energies and free energies of a crystal structure, it is desirable to be able to use these in an energy (or free energy) minimization procedure. Let us consider first the simple case of minimization to constant volume (i.e. within fixed cell dimensions). We write the energy of the crystal as a Taylor expansion in the displacements of the atoms, d, from that current configuration giving:

$$E(\delta) = E_0 + \mathbf{g}\delta + \tfrac{1}{2}\delta\mathbf{W}\delta + \cdots\cdots \tag{18}$$

If we terminate this function at the second order term and minimize E with respect to d, we obtain for the energy minimum:

$$0 = \mathbf{g} + \mathbf{W}\delta \qquad i.e. \quad \delta = -\mathbf{g}\mathbf{W}^{-1} \tag{19}$$

Displacement of the coordinates by δ as given in equation (18) will generate the energy minimum configuration. Of course, in practice, it will not be valid to truncate the summation at the quadratic term, except when very close to the minimum. However, equation (19) provides the basis of an effective iterative procedure for attaining the minimum. Indeed this 'Newton-Raphson' method is widely used in both perfect and defect lattice energy minimization, as it is generally rapidly convergent. Its main disadvantage is that it requires the calculation, inversion, and storage of the second derivative matrix, W. Recalculation and inversion each iteration may be avoided by use of updating procedures due to Fletcher and Powell, which are discussed elsewhere.[9,44–46] The storage problem may become serious with very large structures owing to the high cpu memory requirements. Recourse may be made to gradient methods, for example, the well known conjugate gradients technique, which make use only of first derivatives. Such methods are, however, more slowly converging. The increasing availability of very large cpu memories is, however, reducing the difficulties associated with the storage of the W matrix.

For evaluation of the energy minimum with respect to constant pressure (i.e. with variable cell dimensions), first we note that we can define the six components of the mechanical pressure acting on the solid, corresponding to the six strain components, defined in equation (13), that is,

$$P^{\varepsilon_i} = \frac{1}{V}\left[\frac{\mathrm{d}E}{\mathrm{d}\varepsilon_i}\right] \tag{20}$$

where V is the unit cell volume. The strains can then be evaluated, using Hooke's law,

$$\varepsilon = PC^{-1} \tag{21}$$

where C is the (6×6) elastic constant terms, which may be calculated from W. Substitution of these calculated strain components into equation (21) then yields the new cell dimensions and atomic coordinates. Again, the procedure is iterative, as it is only strictly valid in the region of applicability of the harmonic approximation. With a sensible starting point, however, only a small number of iterations (typically 2–5) is required.

The treatment above assumes that the pressure and corresponding strains are entirely mechanical in origin. However, at finite temperatures there will be a 'kinetic pressure' arising from the changes in the vibrational free energy with volume. These may be written as:

$$P^{\varepsilon_i}_{\mathrm{vib}} = \frac{1}{V}\left[\frac{\mathrm{d}F_{\mathrm{vib}}}{\mathrm{d}\varepsilon_i}\right] \tag{22}$$

where F_{vib} is the vibrational free energy. These kinetic pressures are most simply evaluated by applying small arbitrary strains to the structure and calculating the corresponding changes in F_{vib}. If P_{vib} is added to the mechanical pressure P in equation (20), it enables us to carry out free energy minimization. Parker and coworkers have written a general computer code, PAPAPOCS, for such calculations. Further discussion is given in Reference 42, which also describes how the techniques may be used to calculate lattice expansivity, either directly or by calculating the cell dimension as a function of temperature or by calculation of the thermal Gruneisen parameter.

2.1.9 Defect Simulations

Two techniques are available for calculating the properties of defects: first we may set up a periodic array of defects; second, we may embed the defect in an infinite representation of the surrounding crystal.

2.1.10 Supercell Methods

The simplest procedure for calculating the formation energies, entropies, and hence free energies of defects is to set up a defect supercell, that is, a large periodically repeating structure with the defect being at the centre of each unit cell. The techniques described in the previous section may then be employed. Thus, to evaluate the defect energy we perform a calculation on the perfect lattice, which may be equilibrated either to constant volume or pressure. The lattice energy E_{PERF} is then compared with the value E_{DEF} obtained under the same conditions for the defective lattice. Thus the defect formation energy E_{D} is simply written as:

$$E_{\mathrm{D}} = E_{\mathrm{DEF}} - E_{\mathrm{PERF}}. \tag{23}$$

A similar procedure is, of course, applicable for the entropies and hence free energies. The method is attractively simple, but has a number of drawbacks the principal one being the need for large supercells, especially if large complex defects are being considered. However, we note that supercells containing several hundred atoms are accessible to modern computers. A second drawback is that even with large supercells, the calculated defect energy will inevitably include a term arising from defect interaction as well as formation terms. In certain contexts, however, this may be an advantage, and indeed by calculating the defect energy for different sizes of the supercell, defect interactions may be calculated as a function of defect spacing. Such a study was performed by Cormack *et al.*[47] who investigated the interaction of the two-dimensional shear planes that form in nonstoichiometric oxides. Thirdly, there are problems in including charged defects. Either the defects must be neutralized by including a defect of opposite charge in the unit cell, in which case

the isolated defect formation energy cannot be studied, or electroneutrality is achieved by adding a background neutralizing charge or by making small adjustments to the charges of the other atoms in the unit cell.

Despite these difficulties, supercell methods have found considerable application in defect studies,[47–49] and indeed the results compare well with those obtained using the alternative techniques described below.

2.1.11 Mott–Littleton Methods

In these calculations, the isolated defect or defect cluster is embedded in the crystal, which extends to infinity, and the contrast between this approach and that used in the supercell methods is illustrated diagrammatically in Figure 1. The normal procedure in a Mott–Littleton calculation is to relax all the atoms in a region of crystal surrounding the defect, containing typically 100–300 atoms, until all are at zero force. Newton–Raphson minimization methods are generally used. The relaxation of the remainder of the crystal is then described by more approximate methods in which the polarization, **P** at a point **r**, is calculated for crystals that have dielectric isotropy, from the expression:

$$\mathbf{P} = \frac{1}{4\pi}\frac{q\mathbf{r}}{r^3}(1 - \varepsilon_0^{-1}) \tag{24}$$

where q is the charge on the defect, and ε_0 is the static constant. More complex expressions are used for dielectrically anisotropic crystals. In practice, an interface region is normally used between the two regions described above; in the interface, displacements are calculated using formulae of the type given above, but are evaluated as the sum of the response to individual defects in the inner region, rather than as a response to the net charge of the defect configuration, which is used for the remainder of the outer region. Short-range interactions between ions in the inner region and those in the interface are also calculated explicitly.

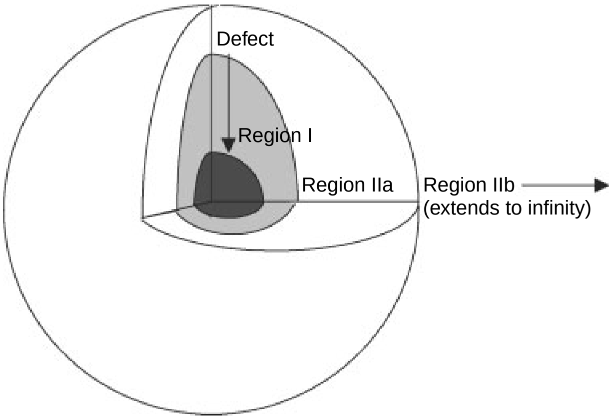

Figure 1 Schematic representation of the Mott–Littleton technique for treating relaxations around defects. (An interface region IIa is included between the inner and outer regions)

The methods have been widely discussed and reviewed in the literature.[9,46,50] Several good automated computer codes are available: the original HADES2 programme written by Norgett[51] was confined to crystals of cubic symmetry; the HADES3 code[52] extended the methodology to include crystals of any symmetry. Leslie[53] developed a program CASCADE, optimized for use on the CRAY vector processing supercomputers. The latest versions of this program permit the inclusion of many-body terms using bond-bending or triple-dipole formalisms. The GULP code written by Gale[38] also includes a Mott–Littleton module. A large number of applications of these techniques are now reported and reviewed in the references given above. Indeed, work using these techniques has helped to establish the quantitative reliability of simulation techniques in solid-state studies.

In addition to energies, defect entropies may also be calculated by related, although distinct, techniques. As with the case of the perfect lattice, defect entropies have two terms – configurational and vibrational – and the former can be calculated using simple combinatorial expressions. The latter arises from the perturbation of the vibrational frequency of the surrounding lattice atoms by the defect. The vibrational defect entropy S_{vib} is a function of the ratio of the perturbed to the unperturbed frequencies, that is,

$$S_{\mathrm{vib}} = -k\ln\frac{\prod_{i=1}^{2N'}\omega_i'}{\prod_{i=1}^{3N}\omega_i} + 3k(N'-N)\left[1 - \ln\left(\frac{\hbar}{kT}\right)\right] \tag{25}$$

To evaluate the perturbed frequencies, Greens function techniques may be used. However, Gillan and Jacobs[54] and Harding[55] have shown that embedded crystallite methods are more effective. Here the initial relaxation of the lattice surrounding the defect is undertaken as in the defect energy calculations. The perturbed force constant matrix for the relaxed region is then obtained. There are problems with the ‘convergence’ of the calculated entropy as a function of the size of the perturbed region; these may, however, be treated by the techniques discussed by Gillan and Jacobs.[54]

Work of Harding and coworkers[50,55] has clearly established the value of defect entropy calculations using these methods. Moreover, we note that comparisons have been made[56] between entropies and energies calculated using supercell and embedded crystallite techniques. It is reassuring that the techniques yield the same defect parameters for large sizes of the supercell and of the crystallite.

Both energy and entropy calculations of the type described above are generally performed at constant volume, or more precisely constant lattice parameter. These may, however, be converted to constant pressure values using the following

expressions:

$$h_p = u_v - V\beta T\left[\frac{df_v}{dV}\right], \quad (26)$$

$$s_p = s_v - V\beta\left[\frac{df_v}{dV}\right], \quad (27)$$

where h_p and u_v are the constant pressure enthalpy and constant volume energy terms, s_p and s_v are the corresponding entropy terms, f_v is the constant volume free energy, the volume derivative of which may be calculated by studying the variation of u_v and s_v with lattice parameter; V is the unit cell volume and β is the expansivity of the solid. Discussion of these relationships is given in References 55 and 57. Work of Catlow *et al*.[58] on AgCl and Jackson *et al*.[59] on UO_2 has shown their value in studying high temperature, defect properties.

In concluding this section, we note that defect calculations may be used to study defect mobilities as well as defect formation and interaction processes. Assuming the validity of the hopping model of defect transport the frequency of defect jumps can then be written as:

$$\nu = \nu_0 \exp\left(\frac{-g_{ACT}}{kT}\right) \quad (28)$$

where g_{ACT} is the activation free energy for the defect migration, that is, the difference between the free energies of the saddle point for the defect jump and that of its ground state. Saddle points may be identified by examining the potential energy surface for the migrating defect (although this may be difficult for crystals of low symmetry); once identified, the techniques discussed above may be used to calculate u_{ACT} and s_{ACT}.

Good discussions of the calculations of activation energies are given by Harding.[55] The validity of the hopping model, discussed in detail in Reference 60, requires generally that $u_{ACT} \gg kT$ and that the 'jump time' for the migration process be far less than the 'residence time' of defects at individual sites. These conditions apply to the great majority of transport processes in solids. However, for materials with very high mobilities, the conditions may breakdown and it becomes necessary to use the dynamical simulation methods discussed in the next section.

2.1.12 Molecular Dynamics Techniques

In contrast to the static methods discussed in the previous section, molecular dynamics (MD) includes thermal energies explicitly. The method is conceptually simple: an ensemble of particles represents the system simulated and periodic boundary conditions (PBC) are normally applied to generate an infinite system. The particles are given positions and velocities, the latter being assigned in accordance with a target temperature. In simulations of crystalline solids, the simulation box will normally be a supercell of the basic unit cell. The system is then allowed to evolve in time by solving the classical equations of motion using a specified time step, t (which is typically 10^{-15}–10^{-14} s). A variety of updating algorithms are available, as discussed in detail by Allen and Tildesley.[61] In the limit of an infinitesimal time step, they all reduce to the simple classical equations of motion:

$$x(t+\tau) = x(t) + v(t)\tau, \quad (29)$$

$$v(t+\tau) = v(t) + \frac{f_i}{m_i}\tau, \quad (30)$$

where f_i is the force acting on the particle of mass m_i.

In the initial stages of the simulation, the ensemble equilibrates, that is, it achieves an equilibrium distribution of velocities and equipartition between potential and kinetic energy. After this period, which may take several thousand time steps, the simulation is run for as long a period as is computationally feasible, and the trajectories of all particles are, if possible, stored.

MD simulations yield rich and detailed information on the system simulated. Structural information is available from radial distribution functions (RDFs), and diffusion coefficients may be calculated from the mean square displacement $\langle \mathbf{r}_\alpha^2 \rangle$ of the particle as a function of time, using the relationship:

$$D_\alpha = \frac{\langle \mathbf{r}_\alpha^2 \rangle}{6t} \quad (31)$$

where D_α is the diffusion coefficient of the particle of type α. Typical results are shown in Figure 2 for water in the CaF_2 and $CaCO_3$ mineral systems.[62] The increase of $\langle \mathbf{r}_\alpha^2 \rangle$ with t clearly shows that diffusion is occurring in the CaF_2 system. Calculation of the velocity auto-correlation function (VAF) and van Hove self-correlation function yields more detailed dynamical information that may be compared with the results

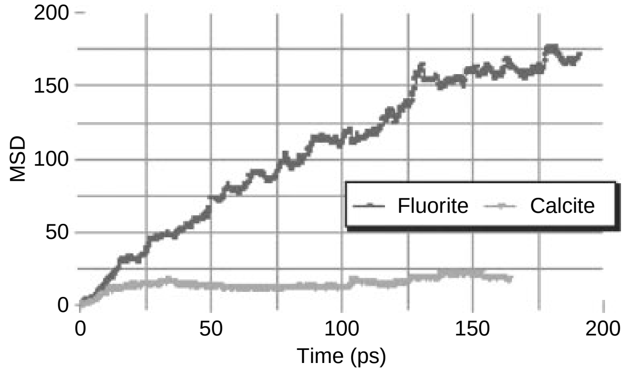

Figure 2 Mean square displacement versus time for H_2O at CaF_2 and $CaCO_3$ surfaces at 300 K

of inelastic neutron scattering studies. For further discussion, we refer to References 57, 61 and 63.

Despite its evident power, the technique has, however, serious limitations, the principal of which are as follows:

1. Even with modern supercomputers it is rarely possible to run simulations for longer than 10 ns. If the probabilities of the events of interest (e.g. a defect jump) are low in a period of this length, then the simulation may be of little value. Thus, in practice, with currently available computer power, diffusion can only be studied for values of the diffusion coefficient D $> 10^{-9}$ cm^2 s^{-1}.
2. Inclusion of polarizability in the potential greatly increases the computational requirements for the simulation. For this reason, most MD simulations performed do not include this term, which may be a serious omission for ionic solids.
3. The calculation of thermodynamic properties is difficult using MD techniques. The case of defects is especially problematic and both formation and migration energies are far more effectively calculated using static simulation techniques.
4. In conventional MD, employing PBC, there are no surface effects. Thus, any process involving the generation or removal of species from the surface cannot be simulated. An example is provided by the generation of Schotty disorder in crystals, which requires displacement of ions to the surface. This cannot be simulated by conventional MD studies.

Despite these limitations, the scope of MD techniques is expanding rapidly mainly owing to the rapid growth in computer power, especially the development of parallel architecture systems. It is now possible to carry out routinely, simulations on several thousand particles, for periods of $\sim$100 ps. Moreover, the scope of the method has been expanded by a number of more specialized developments. The two following examples are of particular importance in the study of inorganic materials.

Constant Pressure MD. The conventional MD technique uses a fixed size for the simulation box, that is, the calculation is performed under constant volume conditions. Using methods developed by Parrinello and Rahman[64] and by Berendsen and coworkers,[65] it is now possible to undertake constant pressure simulations by allowing cell dimensions to vary during the simulation. Detailed discussions are given in Reference 61. The most obvious field of application of this technique is to the study of phase transitions, and useful applications have been reported to the study of melting and glass formation as discussed below.

MD Simulations of Glasses. Increasing use is being made of MD techniques to generate structural models for amorphous solids. The procedure used is simple: a molten system is generated and the simulation is then rapidly cooled to below the glass transition temperature. RDFs and other properties of the resulting simulated glass may then be calculated.

2.1.13 Monte Carlo Techniques

Like MD, Monte Carlo (MC) methods involve the generation of successive configurations of an ensemble of particles representing the system studied. However, unlike MD, there is no temporal connection between the different configurations. The aim of the technique is to generate a sufficient and representative number of configurations from which ensemble averages may then be calculated with acceptable accuracy.

A central feature of the procedure is the choice of a weighting scheme whereby configurations are included according to their probability. In particular, it is desirable to weight the probability of including a configuration according to its Boltzmann factor:

$$\mathbf{W} = \exp\left(\frac{-\Delta E}{kT}\right), \tag{32}$$

where ΔE is the change in energy of the configuration. This may be achieved by an ingenious and simple procedure known as the Metropolis sampling method. Here the Boltzmann factor for a given configuration is calculated and compared with a random number P, which is generated in the range 0–1. If $\mathbf{W} < P$, then the configuration is rejected, but if $\mathbf{W} > P$ it is accepted. It will be seen that, over a large number of configurations, the procedure weights the probability of their inclusion according to their Boltzmann factor. It necessarily involves the generation of configurations that, after evaluation of their energy, are rejected. A number of procedures are available to increase the efficiency of the method by reducing the number of rejected configurations.[61]

The manner in which the sequence of configurations is generated depends on the system studied. For example, in a collection of atoms, a given particle may be selected at random and displaced by a small amount. For molecules, displacement and rotation may be involved. Indeed, care must be exercised in generating configurations in order to maximize the sampling efficiency. One special type of system concerns vacancy disordered compounds in which we are interested in diffusional properties. Here the vacancies are selected at random as is their direction. The Boltzmann factor for the jump is then calculated (or obtained from a 'look-up' table) and compared with the random number P following the normal Metropolis procedure. Such methods have been extensively used by Murch and coworkers to study diffusion in alloys.[66] An application to oxygen diffusion in the superionic oxygen conductor Y/CeO_2 was reported by Murray and coworkers.[67]

We note that a MC 'move' can consist of the insertion or deletion of a particle, to so-called Grand Canonical Monte Carlo technique, for detailed discussion of which and of other technical aspects of MC simulation we refer to Reference 61.

We also note an important class of applications that uses the MC method to explore complex energy surfaces and to find low energy regions, from which minima can subsequently be located by standard minimization procedures. *Simulated annealing* methods have been used with great effect in generating crystal structures from initial random configurations of atoms or ions. The 'energy term' in simulating annealing calculations may take a variety of forms. It is commonly a simple 'cost function' based on coordination numbers and connectivity. Lattice energies, calculated from Born model potentials, may of course be employed, but this procedure becomes computationally expensive. It should, however, be noted that simulated annealing procedures employing energies calculated by electronic structure techniques are becoming feasible. However, in practice it would seem to be more computationally efficient to use simpler procedures to calculate the energy (or cost function), and to refine the approximate configuration generated by simulated annealing by electronic structure methods when the use of such methods is needed.

The 'temperature' used in a simulated annealing study is normally a parameter with no real physical significance. Higher temperatures will result in the acceptance of an increasing number of high energy configurations, allowing the exploration of a wider range of the energy surface but, of course, at increased computational cost. In practice, the simulation usually starts with a high 'temperature', which is then reduced as the lower energy regions of the surface are identified. Simulated annealing like MC methods may also be adapted to the analysis of experimental data. In this case, the 'energy term' becomes the deviation between the calculated data (e.g. the calculated X-ray intensity versus scattering angle for a structural model) and experiment. Such techniques are described as 'Reverse Monte Carlo'.[68]

2.2 Electronic Structure Techniques

The last 15 years has seen an enormous expansion in the applicability of electronic structure methods to problems in solid-state chemistry, and the techniques are now applied in an increasingly routine manner to complex systems. This growth owes more to developments in hardware, algorithms, and detailed aspects of the methodology (such as the functionals used in DFT as discussed below) than to any fundamental developments in theory. As such, it is typical of the way in which much of contemporary computational science has developed.

As we have noted, electronic structure techniques attempt to solve the Schrödinger equation. The traditional approach in quantum chemistry has been to use the Hartree Fock (HF) approximation, in which a determinantal, antisymmetrized wave function is optimized in accordance with the variational principle. The wave function is normally written as an expansion of atomic orbitals (the LCAO approximation). A major weakness of the HF method is that in its single determinantal form it omits electron correlation effects, which can be recovered at considerable expense by perturbation or multiconfigurational methods. The approach does have the advantage of accurately estimating exchange effects (within the limitations of the basis set used to express the wave function). Moreover, the approximations in the method are well defined and the procedures needed to progress to improved accuracy are well defined.

The alternative approach, which is now widely applied, is based on density functional theory (DFT) pioneered by Kohn, Hohenberg and Sham.[69,70] In DFT, the electron density has prime of place. Hohenberg and Kohn showed that the ground state energy of a system is a unique functional of the electron density. The total energy (E_T) is written as:

$$E_T = E^{KE}(\rho) + E^{C}(\rho) + E^{EC}(\rho) + E_{nn} \quad (33)$$

Where the first term is the kinetic energy, the second term, the 'classical Coulomb repulsion' and the third, the 'exchange – correlation' energy; E_{nn} is the nuclear–nuclear repulsion energy. Evaluation of the first two terms is relatively straightforward. There is, however, no simple way of evaluating the exchange – correlation energy and in practice a range of approximate functionals are employed, as discussed below. Once this functional has been defined, the procedure is relatively straightforward. The variational principle is invoked and the energy minimized with respect to ρ. In practice, this is achieved using the Kohn Sham equations, which use a wave function to calculate ρ; the wavefunction is then optimized self – consistently in a manner akin to that used in HF theory.

Good recent accounts of both HF and DFT techniques are given by Abarenkov[71] and Harrison.[72] Here we confine our discussion to a number of general remarks, followed by some specific considerations for applications to solids.

General Considerations

1. *Electronic structure and interatomic potential methods*. There is no inherent superiority of electronic structure techniques. They do, of course, provide information that is inaccessible to interatomic potential methods, but they cannot explore systems of the size or timescales that are frequently needed. IP techniques provide accurate information on structure and transport properties and are often the appropriate technique, even when electronic structure methods are applicable. The simple and obvious guideline is that the appropriate technique is used for the particular problem at hand.
2. *HF and DFT methods.* DFT techniques have enjoyed considerable success in recent years and have been applied to a wide range of systems. However, in the present context, the following points should be made:
   (a) DFT is an approximate method, and although it is not semiempirical in the sense that it includes variable parameters that have been fitted to experimental data, the exchange correlation functionals have

commonly been evaluated by comparison with experimental data.

(b) DFT is a ground state theory. Although it may sometimes be used to make useful estimates of excited state properties (e.g. band gaps), such applications are necessarily limited and approximate.

(c) There is a continuing role for HF theory. The accurate calculation of exchange energies is a particular merit of the approach as is the ability, referred to above, to improve systematically the accuracy of the calculations.

Specific Issues for Solid-state Calculations

Again we refer to the articles of Harrison[72] and Abarenkov[71] for details; but here we note the following:

1. *Use of PBC techniques.* These are obviously the appropriate method for modeling crystalline solids. Moreover, there is an extensive range of high quality software for electronic structure studies based on PBC. The use of the approach becomes more problematic when investigating localized states (e.g. defects, impurities, and sorbed molecules.) In such calculations, the usual procedure is to place the localized state in the centre of a ‘supercell’ (which may comprise several basic unit cells) to which PBC are applied. The approach has the advantage of being straightforward; but, necessarily, interactions between defects and impurities in neighboring cells are included. This is often not a serious problem and indeed the magnitude of the interactions can be estimated. However if we are to apply the methods to studying, for example, problems in catalysis involving molecules adsorbed at active sites, then interactions between species in neighboring cells may become problematic, in which cases one of the alternative approaches outlined below should be used.
2. *Use of the molecular cluster approximation*. This is essentially the other extreme from the PBC approach – in which the region of interest is represented by a finite cluster, which, depending on the nature of the bonding, may be terminated with hydrogen atoms. The approach is clearly crude, as no long-range effects of the surrounding solid are included, but it is a useful method if the chemistry is predominantly local, and allows use of the wide range of software available for molecular quantum mechanical calculations.
3. *Use of embedding techniques.* With these, we attempt to remedy some of the deficiencies of the cluster method by including an approximate representation of the surrounding lattice using interatomic potential methods. There are several variants of the approach, but if implemented properly, such methods can overcome some of the difficulties of PBC methods, for example, catalytic reactions. A recent example of the use of this method is given in Section 3.3.

3 APPLICATIONS

In this section, we describe some topical recent examples of the applications of modeling techniques in solid-state chemistry. Our account cannot be detailed, but we aim to give an impression of the range of applicability of these techniques.

3.1 Prediction of the Structures of Microporous Materials

Microporous materials have been widely investigated over the last 50 years owing to their extensive range of applications in catalysis, gas separation, and ion exchange. Zeolites (originally observed as minerals, but now extensively available as synthetic materials) are all silica or silicate materials, based on fully corner shared networks of SiO_4 and AlO_4 tetrahedra, but with structures that contain channels pores and voids of molecular dimensions. Pore sizes are typically in the range 5–15 A. The aluminosilicate materials contain exchangeable cations, while the microporous structures give rise to the applications in molecular sieving and sorption. Exchange of protons into the materials creates acid sites that promote catalytic reactions including cracking, isomerization, and hydrocarbon synthesis; while metal ions in both framework and extra-framework locations can act as active sites for partial oxidation reactions.

Modeling techniques have been applied extensively and successfully to the study of microporous materials (see e.g. Reference 1). Furthermore, there have been a number of successful applications of minimization techniques to the accurate and indeed to the predictive modeling of microporous structures. Here we highlight a recent significant development, that is, the prediction of new hypothetical structures.

There have been many attempts to predict new microporous structures. Most of them have relied on the fact that the very definition of these materials is based on geometry, rather than on precise chemical composition, occurrence, or function. In order to be considered as a zeolite, or zeolite-type material (zeotype), a mineral or synthetic material must possess a three-dimensional four-connected inorganic framework, that is, a framework consisting of tetrahedra that are all corner-sharing. There is an additional criterion that the framework should enclose pores or cavities that are able to accommodate sorbed molecules or exchangeable cations, which leads to the exclusion of denser phases. Topologically, the zeolite frameworks may thus be considered as four-connected nets, in which each vertex is connected to its four closest neighbors. So far 139 zeolite framework types are known, either from the structures of natural minerals or from synthetically produced inorganic materials. In enumerating microporous structures, a number of fruitful approaches have been developed. Some have involved the decomposition of existing structures into their various structural subunits, and then recombining these in such ways as to generate novel frameworks. Methods that involve combinatorial, or systematic, searches of phase space have also been successfully deployed Recently, an approach based on mathematical tiling theory has also been reported.[73]

It was established that there are exactly 9, 117, and 926 topological types of four-connected uninodal (i.e. containing one topologically distinct type of vertex), binodal and trinodal networks, respectively, derived from simple tilings (tilings with vertex figures that are tetrahedra), and at least 145 additional uninodal networks derived from quasi-simple tilings (the vertex figures of which are derived from tetrahedra, but contain double edges). In principle, the tiling approach offers a complete solution to the problem of framework enumeration, although the number of possible nets is infinite.

Potentially therefore we may be able to generate an unlimited number of possible zeolitic frameworks. Of these, only a portion is likely to be of interest as having desirable properties, with an even smaller fraction being amenable to synthesis in any given composition. It is this last problem, the feasibility of hypothetical frameworks, which is the key question in any analysis of such structures. The answer is not a simple one, since the factors that govern the synthesis of such materials are not fully understood. Zeolites are metastable materials, as shown by the calculated lattice energies reported in Table 1. Aside from this thermodynamic constraint, the precise identity of the phase or phases formed during hydrothermal synthesis is said to be under 'kinetic control', although there is increasing sophistication in targeting certain types of framework using various templating methods, fluoride media, and other synthesis parameters. Additionally, certain structural motifs are more likely to formed within certain compositions, for example, double four rings in germanates, three rings in beryllium-containing compounds, and so on. A full characterization of any hypothetical zeolite must therefore include an analysis of framework topology and of the types of building unit present, as well as some estimate of the thermodynamic stability of the framework. Using an appropriate potential model, lattice energy minimization can, as shown above, provide a very good measure of this stability and well as optimizing structures to a high degree of accuracy.

Table 1 Relative energies (per mole) of microporous siliceous structures with respect to Quartz[39]

Structure	Energy (kJ mol^{-1})
Silicalite	11.2
Mordenite	20.52
Faujasite	21.4

In the method adopted by Foster *et al.*,[74] networks derived from tiling theory were first transformed into 'virtual zeolites' of composition SiO_2 by placing silicon atoms at the vertices of the nets, and bridging oxygens at the midpoints of connecting edges. The structures were then refined using the geometry-based distance least squares (DLS) procedure, before final optimization by lattice energy minimization. Among the 150 or so uninodal structures examined, all 18 known uninodal zeolite frameworks were found. Moreover, most of the unknown frameworks had been described by previous authors; in fact, there is a considerable degree of overlap between sets of uninodal structures generated by different methods. Most of the binodal and trinodal structures, however, are completely new. Using simulated lattice energy as an initial measure of feasibility, a number of the more interesting structures are illustrated in Figure 3. The challenge is now to synthesize these structures.

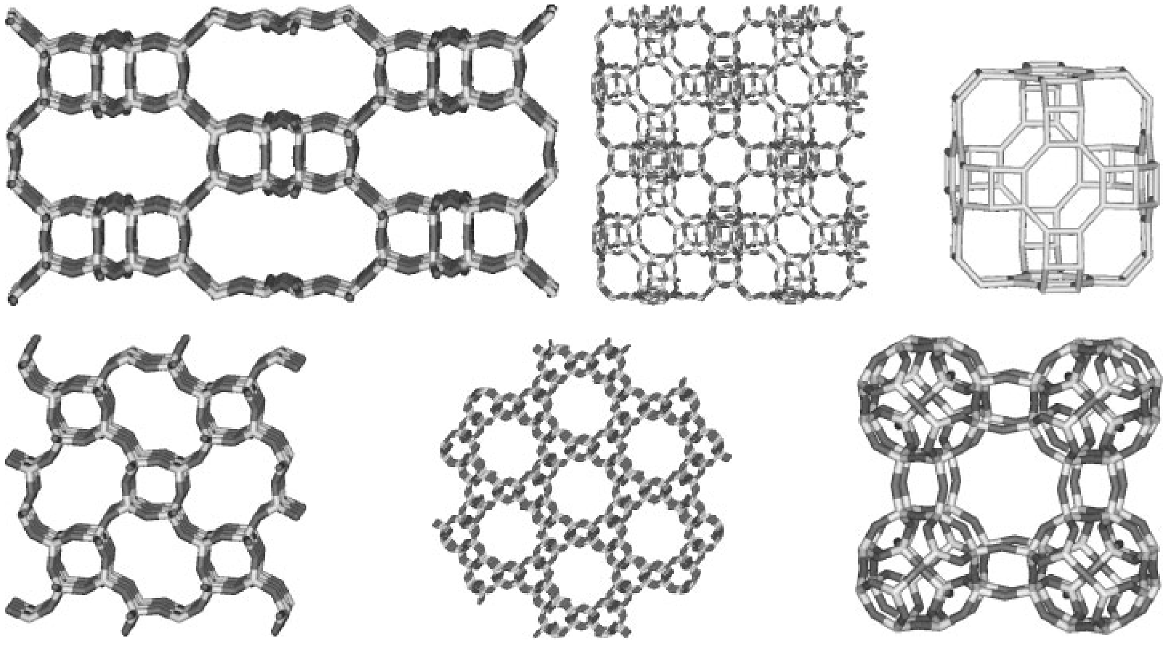

Figure 3 Illustrations of feasible uninodal zeolite structures generated by tiling theory and modelled using lattice energy minimization

3.2 Nanocluster Structures in ZnS

Our next example is an intriguing case study in cluster chemistry. As part of an extensive study aimed at identifying the structures of the critical growth nuclei in the growth of ZnS crystals Spano, Hamad, and Catlow[75,76] have identified a whole series of stable open cluster structures for $(ZnS)_n$ clusters with n ranging from 1 to 80. They have employed simulated annealing and minimization techniques using interatomic potentials but with critical structures also being modelled by DFT electronic structure methods (the results of which validate the interatomic potential-based simulations). The cluster structures have quite different topologies from bulk ZnS. A particularly interesting example is shown in Figure 4. It is an onion-like cluster with an inner core and outer shell. Work is in progress aimed at detecting these structures experimentally.

3.3 Reaction Mechanisms on the Surfaces of Zinc Oxide

A large quantity of methanol, in excess of 22 million tonnes worldwide, is produced annually using the multicomponent $Cu/ZnO/Al_2O_3$ catalyst and feed gas, $CO_2/CO/H_2$. Many experimental studies of this process have been performed but without any definite reaction mechanism for the production of methanol being established. However, it has long been acknowledged that the important rate-determining step is the hydrogenation of adsorbed intermediates, for example, the formate ion, at the active sites. Proposed mechanisms for methanol synthesis require the chemisorption of CO_2 before hydrogenation via formate to methanol. Theoretical studies of these systems have been hampered by the difficulty of modeling the catalytically active polar surfaces of ZnO, as well as the problems associated with the restrictions on the size of the system that can be modelled.

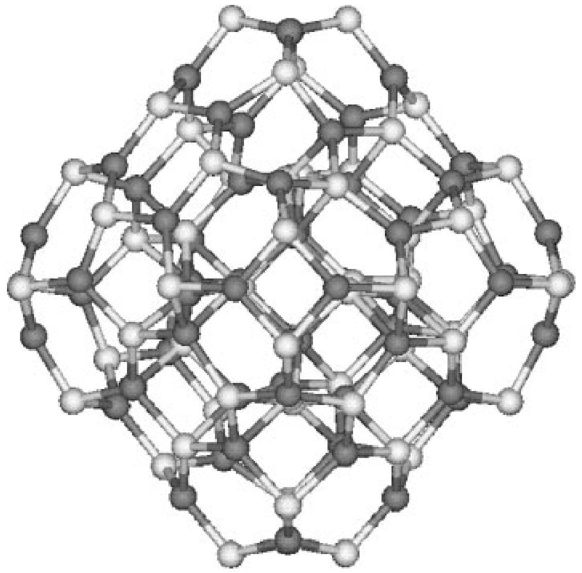

Figure 4 Predicted onion-like structure for $(ZnS)_{60}$

The nature of the active site for sorption/catalysis of CO_2 still remains unclear; as a test system or model catalyst, it has been proposed to use clean oxygen terminated surfaces of zincite. Temperature programmed desorption (TPD) studies have shown that the processes that occur at that particular surface are analogous to those on the industrial $Cu/ZnO/Al_2O_3$ catalyst.[77,78] In this study, we have therefore concentrated on the polar $(000\bar{1})$ oxygen terminated surface. In a given sample, the polar character of the surface necessitates a charge transfer between opposing polar surfaces, in order to quench surface induced polarization of the material, which may be achieved in zincite by abstracting ca. 25% of oxygen ions from the surface layer, thus creating *vacant oxygen interstitial surface sites*. The presence of such sites has been confirmed by optical and ESR spectroscopies;[79–81] they have, moreover, been suggested as the active catalytic sites for methanol synthesis and are therefore the focus of the investigation in the present article.

Recent work of French *et al.*[82] used novel solid-state embedding techniques in order to study important methanol precursors, including carbon dioxide, formate, and methoxy ions. Their study provides insight into the mechanism of methanol synthesis by calculating binding energies, bond lengths, and angles of these and related species. The hybrid approach implemented and applied in this work follows molecular embedded cluster methods developed to treat point defects and related localized states in ionic materials.[83–87]

At the heart of embedding approaches is a definition of a reference system and a single localized state, which causes only minor long-range perturbation of the reference system. In order to characterize the structural properties and interactions in the reference system, it is desirable to split it into structural elements. Zincite, as with many other important metal oxide catalysts, is a polar material; and many physical properties of these materials can be described using an ionic model. In this model, the strong long-range interactions are accounted for by Coulombic forces between nearly spherical ions. These ions, particularly negatively charged anions, are highly polarizable species. Upon perturbation of the reference system by a localized defect, two major effects are witnessed: (1) dramatic short-range effects (e.g. charge transfer and bond breaking) and (2) long-range polarization of electron groups owing to the field of the defect. Therefore, the model can be treated at two levels of approximation. In the present case, the short-range effects were dealt with fully ab initio, by DFT, while the long-range polarization effects were included through the use of the shell model of Dick and Overhauser.[10]

This methodology (details of which are given in Ref. 82) has been implemented within ChemShell, which is a computational chemistry environment, based on the Tcl programming language.[88] A DFT treatment, as implemented in the GAMESS-UK code,[89] was used. The study employed the B97-1[90] exchange correlation functional and TZV2P basis set on O and Zn, which has been reoptimized for the ionic

state of ZnO, along with the standard 6-311 + (2p2d) basis set on all atoms of the adsorbates and a medium quality integration mesh.[89] In this work, interactions in region 2 and interface were dealt with using our recently developed atomistic potentials[91] within the GULP code.[38]

Detailed models of the $(000\bar{1})$–O terminated polar surfaces were investigated using interatomic potentials within the two-dimensional periodic slab model realized within the MARVIN code.[92] Two typical local environments were identified as terrace termination and interstitial vacancy sites; the latter has been used as the active site for the majority of calculations, as illustrated in Figure 5. The atoms highlighted in the figure indicate the surface embedded quantum region. For the calculations reported, region 1 consists of 12 atoms, the interface has 13 Zn sites, while region 2 comprises approximately 3000 atoms and 250 terminating point charges.

A probable reaction sequence for the conversion of the feed gas to methanol has been summarized by Chinchen[93] (Figure 6), where the gas phase and adsorbate species are indicated by (g) and (a) respectively. Reaction 4 is a complex process that includes multiple hydrogenation steps, which we have considered separately. The resulting species, which were not considered by Chinchen and others, were found to be stable, although they may possibly be transient and short lived.

The main catalytically active site that can facilitate the formation of anionic adsorbates is the *oxygen interstitial* site, as described above and illustrated in Figure 5. This site is able to trap an electron and thus adsorption can occur in two different ways; (1) neutral adsorbates approach the active site at which an electron is trapped, to form a surface anionic species and (2) transfer of an electron to the neutral active site occurs simultaneously with the adsorption of neutral adsorbates.

The proposed catalytic cycle is summarized in Figure 7, starting with the adsorption of CO_2 and H_2, CO_2 upon

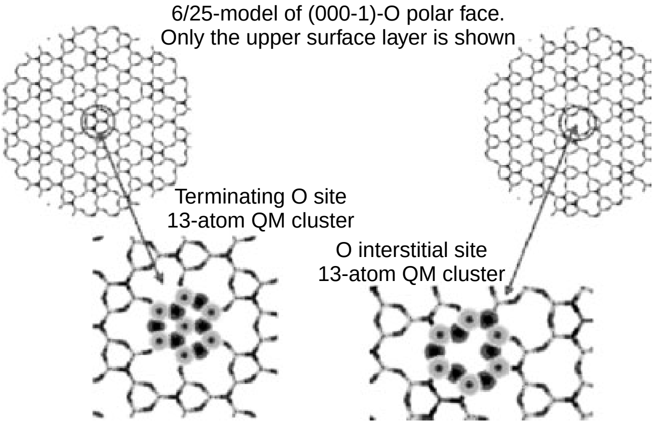

Figure 5 QM regions used for modeling of vacant oxygen interstitial surface sites. Only the upper surface layer is shown

$H_2(g) \rightarrow 2H(a)$
$CO_2(g) \rightarrow CO_2(a)$
$CO_2(a) + H(a) \rightarrow HCO_2(a)$
$HCO_2(a) + 2H(a) \rightarrow CH_3O(a) + O(a)$
$CH_3O(a) + H(a) \rightarrow CH_3OH(g)$
$CO(g) + O(a) \rightarrow CO_2(g)$
$H_2(g) + O(a) \rightarrow H_2O(g)$

Figure 6 Catalytic cycle; all reactants geometries are obtained by energy minimization of embedded clusters

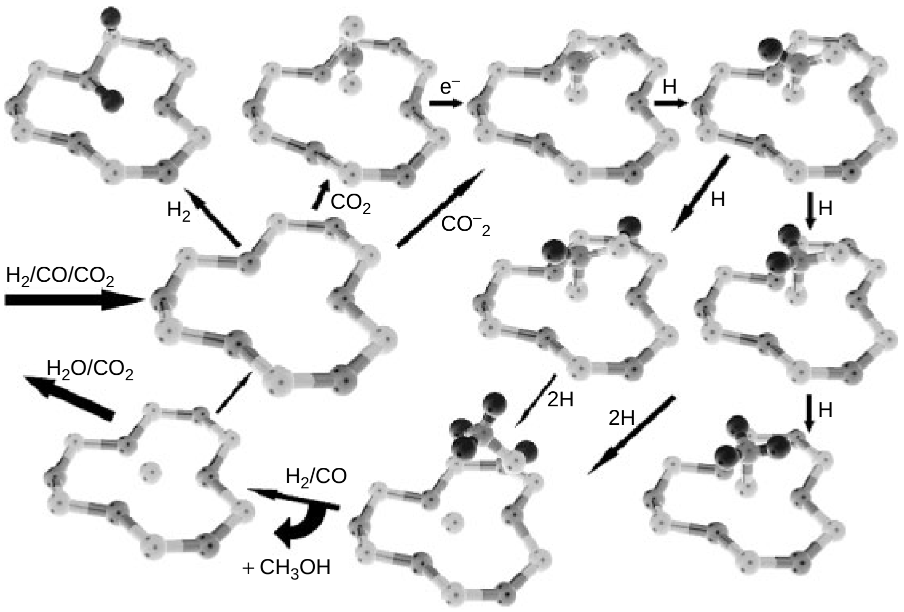

Figure 7 Calculated reaction energy profile for methanol synthesis over ZnO

adsorption in a neutral interstial site retains the linear structure exhibited in the gas phase. Upon adding an electron the neutral CO_2 molecule bends and the extraelectron populates an antibonding level, which leads to a rearrangement from an sp to an sp^2 hybridized configuration. The interaction with the surface stabilizes the radical CO_2^- species.

The reaction then proceeds via the hydrogenation of the adsorbed CO_2^-, by surface hydrogen to the formate ion. The geometry resulting from the calculations is shown in Figure 7. The adsorption of hydrogen leads to a closed shell species. Further hydrogenation can proceed either through the formation of $H_2CO_2^-$ or $HCOOH^-$ as shown in Figure 7. TPD data do not detect these species, which suggests a short lifetime and therefore high reactivity. Computational techniques allow us to differentiate and investigate these different scenarios. Further hydrogenation and interactions of the resulting species with the surface and possible surface defects lead to a large variety of possible intermediates. We show examples of a methoxy ion (CH_3O^-) chemisorbed to the surface and physisorbed methanol. To complete the catalytic cycle, methanol is removed from the surface and the active site is recycled by desorption of carbon dioxide and water.

4 SUMMARY

Computer modeling techniques are now having a substantial impact on a broad range of problems in solid-state chemistry. They provide insight into structures and mechanisms at the atomic level and have an increasingly predictive role. Advances in techniques, algorithms, and computer power offer an exciting future with a great expansion in the predictive and explanatory capabilities of the methods in the future.

1 INTRODUCTION

Stability constants, otherwise known as formation constants, constitute a particular type of equilibrium constant (*see Equilibrium Constant*), that is, for reactions in solution between metal ions or protons (*see Proton*) and ligands (*see Ligand*) or Lewis bases (*see Lewis Acids & Bases*) to form complexes. Following Rossotti and Rossotti,[1] we can define a complex as a species formed by the association of two or more simple species, each normally capable of independent existence. A broad definition of complex formation would not restrict this to a reaction between ions of opposite charge but would embrace association between any electron acceptor, such as the proton, H^+, a metal ion, M^{n+}, or other positively charged species, or even electron-deficient molecules (such as BF_3), and an electron donor such as water, ether, or thioether (*see* ***S-donor Ligands***); ammonia, pyridine, or other nitrogen base (*see* ***Ammonia & N-donor Ligands***); phosphine (*see* ***P-donor Ligands***) or arsine (*see* ***Arsenic: Organoarsenic Chemistry***); hydroxide (*see* ***Oxygen: Inorganic Chemistry***); cyanide (*see* ***Cyanide Complexes of the Transition Metals***); halide (*see* ***Chlorine, Bromine, Iodine, & Astatine: Inorganic Chemistry***); or pseudohalide (*see Pseudohalide*) ion. Since the emphasis in this article will be on the stability of metal complexes in aqueous solutions, important complexes such as $Ni(CO)_4$ or $Ni(PF_3)_4$, metal cyclopentadienyls (*see Cyclopentadienyl*), and many other organometallic compounds (*see Organometallic Complexes*) will not be considered.

Such reactions as $Ag^+ + NH_3 \rightleftharpoons Ag(NH_3)^+$, $Hg^{2+} + Cl^- \rightleftharpoons HgCl^+$, $H^+ + MeCO_2^- \rightleftharpoons MeCO_2H$, and $Cu^{2+} + NH_2CH_2CH_2NH_2 \rightleftharpoons Cu(NH_2CH_2CH_2NH_2)^{2+}$ are typical of 1:1 complex formation, while the reactions $Hg^{2+} + I^- \rightleftharpoons HgI^+$, $HgI^+ + I^- \rightleftharpoons HgI_2$, $HgI_2 + I^- \rightleftharpoons HgI_3^-$, and $HgI_3^- + I^- \rightleftharpoons HgI_4^{2-}$ show that complex formation between electron donors and electron acceptors can take place regardless of their formal charge. The successive coordination of three molecules of 1,10-phenanthroline (*see* ***Ammonia & N-donor Ligands***) with an iron(II) ion to give $Fe(phen)^{2+}$, $Fe(phen)_2^{2+}$, and $Fe(phen)_3^{2+}$ illustrates the buildup of a higher complex, ML_n, where the species M comprises the central atom to which the species L, usually referred to as the ligand (*see Ligand*), is bonded to form a coordination complex (*see Coordination Complexes*). We can generalize these reactions for simplicity as follows:

$$M + nL \rightleftharpoons ML_n \qquad (n = 1, 2, 3, \ldots) \qquad (1)$$

(a) by omitting any reference to specific charges, and (b) by omitting any reference to the number of molecules of solvent that may be closely associated with each of the participating molecules in solution. The relevance of this omission will be more obvious in any later discussion of the chelate effect (*see Chelate Effect*). Polynuclear complexes, M_qL_p (for which $q > 1$, $p \geq 0$), are frequently encountered in aqueous solution chemistry, particularly in hydrolysis reactions where $L = OH^-$.[1]

This article considers the definition of stability constant, distinguishing between thermodynamic and stoichiometric constants as well as between stepwise and overall constants. Attention is given to methods of calculating stability constants from experimental data. This is followed by brief descriptions of experimental methods. Next, perspectives are presented on the uses of stability constants with special reference to determining chemical species distributions in systems that contain huge numbers of metal ion species, ligand species, and species of complex formed between them. Examples of such systems are biological, geological, and industrial fluids. Finally, a view is given of how studies of metal–ligand equilibria have contributed to some of the basic ideas of chemistry.

2 DEFINITION OF STABILITY CONSTANT

The activity of the complex species, ML_n, found in solution at a specified temperature (T) is related to the activities of the component species M and L by the equation

$$\{ML_n\} \rightleftharpoons {}^T\beta_n\{M\}\{L\}^n \qquad (2)$$

where ${}^T\beta_n$ is the activity quotient or thermodynamic stability constant for the reaction

$$M + nL \rightleftharpoons ML_n \qquad (3)$$

and is generally termed the *overall* (or *gross*) *stability constant*. Here and elsewhere the symbols [X], {X}, and γ_X refer to the concentration, the activity, and the activity coefficient, respectively, of the species X.

When the reaction can be represented as a series of discrete stages forming a sequence of complex ions

$$ML_{n-1} + L \rightleftharpoons ML_n \quad (4)$$

the activity quotient at each stage is defined by a thermodynamic stepwise stability constant, ${}^TK_n$ such that ${}^T\beta_0 = {}^TK_0 = 1$, ${}^T\beta_1 = {}^TK_1$, ${}^T\beta_2 = {}^TK_1 \times {}^TK_2$, and in general

$${}^T\beta_n = {}^TK_1 \times {}^TK_2 \times {}^TK_3 \times \cdots \times {}^TK_n \quad (5)$$

Ideally one would wish to measure the activities of all the reacting species in equation (4) but it is not possible to determine activities of single ionic species (at best, mean ionic activities may be determined in some cases) and the determination of activities of uncharged species is fraught with difficulties. However, modern experimental methods (see Section 3) can readily be applied to the determination of concentrations of at least some of the species concerned, leading to stoichiometric stability constants defined by

$$K_n = \frac{[ML_n]}{[ML_{n-1}][L]} = {}^TK_n \times \left(\frac{\gamma_{ML_{n-1}}\gamma_L}{\gamma_{ML}}\right) \quad (6)$$

It must be emphasized that such stoichiometric stability constants are dependent, inter alia, upon the ionic strength of the solution, and, in reporting experimental results, the ionic strength of the experimental solutions should always be specified. Further, the numerical value of a stoichiometric constant will depend upon the units used, viz. mole fractions, molar, molal, millimole, and so on, and which is used should always be made clear.

If M_t and L_t are the total concentrations of metal and ligand in solution and [ML], [M], and [L] the concentrations of individual free species, then for the case where only one complex is present at equilibrium we can write:

$$M_t = [M] + [ML] = \frac{\{M\}}{\gamma_M} + \frac{\{ML\}}{\gamma_{ML}} \quad (7)$$

$$L_t = [L] + [ML] = \frac{\{L\}}{\gamma_L} + \frac{\{ML\}}{\gamma_{ML}} \quad (8)$$

Clearly, if M_t and L_t are known, it will only be necessary to obtain a value for one of the terms [M], [L], or [ML] to calculate the stoichiometric stability constant K_1.[2,3]

However, to calculate the thermodynamic stability constant, ${}^TK_1$, we would need reliable values for all the relevant activity coefficients. As indicated above, these are usually inaccessible directly from experimental measurements and, although some form of the Debye–Hückel equation has sometimes been used to calculate theoretical activity coefficients, certain difficulties often arise here, too. These difficulties and attempts to circumvent them are discussed by Linder, Torrington, and Williams.[4] Many workers have preferred to calculate thermodynamic stability constants by measuring K_n in solutions of different known ionic strengths and extrapolating to infinite dilution when all $\gamma \rightarrow 1$. The associated problems have been thoroughly discussed.[1,2,4,5]

A common procedure is to carry out all measurements in a medium of constant ionic strength, I, where, as Brønsted showed as early as 1927, 'small changes in the concentration of the solute have a negligible effect on its activity coefficients, provided that its concentration is never comparable to that of the 'background salt'.' Clearly the background salt must not form complexes with any of the ions involved in the complex formation being measured (*see Noncoordinating Anion or Cation*). 1 M Potassium nitrate, 1 M sodium chloride, 1 M and 2 M lithium perchlorate, and 3 M sodium perchlorate have been extensively used as inert background electrolytes, but the use of a perchlorate must be avoided with Hg^+, Fe^{2+}, and Ce^{3+} with which it forms complexes, and it gives insoluble complexes with ions such as $Ni(en)_3{}^{2+}$. Potassium ions in the presence of perchlorate ought to be avoided since $KClO_4$ has very low solubility and would potentially cause troublesome precipitation. Biochemists often prefer $I = 0.150$ M NaCl as being more comparable with conditions in the living cell.[6]

When several homonuclear complexes, ML_n ($n = 1, 2, 3, \ldots N$) are in equilibrium, equations (7) and (8) can be extended and generalized:

$$\begin{aligned} M_t &= [M] + [ML] + [ML_2] + \cdots + [ML_N] \\ &= [M]\{1 + \beta_1[L] + \beta_2[L]^2 + \cdots + \beta_N[L]^N\} \\ &= [M]\left\{\sum_0^N \beta_n[L]^n\right\} \qquad \text{with } \beta_0 = 1 \end{aligned} \quad (9)$$

$$\begin{aligned} L_t &= [L] + [ML] + 2[ML_2] + \cdots + N[ML_N] \\ &= [L] + \beta_1[M][L] + 2\beta_2[M][L]^2 + \cdots + N\beta_N[M][L]^N \\ &= [L] + [M]\left\{\sum_1^N n\beta_n[L]^n\right\} \end{aligned} \quad (10)$$

The average number of ligands bound to each central group is

$$\overline{n} = \frac{(L_t - [L])}{M_t} = \frac{\sum_1^N n\beta_n[L]^n}{\sum_0^N \beta_n[L]^n} \quad (11)$$

where $\overline{n}$ is generally termed the *degree of formation* and equation (11) can be written out as a polynomial in [L]:

$$\overline{n} + (\overline{n} - 1)\beta_1[L] + (\overline{n} - 2)\beta_2[L]^2 + \cdots + (\overline{n} - N)\beta_N[L]^N = 0 \quad (12)$$

It is important to note that, for a mononuclear complex, $\overline{n}$ is a function only of the free ligand concentration [L], and does not depend explicitly upon M_t, L_t, or [M].

A plot of $\overline{n}$ against pL (or $-\log$[L]) is called the *formation curve*.[3] If it approaches $\overline{n} = 1$ as pL $\to 0$, we can assume that only one complex, ML, is in equilibrium. If $\overline{n} \geq 1$ at the limiting value, we are assured of the presence of higher complexes. If $\overline{n}$ is found to be a function of [L] only and not dependent on M_t, then N sets of pairs of values ($\overline{n}$, [L]) are in principle sufficient for the computation of the N stability constants β_1, β_2, $\beta_3, \ldots$ and so on. However, experimental work generally gives rise to more than N data sets and, owing to experimental errors, the simultaneous equations formed from neighboring points are often ill-conditioned. In the early days, only graphical methods were available for evaluating experimental data;[1,2,5] but with the increasing availability of high-speed computers, the various curve-fitting methods of Sillén and Dyrssen[7,8] and Rossotti *et al.*,[9] the correction-term method of Irving and Rossotti[10] and the method of corresponding solutions[11,12] have become outmoded and values for stability constants and their statistical weight (standard deviations) can now be obtained by a wide variety of well-tried computer programs. Well-known examples of these computer programs are the early pit-mapping procedure of Sillén (LETAGROP),[13] the widely used MINIQUAD of Sabatini *et al.*,[14] the improved version, SUPERQUAD,[15] and its more recent development, HYPERQUAD,[16] both of Gans *et al.*, the ESTA suite of software developed by May and Murray[17–19] and BEST, a program advanced by Martell and Motekaitis.[20] This essential aspect of the determination of stability constants has been thoroughly discussed[5] and critically reviewed.[21]

3 EXPERIMENTAL APPROACHES

A great variety of experimental methods is encountered in the determination of stability constants,[1–3,5,20,22–24] and only a few types are selected here.

3.1 Potentiometry

If an electrode reversible to the ions of metal M is introduced into a solution of known M_t and L_t in a medium of constant ionic strength and the solution is combined with a reference electrode through a suitable conducting bridge (such as a 'Wilhelm' type electrode[25]), the measured emf at a temperature T K is given by the Nernst equation (*see Nernst Equation*):

$$E = E_{\text{const}} + \left(\frac{RT}{zF}\right)\ln[\text{M}] \qquad (13)$$

where E_{const} must be determined at the particular ionic strength of the experiment, and incorporates the intrinsic electrode parameter as well as relevant activity coefficients and liquid junction potentials. Suitable half-cells and various amalgam electrodes have been used to measure [M] and hence to obtain the stability constants of metal complexes of Cu^{+}, Cu^{2+}, Ag^{+}, Au^{+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, $Hg_2{}^{2+}$, Co^{2+}, Ni^{2+}, Sn^{2+}, Pb^{2+}, Bi^{3+}, Fe^{2+}, Pd^{2+}, and other cations.[1] Ion-specific electrodes have been used in many cases, notably for Ca^{2+} and F^{-}.

3.2 Polarography and Anodic Stripping Voltammetry

Although the redox processes (*see Redox Properties & Processes*) occurring on the surface of a dropping mercury electrode are generally more complex than those in potentiometry, the simplicity of polarographic apparatus has led it to be widely used in equilibrium solution chemistry. If a reversible electrode process is assured, the half-wave electrode potential is given by the Heyrovsky–Ilkovic equation:

$$E = (E_{1/2})_{\text{s}} = \frac{\left(\dfrac{RT}{zF}\right)\ln i_{\text{d}}}{(i_{\text{d}} - i)} \qquad (14)$$

where z is the change in electron number, i_{d} is the diffusion current, and i the current strength at the half-wave potential $(E_{1/2})_{\text{s}}$. Complex formation shifts the half-wave potential toward more negative values; however, if complex formation occurs in steps that overlap, the plot of $E_{1/2}$ against log[L] varies continuously. DeFord and Hume[26] developed the equation

$$\text{antilog}\left(\frac{0.4343E}{RT}\right)\Delta E_{1/2} + \log\left(\frac{I_{\text{s}}}{I_{\text{c}}}\right) = \sum_{0}^{N}\beta_i[\text{L}]^i \qquad (15)$$

where I_{s} and I_{c} are the diffusion currents of the free metal ion and the complex equilibrium system at the value [L].[27]

Details of the application of polarography and various elaborations of this technique to the determination of stability constants are described by Heyrovsky and Kuta,[28] Nancollas,[29] Hartley *et al.*,[22] Beck and Nagypál,[5] and Cukrowski.[30] A major advantage of polarography is its usefulness as a complement to potentiometry for determining stability constants.[31]

Anodic stripping voltammetry (ASV) can be very useful in studies of metal complexation in natural aquatic systems.[32] The technique can be used, under favorable conditions, to determine metal concentrations as low as 10^{-11} mol L^{-1}. Further, and again under appropriate conditions, stability constants may be determined in a manner analogous to that used in polarography. The principle of the technique involves deposition of a metal ion in reduced form on a static mercury electrode followed by reoxidation through reversal of the polarity. The reoxidation current is related to the metal concentration in the analyte. In the presence of a

complexing ligand, the peak potential in the anodic stripping (i.e. reoxidation) step undergoes a shift in relation to the uncomplexed metal and the magnitude of this shift can be used to determine the corresponding stability constant.

3.3 pH Metric Equilibrium Studies

Besides the use of half-cells involving metal ions, special reference must be made to electrodes capable of measuring $[H^+]$ and especially to the modern glass electrode.[4] pH-metry is the most powerful method for the determination of stability constants – indeed, 90% or more of stability constant data have been obtained by this method.[33] Values of $[H^+]$ are readily obtained by a precalibration method.[4,24,34]

Many organic ligands are the conjugate bases of comparatively weak acids and their metal stability constants are readily obtained by pH-metric titrations after a preliminary determination of the important hydrogen-ion stability constants of the ligand acid itself.

For a polybasic acid, H_NL, we can write equation (16) for the total acidity:

$$\begin{aligned} H_t &= [H^+] - [OH^-] + [HL] + 2[H_2L] + \cdots + N[H_NL] \\ &= [H^+] - [OH^-] + [L]\sum_1^N \beta^H n[H]^n \end{aligned} \tag{16}$$

where $\beta^H = [H_nL]/[L][H^+]^n$ is the overall stability constant for a hydrogen–ligand complex, that is, the conjugate acid of the ligand L. $\bar{n}_H$ is the average number of protons bound to each ligand atom (that is not bound to a metal):

$$\begin{aligned} \bar{n}_H &= \frac{\{H_t - [H^+] + [OH^-]\}}{(L_t - \bar{n}M_t)} \\ &= \frac{\sum_0^N n\beta^H[H^+]^n}{\sum_0^N \beta^H[H^+]^n} \end{aligned} \tag{17}$$

If we have measured $[H^+]$ in a solution where M_t and L_t are known, we can calculate all β_n for the metal–ligand complexes from

$$\bar{n} = \frac{\{L_t - (H_t - [H^+] + [OH^-])/\bar{n}_H\}}{M_t} \tag{18}$$

This procedure, essentially based on competitive complexing of the ligand L by metal ions M and protons H^+, has been used very extensively.[1–3,5,20,22–24]

3.4 Competitive Equilibria

The stability of some metal complexes is very large. For example, with ethylenediaminetetraacetic acid (EDTA, Na_2H_2Y) and tripositive lanthanide ions, Ln^{3+}, values of K_{LnY} range from $10^{15.7}$ to $10^{20.0}$ and the equilibrium

$$Ln^{3+} + H_2Y^{2-} \rightleftharpoons LnY^- + 2H^+ \tag{19}$$

lies so far to the right that it would be useless to try to compute the concentration of the free metal ion, $[Ln^{3+}] = Ln_{tot} - 2[H^+]$, from the difference between these two large and nearly equal quantities. In such cases, it is preferable to introduce a second cation, M^{n+}, and to study the position of the new equilibrium, for example, $M^{2+} + LnY^- \rightleftharpoons MY^{2-} + Ln^{3+}$, where the new equilibrium constant is given by

$$\begin{aligned} K_c &= \frac{[MY][Ln]}{[M][LnY]} = \frac{[MY]}{[M][Y]} \times \frac{[Ln][Y]}{[LnY]} \\ &= \frac{K_{MY}}{K_{LnY}} \end{aligned} \tag{20}$$

Although there is no simple electrode with which to measure Ln^{3+}, the determination of a mixture of M, MY, and LnY can be carried out polarographically if the cation M^{n+} is chosen so that its reduction wave precedes and is sufficiently separated from those of all other species in solution and if, of course, $[M^{n+}]$ is proportional to the height of the polarographic wave. In studies of the aminopolycarboxylic acid ligands EDTA and cyclohexanediaminetetraacetic acid (CDTA), Schwarzenbach and Freitag[35] showed that the auxiliary cation M^{n+} could be Cu^{2+}, Cd^{2+}, or Pb^{2+}, and Irving and Conesa[36] extended this to studies of all the lanthanide complexes of propylenediaminetetraacetic acid. K_c can thus be obtained from polarographic measurements and since K_{MY} will be known from earlier experiments, K_{LnY} follows from equation (20).

3.5 Use of Cation Exchange Resins

The partition of a cationic species $ML_n{}^{z+}$ between an aqueous phase and the sodium ion form of a cation exchanger (*see Ion Exchange*) can be represented by

$$z(Na^+)_R + (ML_n{}^{z+}) \rightleftharpoons (ML_n{}^{z+})_R + z(Na^+) \tag{21}$$

where the subscript R distinguishes the resin phase. The stoichiometric partition coefficient for each metal species is given by

$$\phi = \frac{[ML_n{}^{z+}]_R}{[ML_n{}^{z+}]} = k\left(\frac{[Na^+]_R}{[Na^+]}\right)^z \tag{22}$$

and will be constant provided k and the ratio of sodium ion concentrations in the two phases are both constant, a condition that can be met if the resin load and the extent of exchange is low and if the aqueous phase contains a constant and high

concentration of Na^+.[1] These conditions are greatly assisted if M_t is a low concentration of a suitable radioisotope (*see Isotopes & Isotope Labeling*). The overall distribution ratio is given by

$$\phi = \frac{\sum_0^N [ML_i]_R}{\sum_0^N [ML_i]} = \frac{\sum_0^N \phi_n \beta_n [L]^n}{\sum_0^N \beta_n [L]^n} \quad (23)$$

which reduces to $\phi = \phi_0/\Sigma\beta_n[L]^n$ if only the uncomplexed metal ion exchanges with the resin. In this form, the procedure has been used for determining the stability constants of many transition metals with a variety of organic and inorganic ligands.[1] If both M and ML exchange with the resin, computation becomes more difficult, but the procedure has been widely used.[1] Carleson and Irving describe the use of ion-exchange resin for determining the stability constants of indium halides where In^{3+}, $In(hal)^{2+}$, and $In(hal)_2{}^+$ all exchange with sodium ions on the resin.[37]

3.6 Liquid–liquid Partition

Liquid–liquid partition is useful when one of the series of metal complexes, ML_n^0, has a zero charge and can partition into an immiscible organic phase according to Nernst's law, $p_n = [ML_n^0]_{org}/[ML_n^0]_{aq}$.[1,5] Equilibration of an aqueous phase with known M_t and L_t with this immiscible organic phase leads to an experimentally determinable distribution ratio:

$$p_d = \frac{[ML_n^0]}{\sum_0^N [ML_n]} = \frac{p_n \beta_n [L]^n}{\sum_0^N \beta_n [L]^n} \quad (24)$$

from which values of the overall stability constants β_n can be computed. This is especially easy if M_t comprises a suitable radioisotope (*see Isotopes & Isotope Labeling*) of the metal M and is present at a low concentration. As L_t increases, p_d increases steadily to a value p_n; but if cationic complexes also occur in the equilibrium mixture, the distribution ratio passes through a maximum and then decreases, as in the system $MeHg^+/Br^-$/xylene, where the complex MeHgBr is the only extractable species but starts to be replaced by $MeHgBr_2{}^-$ in the aqueous phase as the bromide concentration increases.[38]

3.7 Spectrophotometric Methods

The absorbance of a species, ML_n, of concentration c in a cell of length d is given by $A = \varepsilon cd$, where ε is the molar absorption coefficient at a specified wavelength. Since $[ML_n] = A/\varepsilon d$, we can compute one of the terms needed to determine a series of overall stability constants provided its spectrum is sufficiently distinguishable from those of other species in solution. In a study of the equilibrium $p\mathrm{M} + q\mathrm{L} \rightleftharpoons \mathrm{M}_p\mathrm{L}_q$, a series of solutions can be made up for which $(M_t + L_t)$ is constant and the mole ratio $x = L_t/(M_t + L_t)$ varies from 0 to 1. Some property proportional to $[M_pL_q]$ (e.g. the absorbance in visible spectrophotometry) is measured and plotted against x to give two straight lines (for a stable complex) intersecting at $x = p/q$. For a less stable complex, more or less rounded curves with the same maximum are obtained. For a 1:1 complex, irrespective of the wavelength chosen, $x = 0.5$. While this procedure (Job's method[39]) and its various extensions have been widely used for determining the formula of a particular complex in solution, it is well adapted for determining reliable values of β_n for a series of complexes in equilibrium.[1,5]

3.8 Nuclear Magnetic Resonance Spectroscopy

The application of nuclear magnetic resonance (NMR) spectroscopy to the study of metal–ligand equilibria is growing rapidly. This technique can be used not only to determine stability constants but also to provide information on the structures of the complexes formed as well as the location of the binding sites on the ligand of the hydrogen and metal ions.[5]

In cases of slow exchange, the method comes into its own with simple sets of reactions forming mixed ligand complexes, for example, $AlCl_4{}^-$ and $AlBr_4{}^-$ in equilibrium with $AlBrCl_3{}^-$, $AlBr_2Cl_2{}^-$, and $AlBr_3Cl^-$.[40] Here, each species is clearly identified and integrated intensities unequivocally yield concentration ratios from which stability constants are directly calculated. Beck and Nagypál[5] describe the approach, with examples, in the cases of both slow and fast exchange. The identification of species present and the values of stability constants as determined by potentiometry and NMR spectroscopy are not always in agreement. Such was found to be the case by Crisponi *et al.*[41] in their study of cadmium(II)-ATP (adenosine-5′-triphosphate) equilibria. The discrepancies are attributed to ATP stacking at the higher concentrations required for the NMR measurements as well as to the inherently lower thermodynamic reliability of the NMR data.

An example of the identification, by NMR spectroscopy, of the protonation sites on multibasic ligands is described by Dhansay *et al.*[42]

3.9 Other Methods

Other physical methods often used include measurements of polarimetry, infrared (*see Infrared Spectroscopy*) and Raman (*see Raman Spectroscopy*) spectroscopy, conductivity, and colligative properties such as depression of the freezing point, solubility, and reaction kinetics. These topics and the extensive work carried out on mixed and polynuclear complexes is discussed in many of the books to which reference has already been made.[1,2,5,20,22,23]

4 USES OF STABILITY CONSTANTS

Numerical data on stability constants are needed in many aspects of technology such as extraction metallurgy and the nuclear energy industry, in planning analytical methods involving ion-exchange processes, separations of metals, chromatography, complexometric titrations, and for many aspects of academic, medical, environmental, and industrial research.[20,32,43–45] The toxic effect of some metals in the environment becomes enhanced when any derived complexes can be leached by underground water from a mine, land-fill site, or waste dump. On the other hand, very stable complexes can be effective detoxificants and it is important to be able to calculate the effect of definite concentrations of a particular ligand or mixture of ligands on the final composition of a wide range of elements and compounds in the natural environment[44] or to be able to model the selective action of drugs in the human system.[46,47] In agriculture, the transfer of an essential trace element from the soil to the growing plant and the use of synthetic agents to supplement or control plant nutrients, and many problems of technology, geochemistry, and of a biochemical nature can best be tackled with the aid of quantitative data on stability constants.[20]

Determination of the distribution of all the species (uncomplexed metal ions and ligands plus all the complexes coexisting in equilibrium) in a multicomponent system such as blood plasma, other biological fluids, sea-water, lakes, and other geological fluids is often referred to as *speciation*.[45] Arguably, the best way of carrying out speciation on a system is by calculation, making use of reliable stability constant values inserted into appropriate forms of mass action and mass balance equations.[46] Several databases have been constructed and several suitable computer programs have been developed for this purpose.[43] For example, a recent version of a blood plasma database incorporates 10 metal ion species, over 100 types of ligand and 10 000 complexation reactions between them.[47] Critically evaluated stability constants are to be found in several modern databases.[48–50]

5 STABILITY CONSTANTS AND THEIR CONTRIBUTION TO THE BASIC IDEAS OF CHEMISTRY

In 1941, Sidgwick summarized what he called the relative affinities of common ligands for acceptor molecules and ions; at the time, heats and entropies of compound formation were almost nonexistent and reliance had to be placed on qualitative comparisons. By 1953, stability constants for a number of metal complexes had been reported and it was feasible to ask the following questions: (1) For a given ligand, how does the stability constant vary with changes in the central metal atom? (2) How does the stability vary when the nature of the coordinating ligand, L, is changed? After reviewing all the data available in 1953, Irving and Williams showed that for divalent ions of the first transition series the stability always follows the order Mn < Fe < Co < Ni < Cu > Zn. This is now commonly called the *Irving–Williams Series* (*see Irving–Williams Series*).[51,52] For each cation, the stability increased when donor oxygen was replaced by donor nitrogen in either monodentate or bidentate ligands (see Figure 1). As the number of chelated rings increased so the stability increased, but it decreased with increase in ring size.[53]

The stability order $K_{n+1} < K_n$ was followed unless the added ligand produced changes in the electronic ground state (as with Fe^{2+} and phen), or introduced changes in coordination number (as with Ag^+ and the second molecule of ammonia, or Cd^{2+} and halides).[51–54]

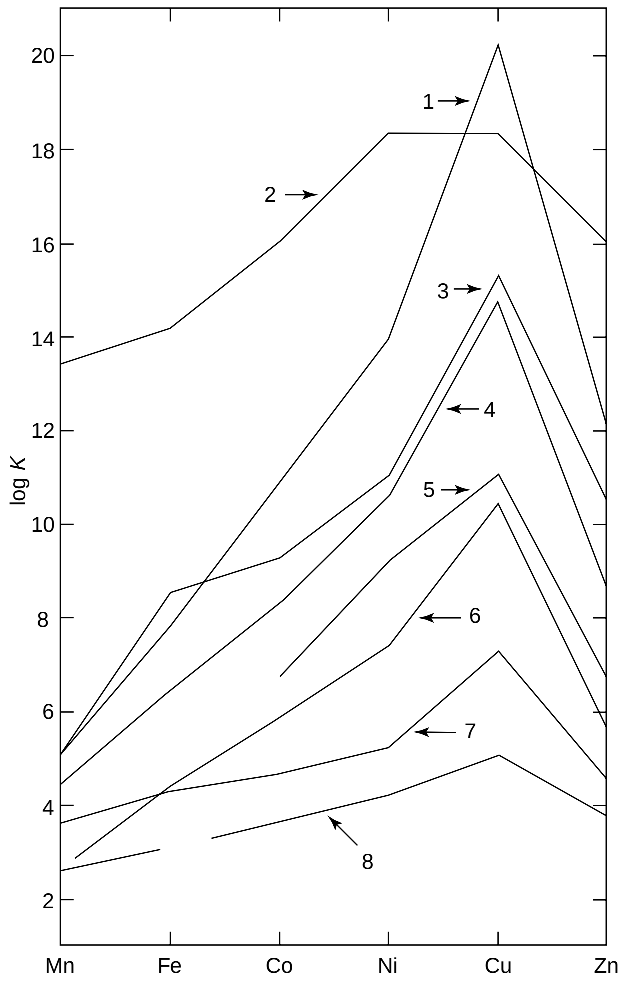

Figure 1 The stability of complexes of divalent transition metal cations. 1, Triethylenetetramine, $NH_2C_2H_4NHC_2H_4NHC_2H_4NH_2$; 2, EDTA, ethylenediaminetetraacetic acid; 3, diethylenetriamine, $NH_2C_2H_4NHC_2H_4NH_2$; 4, norleucine, $Me(CH_2)_3CH(NH_2)CO_2H$; 5, 1,2,3-triaminopropane, $NH_2CH_2CH(NH_2)CH_2NH_2$; 6, ethylenediamine, $NH_2C_2H_4NH_2$; 7, salicylaldehyde, 2-(HO)C_6H_4CHO; 8, oxalic acid, HO_2CCO_2H. For norleucine, 4, the values for log β_2 are plotted

In 1954, Carleson and Irving[37] noted that published data for the stability of a variety of metal halides separated them into two distinct groups. The order of decreasing stability $F^- \gg Cl^- > Br^- > I^-$ was followed by most cations (Group (i)), but was reversed for a few elements (Group (ii)) such as Ag^+, Cu^+, Hg^{2+}, and Tl^{3+}, for which the stability increased in the order $F^- < Cl^- < Br^- < I^-$ as shown in Figure 2.

These observations were in part a precursor of the well-known review of the relative affinities of ligand atoms for acceptor molecules and ions published by Ahrland, Chatt, and Davies in 1958.[55] By using quantitative measurements of stability constants measured for aqueous solutions and supplementing these by heats of dissociation (ΔH), association constants for metal complexes measured at specified temperatures ($1/K_p$), and a mass of qualitative information, they noted two regularities: (1) There was, in general, a great difference between the coordinating affinities of the first and second element from each of three vertical groups of ligand atoms in the periodic table (*see* ***Periodic Table: Historical Aspects***), viz. between N and P, O and S, and between F and Cl. (2) There were two classes of acceptors (*see Class A & Class B Behavior*). The larger, class (a), which includes the hydrogen ion, forms its most stable complexes with the first ligand of each group, that is, N, O, or F. The characteristic of the less numerous group, class (b), is most pronounced in the central part of the periodic table in a roughly triangular region, with copper at its apex and extending to Ir and Hg at its base. In their lower oxidation states, these are also the elements that form stable alkene complexes and have electrons from the lower d-orbitals available for π-bonding.[55]

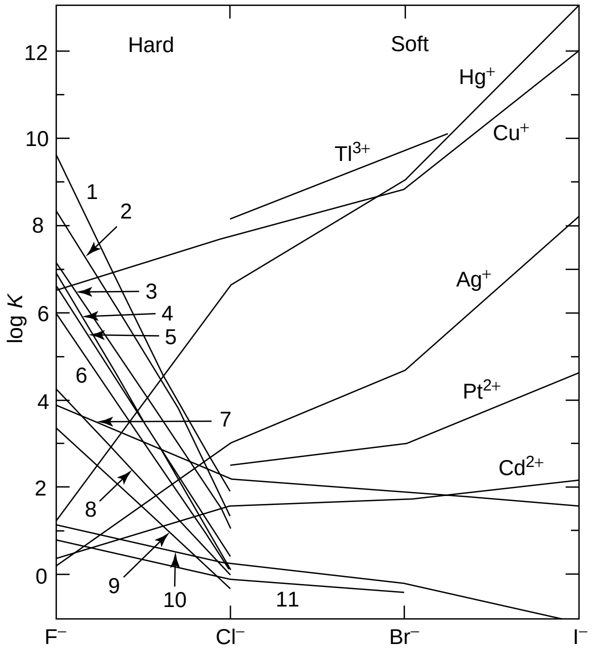

Figure 2 The stability of halogen complexes of various cations. 1, Zr^{4+}; 2, Th^{4+}; 3, Sc^{3+}; 4, Pu^{4+}; 5, Fe^{3+}; 6, UO_2^{2+}; 7, Sn^{2+}; 8, In^{3+}; 9, La^{3+}; 10, Hg^{2+}; 11, Zn^{2+}

Later workers have correlated the classification of elements in class (a) and class (b) with Pearson's principle of hard and soft acids and bases (HSAB principle)[56] (*see* ***Hard & Soft Acids and Bases***) on the basis that class (a) metal ions are hard acids and class (b) are soft acids. Borderline elements in the Ahrland–Chatt–Davies classification tend to be harder in the higher oxidation states and softer in their lower oxidation states.

While the class (a)/class (b) approach and the HSAB principle of Pearson are excellent qualitative methods for interpreting and classifying the phenomena encountered in many donor–acceptor reactions, progress toward establishing a more quantitative basis for these theories has been slow.[5,57] Drago's E and C parameters[58] (*see Drago Parameters*) represent a quantitative approach to a related problem: they allow the heat of association for a given acid–base adduct to be estimated if the empirical E and C parameters are known for both acid and base (*see Drago–Wayland Scheme*). Building on this approach, the parametric correlation work of Hancock and Marsicano[59] has provided valuable insights into the nature of donor–acceptor reactions. Very recent work[60] involving density functional theory calculations augurs well for the prediction of stability constants of complexes of metal ions with monodentate ligands (*see Monodentate Ligand*), and may also lead to a quantitative foundation for theories of metal complex formation reactions.[61]

Discussions in other sections of this encyclopedia deal with the chelate (*see Chelate Effect*) and macrocyclic (*see Macrocycle*) effects, which are also pertinent to our understanding of metal complexation reactions. The factors contributing to these effects are admirably discussed in detail by Martell and Hancock.[62]

Glossary

Dynamic NMR: NMR spectra in which broadening or averaging is observed owing to exchange of nuclei between different chemical environments. This is the method by which nonrigidity or fluxionality is generally detected
Fluxional molecule: a stereochemically nonrigid molecule in which all interconverting structures are equivalent
Stereochemically nonrigid compound: a compound that undergoes intramolecular rearrangements at rates that affect the NMR line shapes in generally accessible temperature ranges
Stereodynamics: dynamics associated with interconversion of stereoisomers or conformers

Abbreviations

DNMR = dynamic NMR; T_c = coalescence temperature; T_I = temperature at which initial broadening occurs in a DNMR spectrum; T_{LL} = low temperature at which broadening is no longer observed in a DNMR spectrum (usually 5–10 °C below T_I); T_1 = spin–lattice relaxation time; EXSY = 2D NMR method for evaluating exchange sites and rates; PSEXSY = phase-sensitive EXSY; HMQC = Indirect method for observing NMR of low abundance nuclei, such as ^{15}N, ^{57}Fe, ^{13}C, and so on, using the coupling to a sensitive nucleus, often ^{1}H; NOESY = Nuclear Overhauser Effect Spectroscopy, a 2D NMR method for assignment of resonances based on proximity; SIT = Spin Inversion Transfer; sp = square pyramidal; tbp = trigonal bipyramidal; Tp = hydrido(trispyrazolylborate); Tp′ = hydridotris(3,5-dimethylpyrazolylborate).

1 INTRODUCTION

Molecules that undergo intramolecular rearrangements at rates that affect the NMR line shapes in generally accessible temperature ranges are said to be stereochemically nonrigid. This terminology was originally proposed by Muetterties[1,2] and was popularized from 1966 when Cotton, Davison, and their coworkers produced a long series of articles entitled ‘Stereochemically Nonrigid Organometallic Compounds.’[3–8] Cotton’s retrospective description of these early developments provides a review of the early work.[9] Over the next eight years the use of NMR to study rearrangements of this type became sufficiently widespread, so that in 1975 an entire book was devoted to the subject of Dynamic Nuclear Magnetic Resonance Spectroscopy (abbreviated DNMR).[10] This book still provides the most comprehensive treatment of the subject and is a recommended starting point for further study. The fundamentals regarding the chemistry are treated well there, but the recent advances in multinuclear and two-dimensional NMR spectroscopy, such as EXSY and HMQC, have vastly improved the technology for detecting and investigating nonrigid processes.[11,12] Since that time, there have been a number of shorter reviews with particular emphasis on inorganic and organometallic chemistry that are recommended.[13–24] Although dating from 1988, the extensive review by Mann[13] is still a particularly valuable resource. Owing to the large number of references subsequent publications tend to focus on recent developments rather than being comprehensive. Orrell’s review[23] includes many of the most recent references. Mann’s book[24] includes abundant examples of applications of DNMR and illustrates the applications of more modern NMR techniques.

The subset of nonrigid molecules in which all observable interconverting species of a given type are structurally equivalent are designated as being fluxional.[25,26] Although this formal distinction was made previously, current usage often employs fluxional and stereochemical nonrigidity interchangeably. For example, as a static structure, separate resonances would be expected for the equatorial and apical positions of a trigonal bipyramidal molecule. The rapid rearrangement of the carbonyls in $Fe(CO)_5$ (**1**) is an example

of a fluxional process, which gives rise to a single resonance in the room temperature ^{13}C NMR spectrum. Presumably, the formation of a square pyramidal intermediate provides a pathway for this interconversion, as shown in equation (1). There are, however, alternative paths that differ in the details by which nuclei are permuted among the sites. It was well known in 1966 that the variations in line-width in the NMR spectra allowed the determination of rates of rearrangement, but using NMR to distinguish possible mechanisms was first used[3] with the classic example of a fluxional organometallic, $Cp_2Fe(CO)_2$ (**2**). Although this molecule had been formulated as (η^5-Cp)Fe$(CO)_2$(η^1-Cp), only singlets were originally observed for the cyclopentadienyl ligands in the ^1H NMR spectrum.[27] Lowering the temperature resulted in broadening of one singlet, which eventually decoalesced into the AA′BB′X spectrum expected for the η^1-Cp ligand. The observation that the A portion of the spectrum broadened differently than that of the B portion provided definitive evidence that the path involved a rearrangement in which the iron moved from one carbon to the immediately adjacent carbon, rather than randomly to other positions, or across the ring (see equation 2). NMR line shape analysis often allows the elimination of some mechanisms or provides a consistency with a limited number of mechanisms. Nevertheless, the primary use of NMR line shape analysis has often been for the determination of rates of rearrangement and for evaluating barriers to rearrangements. The timescale of the NMR measurements generally allows evaluation of barriers between 40 and 80 kJ mol^{-1}.

1.1 Measurement of Barriers to Interconversion

The magnitude of errors arising from neglect of coupling and chemical shift variations with temperature was not well recognized in the early- 1960s, and it is understandable that exceptionally large errors in activation energy were often obtained. Unfortunately, even after 40 years, many researchers fail to recognize the problems and often report barriers that may be in error by more than 100%. Since we will wish to compare rearrangement barriers, it will be necessary to establish the reliability of the data and determine a practical definition of barrier. That is, one may consider $\Delta G^{\ddagger}$, E_a, or a potential function maximum. Although one may debate which has the most theoretical significance, the practical situation is that $\Delta G^{\ddagger}$ is experimentally the most accessible, most reliable, and subject to the least experimental error.

Computer programs for calculation of line shapes are readily available.[28–31] Modern programs for personal computers, such as gNMR,[31] have user-friendly graphical interfaces that allow rapid calculation and display of spin-coupled spectra as a function of exchange rate. Careful line shape analysis, however, must include intrinsic variations of chemical shift with temperature and is a tedious procedure. Considering the rate ranges available (often less than a factor of 100), inaccuracies in E_a are sufficient to make comparison of results based on temperature variations questionable. It has been our experience that, for intramolecular reactions, significant activation entropies are not encountered, and that, in carefully executed experiments with large spans in rate (more than a factor of 1000), values between 12.3 and 13.5 are usually found for log A in Arrhenius plots. Values outside of this range usually indicate that the E_a is suspect. For example, the original alkene rotation barrier in the Rh–alkene complexes was reported to have log $A \sim 5$ and $E_a \sim$ 6 kcal mol^{-1} (25 kJ mol^{-1}),[32] whereas the more recent values are log $A = 12.5$ and $E_a = 15.0$ kcal mol^{-1} (62.7 kJ mol^{-1}).[33] In principle, one could encounter a situation, particularly in coordinatively unsaturated systems, in which a major solvent reorganization in the transition state produced a major deviation. Nevertheless, this situation appears to be rare. In most situations, one can reasonably accurately reproduce the variations in rates with temperature in these nonrigid systems by assuming log $A = 12.8$ or assuming $\Delta G^{\ddagger}$ is independent of temperature.

Since in many situations the information of greatest interest is the relative rearrangement rates among complexes, the variations in rates reflected by differences in $\Delta G^{\ddagger}$ are adequate for most purposes. The greater reliability of $\Delta G^{\ddagger}$ determined from the most accurate rate obtained at a given temperature suggests that one should focus on comparisons of $\Delta G^{\ddagger}$ values.

The errors and problems in evaluating rates has been reviewed elsewhere,[34–37] but a convenient and accurate evaluation of the rate can be obtained as the resonances begin to broaden above the limiting low-temperature spectrum by using equation (3).

$$k = \pi W \quad (3)$$

In this expression, k is the first-order rate constant for leaving one site and W is the broadening in excess of the natural line-width (in Hz). Thus, if one assumes that the low-temperature limit is reached when the excess broadening is $\approx$1 Hz, one can make a fairly accurate estimate of $\Delta G^{\ddagger}$ from this temperature (see Table 1). One might note for a rule of

Table 1 Approximate free energies of activation determined by the temperature at which a low-temperature limiting spectrum is reached[a]

T	kcal mol^{-1}	kJ mol^{-1}
−160	6.1	25
−140	7.3	30
−120	8.4	35
−100	9.5	40
−80	10.7	45
−60	11.8	49
−40	13.0	54
−20	14.2	59
0	15.3	64
20	16.5	69
40	17.6	74
60	18.8	79
80	20.0	84
100	21.2	89
120	22.3	93
140	23.5	98
160	24.7	103
180	25.9	108
200	27.0	113

[a]The best values are obtained at the temperature, T_I, when broadening just becomes perceptible in ^1H NMR. Since larger sweeps are used for ^{13}C and ^{31}P NMR, larger line-widths are needed to be perceptible and the free energy of activation may be slightly overestimated.

thumb that this corresponds to 64 kJ mol^{-1} at $T_I = 0\,°C$ and changes by ≈5 kJ mol^{-1} for each 20 °C interval.

Formulae also exist for the point at which two resonances of equal intensity coalesce to a single resonance upon raising the temperature,[38,39] and if from the Eyring rate equation (assuming a transmission coefficient of one) $k = (k_bT/h)K^{\ddagger} = (k_bT/h)\exp(-\Delta G^{\ddagger}/RT)$, then one obtains equation (4). Equation (5) follows from using the rate expression for NMR coalescence.

$$\Delta G^{\ddagger} = 2.303RT\left(10.32 + \log\frac{T}{k}\right) \qquad (4)$$

$$\Delta G^{\ddagger} = -RT_c \ln \pi\Delta\nu\left(\frac{h}{k_bT_c2^{1/2}}\right) \qquad (5)$$

In equation (5), $\Delta\nu$ is the separation between the resonances, h is Planck's constant and k_b is Boltzmann's constant. The temperature at which this coalescence occurs is often reported as T_c. Since the rate depends on the chemical shift difference between the sites in the absence of exchange at that temperature, T_c varies with the field strength of the spectrometer. Since field strengths between 60 and 800 MHz are now in use and variations in chemical shift with temperature are often neglected, T_c can be a rather misleading indicator of barrier height, and its use is not recommended by this author. Furthermore, it should be noted that equation (4) only applies for the case of equal intensities and no coupling between the nuclei. There is also a persistent problem with the definition of k from equation (4) in chemical terms (see below). Thus T_I, the temperature where initial broadening (≈1 Hz) is observed, will be reported here where possible. T_I is independent of field, and it provides an indication of the probable reliability of the energy barrier determination. This temperature is slightly above the temperature T_{LL} at which the 'limiting low-temperature' spectrum is obtained. Upon reaching this low limit, the rotation is often considered to be 'frozen out.' One should note that the motion has not actually stopped, but has merely slowed to the point where it no longer affects the NMR spectrum significantly (e.g. a rate constant $< \approx 0.03s^{-1}$).

Most modern programs for the calculation of rates of exchange are cast in the form of matrices representing probabilities of transitions between sites and the relative populations of those sites. The 'rate constant' obtained from these programs often represents the sum of nuclei moving from all sites or an overall rate constant. It is the responsibility of the user of the program to deconvolute the 'rate' produced by the program into the rate for leaving a particular site or for the rate of the reaction expressed in chemical terms. This problem has been discussed for some complicated cases by Green *et al.*[39] and was covered in a previous review for simpler systems.[16] Green's approach focuses on an overall rate constant, k_{chem}, and there are alternative choices to that approach; nevertheless, a reliable check is provided by comparing results from computer calculations with those from equation (1) for an elementary step in the rearrangement. In most cases, difficulties can be eliminated by cleanly defining 'rate' in terms of a rate constant for departures of nuclei from a given site. A prudent investigator should consider careful definitions of (1) rate versus rate constant, and (2) probability versus population (both indicated as p). In complex cases, it is important to delineate nuclei that leave a given environment and go to a different one from those that return to the same environment.

Equation (4) is the expression for the free energy of activation in terms of coalescence temperature; however, the k used in the derivation may have the ambiguity of a factor of 2 as discussed above for relating 'rate' to rate constant. Furthermore, we have taken the transmission factor (f) in the Eyring expression to be 1. This has been a commonly recommended assumption,[38–40] although a case can be made for using a factor of 1/2 in the case of a symmetrical well with equal populations.[41] The choice of f as either 1 or ≈1/2 produces a 0.4 kcal mol^{-1} or 1.7 kJ mol^{-1} difference in $\Delta G^{\ddagger}$. The evaluation of a conventional transmission factor in complicated cases can be more difficult. If the k has been defined in terms of nuclei leaving the site and going on to other sites, however, a transmission coefficient of 1 is appropriate. Several classic papers on obtaining energies from NMR data[37–40,42] provide further discussion of these points. The details of obtaining rates using computer calculations from line shapes are covered in several volumes.[37,43–45] One

of the most commonly used is that developed by Binsch[46] or modern modifications thereof,[28–31] such as used in g-NMR.[31] Rate data can also be obtained *via* 2D methods and magnetization transfer methods. Similar problems in defining the exchange matrices used to obtain rates from EXSY experiments require an analysis of similar factors to those above.[47,48] Saturation transfer or magnetization transfer experiments also provide rate data in which clearly defined rate constants are important.[49–52]

Modern NMR spectrometers allow routine application of pulsed methods, which allow determination of rates and exchange patterns by alternatives to line shape analysis. Somewhat slower rates can be determined by magnetization transfer experiments, such as SST and SIT. In saturation transfer (SST) experiments,[49–52] a resonance is irradiated for sufficient time to saturate it and allow its magnetization to equilibrate with that of any nuclei with which it might exchange. This generally would result in a decrease in the intensity of resonances involved in the exchange and the fraction of the intensity that remains depends upon the rate of exchange and the relaxation time of the nuclei (equation 6). This is particularly effective for rate constants $\sim 0.1 - 1\text{sec}^{-1}$.

$$k = \left(\frac{1}{T_1}\right)\left(\frac{M_0}{M-1}\right) \tag{6}$$

The method requires the measurement of the relaxation time of the nuclei at the site to which saturation magnetization is transferred (site A). This can be easily determined when $k \ll 1/\text{T1}$ with a standard inversion-recovery (180°-τ-90°) sequence[52,53] that is available on most spectrometers. Since T_1 will vary somewhat with time, one can extrapolate T_1 into the region of interest or attempt to measure it. This is straightforward if the T_1 for that site (T_{1A}) is the same as the site saturated (T_{1B}) since both recover at the same rate. If T_{1A} is very different than T_{1B}, analysis is much more difficult since nuclei from the faster relaxing site migrate to the slower relaxing site and *vice versa* during the measurements. Hence, the observed T_1's are composites of both and the T_1 for the slower relaxing site will be artificially shorter owing to magnetization being transferred into it. This is somewhat like the SIT experiment described below where only one resonance is inverted. Fortunately, most cases involve relaxation times that are similar. The case of metal-hydride-dihydrogen exchange is perhaps the most common situation in which the relaxation times are very different and mistakes are made evaluating T_1's for a particular site.

Potential errors arise from competing nuclear Overhauser effects, which can increase the intensities. Alternatively an nOe can be used to enhance the magnetization at a site and the enhancement can be transferred. This approach is more useful for ^{13}C and ^{31}P NMR. Saturation of a resonance is straightforward for ^{1}H NMR spectra since a second frequency can be readily set to allow saturation of a resonance before the 90° pulse is delivered to obtain the spectrum. For ^{13}C and ^{31}P NMR this can be achieved by setting the spectrometer frequency for the resonance, turning on the power at low level to saturate the resonance and then using a high-power 90° pulse.

An alternative is to use a ''soft pulse.'' The usual 90° pulse is several 10s of microseconds and results in a large bandwidth of frequencies. The soft pulse only affects a narrow range of frequencies and can be used to effectively produce a 180° pulse and invert a resonance. This inverted magnetization then recovers as in a T_1 experiment, but during the recovery, magnetization can be transferred to and from other nuclei. Unlike the SST experiment, this SIT experiment is followed with time and the intensities of the resonances depend upon the exchange rate and relaxation times. The method was originally developed for biochemical NMR[54] and several methods for producing the soft pulses are available[55,56] (UBURP256[56] being relatively popular). The intensities versus time are fitted to exponentials and the rates can be derived from them.[35,36,57] This approach was used in earlier studies of organometallics for observation of hydrides exchanging with carbenes and vinyls.[58,59] A recent study of ring inversion provides an example of its application including experimental parameters.[60] Other relaxation methods have been discussed in the review by Orrell.[23]

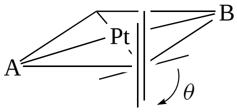
Modern spectrometers allow ready access to 2D spectra and menu-driven NOESY experiments are frequently used for assigning proton spectra based on correlations of Overhauser enhancements of intensity. Generally, proton spectra are plotted on both x and y axes and cross peaks are observed where nOe enhancements are large. These cross peaks allow assignments of nuclei, which are in close proximity. If exchange is occurring, cross ''peaks'' will also be observed between exchanging nuclei. By altering a time delay, one can emphasize the exchange peaks and then the experiment is often designated as an EXSY. Optimum results are often found for a fast exchange rate constant ($\sim 1\,\text{sec}^{-1}$) and short delay times. It is possible to delineate Overhauser effects from exchange effects using phase-sensitive experiments, although it is often convenient to discard phase information and use magnitudes. Frequently only a minor modification of NOESY parameters allows effective use of EXSY experiments to ascertain which nuclei are exchanging with which. One can obtain quantitative rate date by analyzing volumes of cross peaks,[12,35] but 1D methods would appear to give more accurate results.[36] Modern methods have most recently been reviewed by Bain.[37]

2 ALKENE AND ALKYNE ROTATIONS: PARADIGMS FOR STEREOCHEMICAL NONRIGIDITY

Conformational equilibria and rotational interconversion of conformers of metal–alkene complexes play a crucial

role in asymmetric hydrogenation[61,62] and asymmetric hydroformylation.[63] Selectivity in reaction chemistry can be related intimately to relative stability of conformers;[64] hence there are practical reasons for studies of nonrigidity. As indicated in earlier reviews,[10,13,16] rotation about an axis from the metal to the midpoint of an η^2-alkene or η^2-alkyne is a commonly observed and generally accepted phenomenon and is sometimes called '*propeller rotation*.' DNMR spectra are the prime indicators of alkene rotation processes; however, only a limited number of experiments using complexes with chiral centers allow the distinction between rotation about the metal–alkene axis and a rotation about the carbon–carbon axis (see below). Nevertheless, except for intermolecular exchange, rotations or oscillations about metal–alkene or metal–alkyne bonds would appear to account for the vast majority of the DNMR spectra in these complexes. An extended discussion of stereochemical nonrigidity in alkene complexes will follow, since it provides an opportunity to examine pitfalls and provides caveats for interpretations of results for other nonrigid compounds.

Attention originally focused on analogs of Zeise's salt and corresponding Rh^I systems. Crystal structures of these compounds show that the C–C axis of the alkene is perpendicular to the coordination plane of the metal and the other ligands. Hence, a potential minimum is generally assumed for the alkene orientation in which the plane containing the metal and the alkene carbon atoms produces a dihedral angle of 90° with that defined by the metal and other ligands (see **3**).



(**3**)

The first indications that the ethylene moiety was not rigidly fixed in the complex were the unusually large temperature factors for the carbon atoms in the X-ray structure determination of platinum–alkene derivatives and temperature dependence in the NMR spectra of the solids.[65–67] The early X-ray results implied an angular amplitude of oscillation of ≈20° in *trans*-$PtCl_2(C_2H_4)(NHMe_2)$. Oscillations estimated from NMR results for $[PtCl_2(C_2H_4)]_2$ and Zeise's salt indicated a 19° oscillation about the metal–alkene axis and a 29° oscillation about the C–C axis.

An AA′BB′ proton spectrum was observed in solutions at low temperature for the ethylene moieties in $(\eta^5\text{-}C_5H_5)Rh(C_2H_4)_2$. The coalescence of this pattern upon raising the temperature led Cramer to ascribe these variations in the spectra to complete rotation of the alkene ligands. The analysis of the temperature dependence of the NMR spectra, which was carried out in 1964, implied barriers to rotation in $(\eta^5\text{-}C_5H_5)Rh(C_2H_4)_2$ and $(acac)Rh(C_2H_4)_2$ of ≈25 kJ mol^{-1}. This original study did not take into account the variations in chemical shifts with temperature and thus gave an anomalously low activation energy for a process which showed initial line broadening at ≈ −15 °C and a coalescence temperature of ≈50 °C for resonances separated by 110 Hz.[32] A subsequent reevaluation of the activation energies, including approximations for coupling,[33] found an activation energy of 65 kJ mol^{-1} for η^5-$CpRh(C_2H_4)_2$. The advantages of using initial broadening to estimate barriers is obvious as reference to Table 1 would have predicted a 60–65 kJ mol^{-1} barrier.

Few attempts have been made to map out accurately the potential function for the rotation of ethylene on a metal center from experiment. Most NMR studies report E_a or $\Delta G^\ddagger$ and consider the point no further. If one considers only differences in interactions with d_{xy} and d_{xz} on a square-planar metal, then a maximum at $\theta = 0°$ would be a reasonable assumption. Routine NMR methods of line shape analysis, however, provide only a measure of the highest point on the potential in the rotation. Hence, NMR generally yields no indication of local maxima or minima during the rotation. The details of potential functions and distortions from idealized structures have been discussed elsewhere.[20,68] Early molecular orbital calculations suggested that local minima may also be anticipated.[69] Thus, for $(NH_3)Cl_2Pt(C_2H_4)$, a double minimum was obtained with a conformation of maximum energy at $\theta = 22.5°$ and minima at $\theta = 0°$ and 90° with a difference in energy between the minima of 106 kJ mol^{-1}.

MO calculations suggest that exceptional care must be taken in the interpretations and extrapolations from the 'barrier to rotation' obtained by NMR and a detailed description of the real potential function for rotation of an alkene. The barrier to rotation ($\Delta G^\ddagger$) can be readily determined and perhaps may best be viewed as a very useful correlation of interconversion rates as a function of temperature.

The Dewar, Chatt, and Duncanson[70,71] concept of the bonding of metal–alkene complexes (*see Dewar–Chatt–Duncanson Bonding Model*) provides an adequate theoretical framework for considering rotation of alkenes, even though other treatments suggest a somewhat more complicated situation.[72,73] It would appear that the σ-donation/π-back donation concept is essentially correct. Therefore, we may anticipate that a qualitative appreciation of rotational barrier heights should be derivable from considerations of relative degrees of σ-donor and π-acceptor ability of the alkene or alkyne ligands in various orientations.

2.1 Characterizing Rotations and Barriers

Before attempting to rationalize the experimentally determined barriers in terms of bonding theory, we must acknowledge the possible errors in NMR determinations of barriers and the one-parameter relationship of $\Delta G^\ddagger$ or E_a

to a potential function. Even for symmetrical alkenes it would not be prudent to attempt to describe the motion involved in an ‘alkene rotation’ in too great a detail. Thus any contortions, such as twisting, tilting, or skewing, that the alkene might execute are not realistically open to experimental verification. Nevertheless, the extent of idealization must be recognized. A rotation about an axis between the metal and a point midway in the C=C bond is probably a fairly accurate description of the movement in symmetrical alkenes. One must recognize, however, that some alkenes are severely distorted[68] and that an eccentric rotation would be anticipated.

A substituent often causes tilting or partial rotation of the alkene and displacement out of the coordination plane of the metal.[68] One of the more informative structures demonstrating these effects is that of $PtCl_2[Me(O)S(C_6H_4Me)](Me_2C{=}CH_2)$.[74] The alkene in this complex is rotated away from the perpendicular by ≈6°. Thus the minimum in the rotational potential is at $\theta = \approx 84°$. Furthermore, the alkene is displaced from the coordination plane such that the substituted carbon is slightly further from the plane. This effect is more pronounced with aromatic substitutents,[68] and can become extreme if conjugation or interaction of the substituents with the metal occur (e.g. vinyl alcohol).[75] In the vinyl alcohol derivative, the midpoint of the C=C bond lies 0.59 Å from the coordination plane.[75] Thus, if one assumes the axis of rotation is in the coordination plane, it might intercept the C=C axis closer to one end, rather than midway between the carbon atoms (Figure 1).

The nomenclature has not been consistent in attempts to describe deviations from the idealized configurations.[68] We will generally refer to a deviation in θ simply as partial rotation. The term twist has been used for this, but has often been used to describe rotational distortion about the C=C axis. Partial rotation about the remaining axis has been called *skewing*. The stereochemically nonrigid process of ‘alkene rotation’ primarily involves changes in θ, but would also

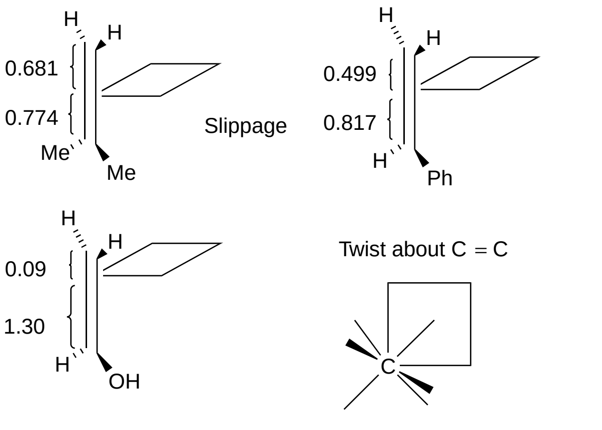


Figure 1 Slippage and twist in alkene complexes (distances in Å)

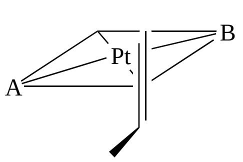
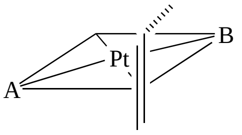
include some variations in twist and skew as θ varies. As the motion also involves some eccentric motion (see above), one must recognize that the term propeller rotation is an idealized description of the process.

Substitution also introduces the possibilities of isomerism. In certain cases, conformers differing by a 180° rotation about θ are no longer energetically equivalent and produce further complications in the potential surface. Thus, viewing down the metal–alkene axis of an unsymmetrical complex of propylene, one can readily predict the nonequivalence of well depths for conformations with the methyl groups endo or exo to a substituent, for example, (**4**) or (**5**). Hence the minima will not be at exactly $\theta = 90°$ and 270° and they will not have the same energy.

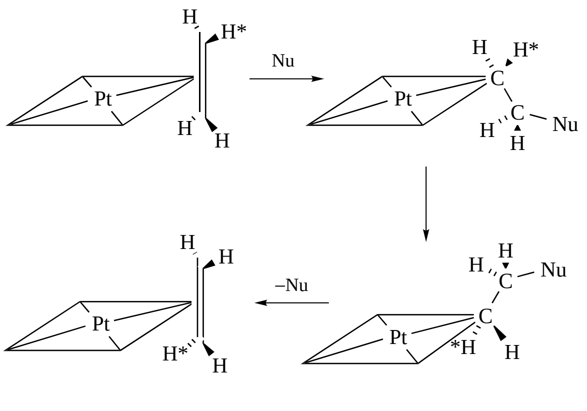


(**4**) *endo*



(**5**) *exo*

Although it is generally agreed that rotation about θ occurs in most cases, it is relatively difficult to prove this point and two caveats are in order: (1) intermolecular exchange can produce NMR spectra very similar in nature to rotation (especially in coordinatively unsaturated d^8 complexes); and (2) addition–elimination reactions can produce an identical interchange of protons. Retention of coupling constants to the spin of the metal in ^{195}Pt and ^{103}Rh complexes and those with ^{31}P in other ligands or failure to observe exchange with free ligand can eliminate intermolecular exchange as a pathway. This apparent rotation from addition–elimination, however, does not dissociate the alkene and may proceed as follows (in equation 7, Nu is a nucleophile, such as pyridine or phosphine). A $\pi \rightarrow \sigma$ interconversion has been demonstrated for the pyridine nucleophile[76] and could presumably also occur with electrophiles other than protons.[77]



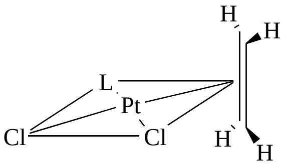
(7)

2.2 Factors Influencing Barrier Heights

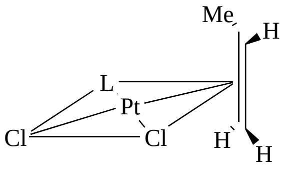
Metal–alkene rotation in square complexes has been reviewed by Mann.[13] Examination of these results indicates that increasing steric interactions with cis ligands, substituting the alkene, particularly with fluorine, and using metals in the lower rows of the periodic table increases the barriers. These square-planar complexes provide models for alkene and alkyne rotation in all complexes and many trends carry over to other complexes. It is often difficult to assess the accuracy of barriers reported in the literature. Frequently, inappropriate approximations, such as neglect of coupling, gave rise to gross errors. It is the experience of this author that reference to Table 1 and estimating the initial broadening temperature often provides a more reliable and accurate barrier than that calculated in the original literature. Differences on the order of 1 kJ mol^{-1} generally cannot be given much credence. It is often difficult to reproduce temperatures accurately enough to achieve accuracy of this level. The best procedure is the comparison of rates at the same temperature using line shape analysis. Although checking the temperature using peak separations in methanol is in common use, this author recommends using an internal temperature standard such as $[PhB(pz)_3]_2Co$,[78] which has an enormous temperature dependence in the phenyl proton separations.

A large number of Pt^{II}–ethylene complexes have barriers reported to be between 44 and 58 kJ mol^{-1} and have coalescence temperatures below 0 °C. Comparisons of complexes with very bulky cis substituents show significant, although not large, increases. For example,[79] in the *cis*-Cl_2LPt(ethylene) series, there is an increase in the order Et_3As (46 kJ mol^{-1}), Ph_3As (49 kJ mol^{-1}), and $(2\text{-MeOC}_6H_4)_3P$ (58 kJ mol^{-1}). In these cases, the electronic influence is not as great as probed by the CO stretching frequency in the analogous $PtCl_2L(CO)$ complexes, for which values of 2101, 2106, and 2103 cm^{-1} are observed. Here also the increase in the size of arsenic compared to phosphorus is offset by the longer bond length, and the steric influence of the ligand substituents is enhanced by the shorter Pt–P distance. Thus, in a series of cis complexes, nonbonded interactions tend to dominate variations in barrier with cis ligands. The trans ligand cannot have an appreciable steric influence under normal circumstances; however, major changes in donor or acceptor strength can be anticipated to effect only modest changes in barriers. For example, replacement of a *trans*-chloride by trifluoroacetate produces a lowering of the barrier by ≈2.5 kJ mol^{-1} (a difference which might be considered of only marginal significance in the absence of very careful measurements).

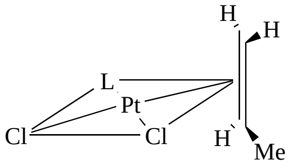
The importance of steric interactions with cis ligands can be more clearly seen in alkene substituent effects. The barrier increases significantly in the PtCl(acac)(ene) series where ene = substituted ethylene compared to ene = ethylene. The *cis*-Cl_2(DMSO)Pt(alkene) series (**6**)–(**9**), studied by Boucher and Bosnich,[80] is particularly instructive. The rotation in the ethylene begins to produce broadening about −47 °C, whereas the propene conformers broaden at ≈ −20 °C and no broadening is observed in the *trans*-butene complex up to +50 °C. T_I's imply barriers of 53, 59, and >75 kJ mol^{-1}. This demonstrates the general increase in barrier observed upon alkyl substitution and can clearly be ascribed to steric effects. The dramatic increase in barrier in comparing propene to butene can be attributed to the interaction of the methyl group attached to the alkene and the bulky sulfoxide. The increased interaction is suggested by the differing stabilities of the endo and exo isomers of the propene complex. These two conformers can be interconverted by a ≈180 °C oscillation ($\theta = 90° \rightarrow 0° \rightarrow 270°$) with the propene methyl passing by the chloride. Presumably a 360° rotation would occur rapidly only at higher temperatures owing to interaction of the methyl group with the sulfoxide. Since the stereochemistry of *trans*-butene requires that a methyl group pass near the sulfoxide in a rotation, its barrier is dominated by that interaction. This suggests that, in the propene complex, the potential maximum in the $90° \rightarrow 180° \rightarrow 270°$ path is at least 12 kJ mol^{-1} more than in the $270° \rightarrow 0° \rightarrow 90°$ path. The contribution from the methyl group interaction with the halogen is also probably increased since the twisting possible in the propene complex may be suppressed in the butene complex.



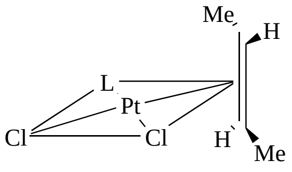
(**6**)



(**7**) $\theta = 90°$



(**8**) $\theta = 270°$



(**9**)

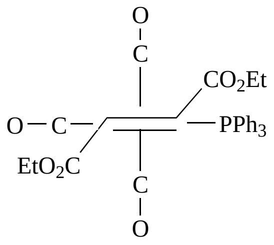
The most effective approach to interpreting the barriers for a wide range of compounds lies in the consideration of the relative interactions within the Dewar, Chatt, Ducanson model of metal–alkene bonding.[70,71] An extended Hückel MO approach has explored the interactions of the valence orbitals and examined the important interactions. A comprehensive extended Hückel MO treatment of ethylene bonding and rotational barriers by Albright, Hoffmann *et al.*[81] presents an excellent analysis and the reader is referred to their paper for further discussion. We have found that the following approach, which considers only three orbitals on the metal and the π and π^* orbitals of the alkene, provides the essential elements for understanding the barriers to rotation. Naturally, steric effects and secondary interactions with other orbitals modulate these primary interactions.

The donor component of the metal–alkene bonding is a symmetric interaction and to a first approximation is

independent of the orientation of the alkene relative to the other ligands (Figure 2). It is the back-bonding interaction, which is most sensitive to the orientation of the alkene. This is most cleanly illustrated in six-coordinate complexes, where one can readily predict preferred orientations by considering competitions for back donation of electron density.

In the absence of interaction with other ligands or orbitals, the back-bonding interaction in the *yz* plane for the $\theta = 90°$ orientation would be degenerate with that in the *xz* plane for the $\theta = 0°$ orientation. Thus, for the chromium and molybdenum derivatives $M(CO)_5$(ethylene), there would be no preference for either the *yz* or the *xz* plane. In fact, at this level of approximation, no barrier would be expected for a rotation from the *yz* to the *xz* plane, that is, the interaction with a linear combination of *xz* and *yz* would also be equivalent in energy.

If one of the cis carbonyls is substituted by a phosphine, the degeneracy is lifted and the preferred conformation is one in which the alkene lies along the O–C–M–P axis,[82,83] (**10**). If the phosphine is on the *x* axis, then the orientation along *x* involves a back-bonding competition for the electron density in the *xz* orbital between the ethylene π^*, the carbonyl π^*, and the phosphine unfilled *d* orbital, whereas orientation along *y* involves a competition between the ethylene π^* and two carbonyl π^* orbitals. The weaker acceptor ability of phosphine thus produces a richer back-bonding capability for the alkene in the *xz* plane than in the *yz* plane. Therefore, the bond is stronger when the alkene is oriented in the *x* direction. The barrier thus arises from the differential bonding in the two directions. This is an important feature: the overall strength of the metal–alkene bond will not correlate directly with barriers, since it is the differential strength, which is important. Hence, it is quite feasible to have a situation where a weakly bonded alkene could have a high barrier to rotation and a strongly bonded alkene could have a low barrier.



(**10**)

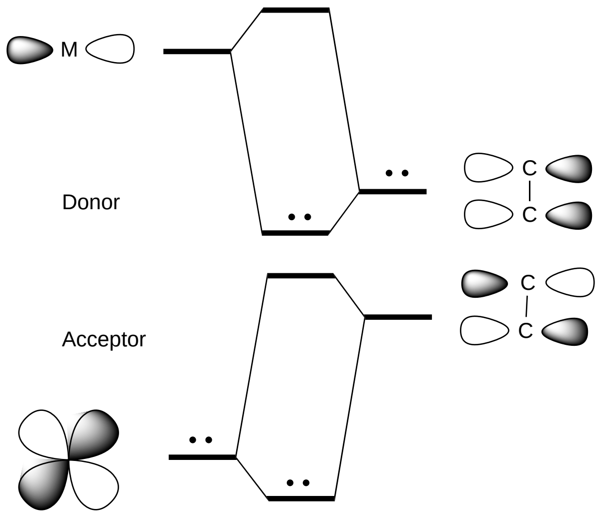


Figure 2 Donor and acceptor components of a metal–alkene bond

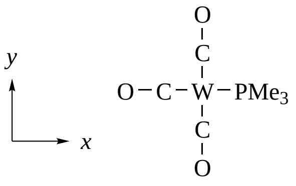
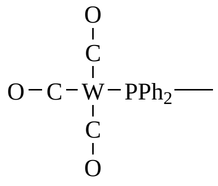
The origin of the differential interaction can also be illustrated in MO terminology by considering the effect of other ligand orbitals on the levels involved in back donation. An unfilled ligand orbital of the same symmetry would lower the bond order in the Mo–alkene π^* in proportion to the magnitude of its interaction. Thus, one can qualitatively estimate the effect on the barrier by considering the relative energies and overlap of the competing orbitals. Although these interactions are a major factor in the bonding, attempting to describe all barriers and orientational preferences to this limited set of interactions will obviously lead to failure when these effects do not dominate. For example, when a large differential in back-bonding capability in the *xz* and *yz* planes exists, as in the case of cis-phosphine-substituted alkene complexes, then one can confidently predict the preferred orientation. When the differential interaction diminishes, other effects may dominate and exert control over the orientation. Thus when the *x* and *y* orientation are degenerate, the simple model would predict that no preference should exist either for the *x* or *y* direction or anywhere in between. Nevertheless, there is a preference for lying parallel to the other ligands. This can be traced to an unfavorable interaction of the filled alkene π orbital with the filled metal *xy* orbital.[81]

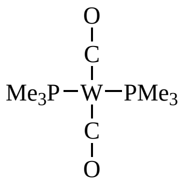
As shown in (**10**), a large differential in back-bonding capability in the *xz* and *yz* planes exists in the alkene complexes *cis*-$(CO)_4(PMe_3)$W(ene) (**11**), $(CO)_3$(diphos)W(ene) (**12**), $(CO)_3(PMe_3)_2$ W(ene) (**13**), and $(CO)(PMe_2Ph)Cl_2$Ru(ene) (**14**). The horizontal (*xz*) is preferred to the vertical (*yz*) in each complex, illustrating that the plane containing the orbital with greatest back-bonding ability is preferred. Note also that the presence of an additional phosphine enhances the effect and raises the barrier by $\approx 40\,kJ\,mol^{-1}$ in comparing (**11**) and (**13**) with ene = dimethyl fumarate, that is, $\Delta G^\ddagger$ of 40 and $80\,kJ\,mol^{-1}$.[79,80] Thus, any steric effect which might have been anticipated to destabilize the orientation parallel to the M–P bond is not sufficient to overcome the electronic control of conformational preference. The barrier for (**14**) is less than $40\,kJ\,mol^{-1}$.

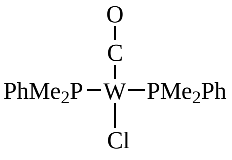
A particularly interesting case is that of *trans*-bis(ethylene)Mo(diphos)$_2$, (**15**) in which the ethylene ligands are staggered but align themselves along the Mo–P bonds.[84,85] The alignment along the Mo–P bonds is attributable to the repulsive interaction of the filled π orbital of ethylene with the filled *xy* orbital of the metal. The staggering of the ethylenes





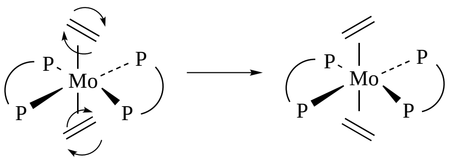
(**11**) (**12**)





(**13**) (**14**)

follows from the sharing of the electron density in the same d orbital in the eclipsed form relative to the effective utilization of both orbitals in the staggered form: one π^* to each d. Further analysis suggests that the rotations should be concerted, and that the motions of the top and bottom ethylene are concerted with the two ligands synchronously turning and remaining perpendicular to each other, as shown in equation (8).



(8)

(**15**)

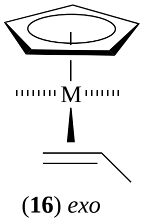
A more recent study[86] of series of $W(CO)_4(ene)_2$ complexes by ^{13}C NMR showed that from the highest barrier, for l-pentene rotation ($\Delta\ G^{\ddagger} = 45.8\,\mathrm{kJ\,mol^{-1}}$), to the lowest barrier, for cyclohexenone ($\Delta G^{\ddagger} = 38.8\,\mathrm{kJ\,mol^{-1}}$), there was only a difference of $\sim 7\,\mathrm{kJ\,mol^{-1}}$. It appears that the different steric effects of the alkenes in these complexes have little effect on the barrier to rotation.

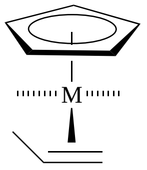
Since Cramer's early studies on ethylene and tetrafluoroethylene complexes,[32,33] a rule of thumb developed that fluorinated alkenes would rotate much slower than the corresponding unfluorinated alkenes attached to the same metal fragment. High barriers to rotation are the norm for C_2F_4 and this has been attributed to increased back bonding and the formation of a metallacyclopropane-like structure.[87] One might note that, in $Rh(acac)(C_2H_4)(C_2F_4)$, the 56 MHz ^{19}F NMR spectrum showed a single environment for the fluorines, which could have been interpreted as fast rotation for the C_2F_4. At higher fields, however, an AA′BB′X pattern is observed, indicating that fluorinated ligand rotation is slow on the NMR timescale.[88]

2.3 Rotations of Alkenes in Cyclopentadienyl Complexes

For $CpRh(C_2H_4)(C_2F_4)$, the ethylene rotates rapidly on the NMR timescale but the C_2F_4 appears rigid. The $CpRh(C_2H_4)_2$ has an $E_a = 62.7\,\mathrm{kJ\,mol^{-1}}$ ($T_I = 0°$ and Table 1 would suggest $\Delta G^{\ddagger} = 64\,\mathrm{kJ\,mol^{-1}}$). Cp*Ir $(C_2H_4)_2$ has a $T_I = 110°$ indicating $\Delta G^{\ddagger} = 86.5\,\mathrm{kJ\,mol^{-1}}$.[89] It is therefore surprising that Hughes has observed that $Cp^*Ru(trifluoroacac)(C_2F_4)$ and $Cp^*Ru(Cl)(t\text{-}BuNC)(C_2F_4)$ have relatively low barriers of $\Delta G^{\ddagger} = 53$ and $59\,\mathrm{kJ\,mol^{-1}}$, respectively, as determined by line shape analysis ($T_I \sim -30°$, $\Delta G^{\ddagger} = 56\,\mathrm{kJ\,mol^{-1}}$, Table 1). There is apparently only one other reference to a low barrier for C_2F_4,[90] but this could be an accidental equivalence. It thus appears that these Cp*Ru complexes are the first examples of low barriers for propeller rotation. Hughes' paper provides a summary of references to this area.[88]

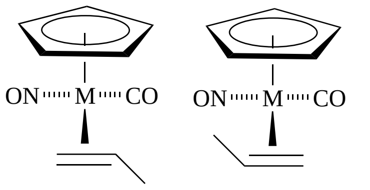
A cyclopentadienyl group can be presumed to occupy three coordination positions; thus CpM(CO)X(alkene) complexes can be conveniently considered as octahedral systems. Reference to Mann's review[13] indicates that a wide range of barriers are observed in these extensively studied systems. The introduction of the cyclopentadienyl moiety as well as other ligands produces the possibility of several isomers. Thus a propene complex can exist in endo and exo forms,[91] as in (**16**) and (**17**), and a substituent on the alkene can be cis or trans to other ligands. The use of 'cis' and 'trans' is inconvenient owing to the nature of the interconversion via rapid rotation. Thus, in $[CpM(CO)(NO)(propene)]^+$ complexes, the rotation of the exo isomer with the methyl group cis to NO (**18**) produces the endo isomer with the methyl group trans to NO (**19**).[92] It should be noted that the rotation does not change the configuration at the metal or alkene stereogenic center. Since the chirality at the substituted carbon is retained during the rotation, it is most convenient to use chirality descriptors. (Note that the chirality at the metal center is given first, so that (**18**) is (R,S)-exo, whereas (**19**) is (R,S)-endo.) It should be noted that once the other two ligands are not the same, the stable conformation may not have the alkene exactly parallel with the ring (see below).





(**16**) *exo* (**17**) *endo*

A single barrier is often reported for propene complexes; however, since the free energy of the endo isomer is usually less than that of the exo isomer, the direction of the path should be stipulated, that is, exo to endo, because the endo to exo barrier usually differs by 2 to $12\,\mathrm{kJ\,mol^{-1}}$. Secondly, there are two routes by which one can proceed from exo to



(**18**) (*R,S*)-*exo* (**19**) (*R,S*)-*endo*

endo: a clockwise rotation and a counterclockwise rotation. One of these involves passing the methyl group by the cyclopentadienyl ring and the other less energetic path only requires a vinyl proton to interact with the ring. Only the lowest energy path is usually reported, although experiments can be designed to determine the differences.

In the symmetrical $CpM(CO)_2$ systems, endo–exo isomerism exists and the C=C is effectively parallel to the ring and bisects the coordinates on which the other ligands might be assumed to be located; this is the orientation shown in (**16**) and (**17**). The introduction of a group with a large difference in π-acceptor ability relative to carbonyl either enhances or depletes the back-bonding ability of the orbital parallel to the bond. It is most convenient to consider that the orbitals and the molecule are reoriented along a Cartesian system, as shown in Figure 3.

Again, in this situation, one would expect the alkene to try to align along the axis of greatest back-bonding capability. Thus, in a nitrosyl carbonyl complex, one would expect the alkene to align with the M–C–O bond.[81,91,92] The alignment is not perfect, owing to steric interactions and other orbital interactions; nevertheless, it has a profound effect on the stability of conformers and barrier heights.

For example, in $[CpFe(CO)_2(propene)]^+$, the equilibrium constant is ≈19 in favor of exo; however, in the $[CpMo(NO)(CO)(propene)]^+$ system, the constant is only 1.7. The orientational preference induced by the NO relieves

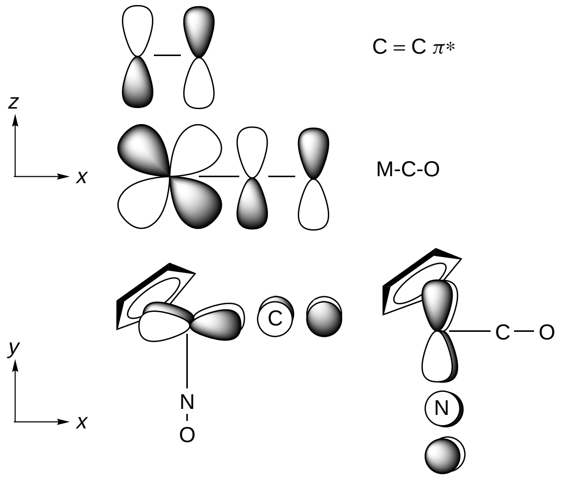


Figure 3 Orbital interactions for a CpM(NO)(CO) fragment

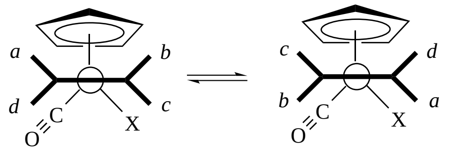
the steric interaction of the methyl with the Cp ring in the endo isomer. The barrier is also significantly higher in the Mo complex, not only because the back bonding is greater (a neutral versus a positively charged complex), but because there is a large differential in the back-bonding capability in various orientations available to the alkene.[91–93]

The use of prochiral alkenes such as propene,[91] 2-butene,[91] *trans*-dideutereoethylene,[94,95] dialkyl fumarates,[96] and *trans*-dimethoxyethylenes,[94] have allowed detailed structural and mechanistic studies of alkene complexes. The diastereomers produced upon binding of prochiral alkenes to CpM(CO)X centers provided the key complexes to prove that interconversions occurred by rotations about the metal–(C=C) axis. Thus observations[91,96] that neither the chirality at the metal nor at the alkene is changed in the rearrangement of a trans-substituted alkene provided proof that the nature of the dynamic process was a propeller rotation. Note that in equation (9) the equilibrium between (**20**) and (**21**) averages environments b and d separately from a and c. A key feature is that olefin rotation does not alter the chirality at the olefin because of the olefin-metal bond.



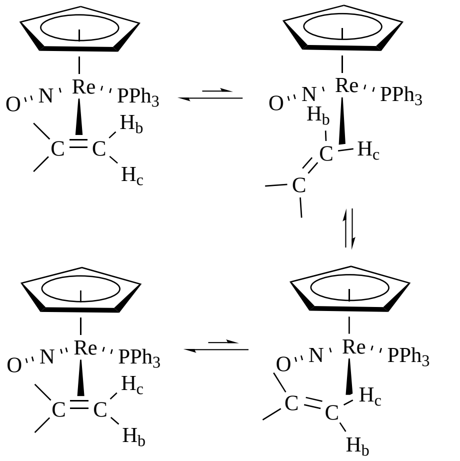
(**20**) (**21**) (9)

2.4 Alkene Nonrigidity Other than Rotation

Gladysz has carried out an investigation of $[CpRe(NO)(PPh_3)(alkene)]^+$ complexes[97] and has observed comparable results to those above in most cases. A $\Delta G^{\ddagger}_{369} = 68.6\,\text{kJ mol}^{-1}$ was determined from the ^{13}C NMR spectra at T_c for $[CpRe(NO)(PPh_3)(C_2H_4)]^+$ and is typical of this system. A $T_I \sim 30\,°C$ suggests a barrier of $\approx 71\,\text{kJ mol}^{-1}$. One might note that ^{13}C NMR provides advantages for determining barriers owing to the absence of coupling between ^{13}C nuclei. Unfortunately, however, the low sensitivity for broad resonances often makes it difficult to examine broad spectra. Use of equation (3) and initial NMR line broadening is recommended. As discussed above and by Hoffmann,[93] the preferred orientations can generally be predicted on the basis of π-interactions. Gladysz has cast his arguments in terms of interactions with the d orbital HOMO.[98,99] His papers serve as a source of recent references in this area.[98–101] The comprehensive study by Boone and Gladysz[101] provides a particularly useful summary of this area. There have also been recent studies[102,103] of fluxionality in $[Cp^*Ir(NO)(ethylene)]^+$, which are also consistent with propeller rotation of the olefin.

Prior to 1992, it was generally accepted that inversion of chirality in olefin binding would require complete dissociation of the olefin in an intermolecular process unless

the olefin was tethered to a ligand. There is, however, a spectacular result[97] that showed that the chirality of the alkene is not maintained in some *intramolecular* rearrangements of CpRe(NO)(L)(alkene). Although the result could be interpreted as a rotation about the C–C axis of the alkene, the most reasonable interpretation is that the metal takes an end run around the alkene (equation 10). The barrier ($121\,\text{kJ mol}^{-1}$) for the ''end-run'' pathway is above that which is accessible by NMR, but indicates that the process could occur with lower barriers in some cases. There is substantial evidence that C–H σ-bonds can interact strongly with rhenium and iridium in low oxidation states. Deuterium-exchange studies by Faller and Felkin[104] provided early evidence that suggested that *t*-butylethylene interacted via the C–H bond without prior coordination of the alkene. A number of σ-bond complexes of C–H bonds are now known, but are usually tethered to the metal and termed ''*agostic*;'' nevertheless, there is growing evidence that nonrigid processes involving σ-bonded C-H complexes should be observable by DNMR (this will be discussed below and in more detail in Section 9.2).



(10)

Harman has developed an analog of the CpRe(NO)(L)$^+$ systems using hydrido(tris)pyrazolylborate, Tp, complexes.[105–109] The [TpRe(CO)(PMe$_3$)] moiety is more electron rich than its counterpart and will even bind naphthalene in an η^2-fashion. Ethylene rotation in TpRe(CO)(L)(ene) has a barrier of $40.0\,\text{kJ mol}^{-1}$ as determined by SST experiments. Substantial variation of barriers correlated with basicity were noted with different L groups: L = *t*-BuNC, $32\,\text{kJ mol}^{-1}$ estimated from extensive broadening $\sim -85\,°\text{C}$; L = py, $51.0\,\text{kJ mol}^{-1}$ (SST); L = 1-methyl-imidazole = MeIm, $52.3\,\text{kJ mol}^{-1}$.[108] Generally, olefin rotation occurred at lower barriers than for interfacial interconversion ($>84\,\text{kJ mol}^{-1}$). A thorough study of binding of olefins with MeIm ligand was carried out.[105] Since the rhenium fragment is chiral diastereomers are formed with prochiral olefins; hence, rotamers interconvert faster than diastereomers. The interconversions of rotamers for propene are shown in Figure 4; diastereomer interconversions involve barriers of $\sim 134\,\text{kJ mol}^{-1}$.

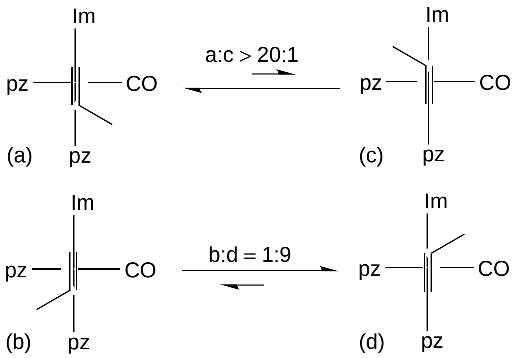


Figure 4 Interconversion of rotamers for TpRe(CO)(MeIm)(propene)

The TpRe(CO)(PMe$_3$)(thiophene) complex shows a selectivity of 3.2:2.0:1.0 for diastereomer (**22**) to (**23**) to an η^1-*S* isomer, as shown in Figure 5. This complex, as well as other thiophene complexes, offer the potential for an intramolecular face flip via formation of an η^1-*S* intermediate that could invert at sulfur to interconvert diastereomers. Nevertheless, SST experiments showed that the lowest energy path for interfacial exchange occurred *without* passing through an η^1-*S* intermediate.[109] The interfacial (face flip) for the thiophene complex (R=H) occurred with a $\Delta G^\ddagger = 79.4\,\text{kJ mol}^{-1}$ whereas the intrafacial (ring-walk on the same face) occurred at higher energy, $\Delta G^\ddagger = 83.6\,\text{kJ mol}^{-1}$. Many aromatics and heteroaromatics, in fact, underwent intramolecular interfacial interconversions at lower energies than migrations on the same face of the arene. A key feature is that this occurs in most of the arene systems at free energies of activation lower than those in the alkenes. It is therefore probable that these interconversions also involve agostic intermediates as suggested by Gladysz ''end-run'' olefin interconversions.

2.5 Rotations in Other Geometries

Eisenberg[110] has examined [Ir(^{13}CO)(diphos)(ethylene)$_2$]$^+$ by ^{1}H, ^{13}C, and ^{31}P DNMR.

At the slow exchange limit ($-90\,°\text{C}$), four ethylene proton resonances are observed, see (**24**). Upon raising the temperature, a propeller rotation ($\Delta G^\ddagger \sim 38\,\text{kJ mol}^{-1}$) in the trigonal bipyramidal complex averages two environments to yield an AA′BB′ pattern in the ^{1}H{^{31}P} spectrum. A second dynamic process averages the ^{31}P resonances ($T_c = -10\,°\text{C}$) in the ^{31}P NMR and the ^{31}P-^{13}C coupling in the ^{13}C NMR at the same time that nonequivalent ^{1}H protons for the diphos backbone become equivalent ($\Delta G^\ddagger \sim 46\,\text{kJ mol}^{-1}$). This can be attributed to a pseudorotation in the trigonal bipyramidal structure similar to that shown in equation (1). It should be noted that the pseudorotation favors certain permutations because this does not average the AA′BB′ pattern of the ethylenes. At higher temperatures, exchange with free ethylene occurs.

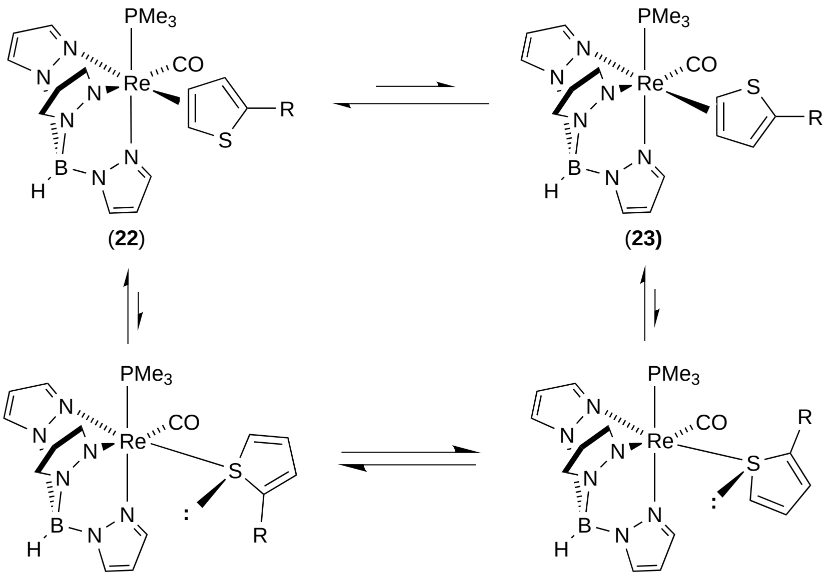

Figure 5 Diastereomer interconversion in TpRe(CO)(MeIm)(thiophene)

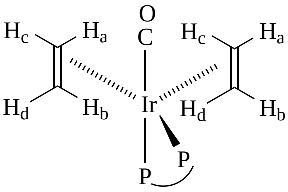


(**24**)

2.6 Rotations in Solids

Although some of the initial studies of olefin rotation employed solid-state methods, relatively few studies have been carried out recently. Studies of relaxation in the solid-state ^{2}H spectra of (acac)Rh(ethylene-d_4)$_2$ indicated a free energy of activation of 56.5 kJ mol^{-1}.[111] Olefin rotation in deuterated (Ph$_3$)$_2$Pt(ethylene) and K[Cl$_3$Pt(ethylene)] was characterized by long T_1's for the ^{2}H, which indicated slow rotation.[112] This indicates barriers in the solids of >80 kJ mol^{-1}. Measurements in solids can be influenced by nearest neighbor interactions and thus do not necessarily correlate with barriers measured in solution. It is possible, however, to measure very low barriers in solids and this can potentially overcome the practical lower limits that are imposed by solution studies. One should note, however, that, in certain cases, low barriers can be determined in solution using ^{1}H relaxation times rather than line shapes, SST, or EXSY spectra. The dipolar relaxation of the protons in complexes containing a ^{13}CH$_3$ group can be analyzed as a function of temperature to yield a barrier. For a variety of organometallics, the activation energy for methyl rotation is ∼12 kJ mol^{-1}.[113] ^{2}H relaxation studies give a 10.9 kJ mol^{-1} barrier for the three equatorial methyl groups in [Cp*WMe$_4$] PF$_6$.[114] The axial methyl group has one of the largest barriers known for methyl rotation of 26.8 kJ mol^{-1}. The measurement of motional barriers in solids has been reviewed by Duer.[115]

2.7 Rotations of Alkynes in Cyclopentadienyl Complexes

Alkyne complexes have behavior directly analogous to the alkene complexes,[13,20] except for having somewhat higher barriers, and will not be discussed in great detail. They do, however, present an example of the potential problems arising from assuming cationic species will have lower rotational barriers. For example, [CpMo(CO)(HOCH$_2$C≡CCH$_2$OH)$_2$]$^+$ has a barrier more than 42 kJ mol^{-1} higher than the neutral complex CpMo(Cl)(ClCH$_2$C≡CCH$_2$Cl)$_2$.[116] Thus replacement of CF$_3$C≡CCF$_3$ by PhC≡CPh in CpWCl(CF$_3$C≡CCF$_3$)$_2$ increases the barrier by 12 kJ mol^{-1}.[117] The orientation of one of the MeC≡CPh (Me cis or trans to Cl) produces a 6-kJ mol^{-1} differential in barrier of the other MeC≡CPh in CpMoCl(MeC=CPh)$_2$.[116]

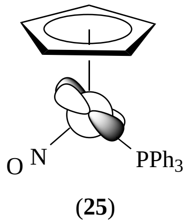
Templeton has carried out extensive studies of rotational barriers of alkynes and has calculated a number of rotational energy profiles; his papers provide leading references to earlier work.[118] Pyrazolylborate analogues also show similar behavior[119] and this work as well as earlier reviews provides leading references.[13,20]

3 CARBENE ROTATION

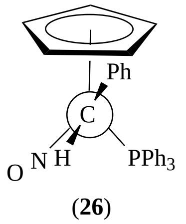
Renewed interest in metal carbenes, particularly N-heterocyclic carbenes, has resulted from recent progress in

ring closing metathesis[120–122] and the preparation of relatively stable carbenes that are active catalysts.[122] Recent reviews provide leading references for activity in physical aspects of the area.[123,124] Theoretical studies indicate that conformational equilibria play a key role in the catalysis.[125–129]

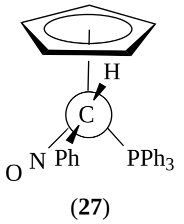
The symmetry of the *p*-orbital in a carbene ligand is directly analogous to that in the π^*-orbital of an alkene and, consequently, similar orientation effects are expected for carbene complexes as found in alkene complexes[93,130] in electronically asymmetric complexes, such as (**25**). The extensive studies of rotational barriers and conformational preferences by Brookhart[131] and Gladysz[132,133] provide leading references to earlier work. Typical examples of conformational isomerism are (**26**) and (**27**). The nomenclature can be easily confused, but (**26**) has been termed *synclinal* and (**27**) described as the *anticlinal* conformer.[131,132] Synclinal isomers have been shown to be more reactive than *anticlinal* isomers in $[CpFe(CO)(PR_3)(carbene)]^+$ complexes.[131] The conformational isomers control the stereochemistry of reactions of the carbene.[133] Diastereomerically pure $CpMn(CO)(PR_3)(carbene)$ complexes have also been prepared.[134] The electronic asymmetry in $[Tp'W(CO)(PhC_2Me)({=}CH_2)]$ gives rise to a very high barrier (not detectable by NMR) for rotation of the methylene.[135,136] Rotational isomers are observed in the amido complexes $TpMo({=}CHR)(NAr)(CH_3)$ (**28**), $TpMo({=}CHR)(NAr)(OCH_3)$ (**29**), and $TpMo({=}CHR)(NAr)$(OTf) (**30**).[137] The variations in ligands produces a significant variation in barriers to rotation: (**28**) > (**29**) > (**30**). Other arylamido complexes show increased rotational rates in alkylidenes as alkoxide substituents become more electron donating.[138–140] Vinylidenes with similar ligands, such as $[Cp^*(Ph_2PCH{=}CH_2)_2Ru{=}C{=}CH_2]$, show a low barrier to hindered rotation (<28 kJ mol^{-1}) owing to a lack of electronic asymmetry.[141] Other examples are covered in a review.[123]



(**25**)

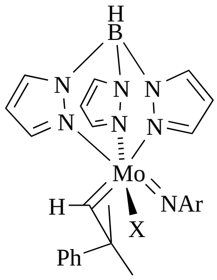


(**26**)



(**27**)

Barriers to carbene rotation in N-heterocyclic carbenes (NHC's) appear to be dominated by steric interactions, and they can also be observed in square-planar complexes using the diastereotopic protons in benzyl, butyl, and ethyl derivatives.[142] For example, the COD derivative (**31**) shows diastereotopic methylenes owing to a lack of a mirror plane through the Ir–C(carbene) plane. These do not average at high temperature indicating a barrier greater than 92 kJ mol^{-1}. The carbonyl analogues (**32**) show averaging of the methylene

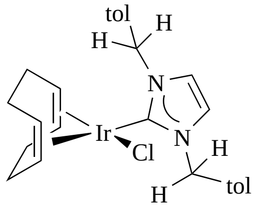


(**28**) X = Me

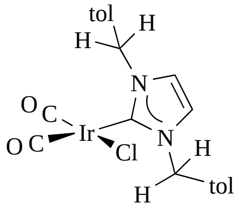
(**29**) X = OMe

(**30**) X = OTf

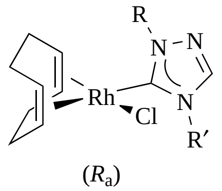
protons that indicates a 65-kJ mol^{-1} barrier to rotation. Steric interactions influencing barriers have also been observed by Hermann.[143,144] With unsymmetrically substituted NHC's or triazolinylidenes, enantiomers, for example (**33**) and (**34**), are produced upon binding to the square-planar complex.[145,146] With chiral substituents, diastereomers can be separated when the rotational barrier is high and they have been used for asymmetric catalysis.[146] When two carbenes are present in a cis complex, the axial chirality allows three isomers (**35–37**). For some bis carbene complexes, the restricted rotation can cause broadening at room temperature in the proton NMR spectra.[147] An alternative to preventing rotation by steric interactions is to tether the carbene to a cyclopentadienyl group to prevent rotation (**38**).[148]



(**31**)

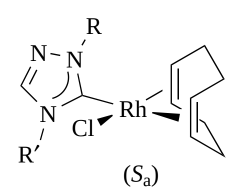


(**32**)



(R_a)

(**33**)



(S_a)

(**34**)

Other types of hindered rotation besides rotation about the M=C can occur. Hindered rotation about the C–C bond between the α-carbon and ipso-carbon of the phenyl in the M=CHAr is observed in both iron and rhenium compounds with $\Delta G^{\ddagger}$ 42–50 kJ mol^{-1}.[132,149]

Compounds such as $[Cp^*(Ph_2PCH{=}CH_2)_2Ru\ {=}C{=}CH_2]$ show a low barrier to hindered rotation about the Ru=C;

however, DNMR spectra are observed owing to restricted rotations about other single bonds, that is, Ru-P and P-C.[141]

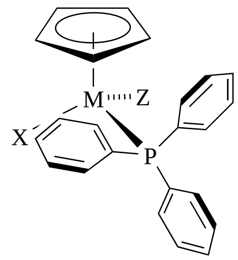
4 HINDERED ROTATION ABOUT SINGLE BONDS

In investigations of diastereomers, there is a common problem wherein barriers are low enough that averaged spectra are observed at room temperature. Upon lowering the temperature, isomers can be observed, but it is difficult to tell whether these are the isomers or conformations that are frozen out owing to relatively high barriers to rotation about single bonds.[150] This is a particularly important distinction to be made when diastereomers are being used for asymmetric catalysis.

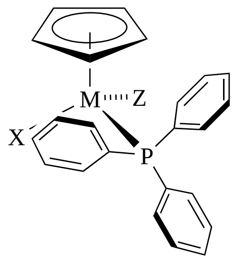
4.1 Restricted Rotation About M-P and P-C Bonds

Hindered rotations of M-P bonds involve barriers generally much less than $60\,\mathrm{kJ\,mol^{-1}}$ and with bulky phosphines may have barriers $\sim 40\,\mathrm{kJ\,mol^{-1}}$. Since the rate at which resonances will coalesce depends on the reciprocal square of the chemical shift difference, the increasing use of higher field NMR spectrometers yields many instances where conformational effects are a source of broadening that can be observed. Since conformational interconversions do occur at rates that can be studied by NMR, and although barriers are low, there have been extensive studies of hindered rotation in P–M bonds.[151–168] Generally these involve phosphines containing bulky substituents, such as *t*-butyl, *o*-tolyl, and mesityl groups. The barriers can be high enough ($\sim 60\,\mathrm{kJ\,mol^{-1}}$) to show broad resonances at room temperature in some cases, such as Pt(mesityl$_2$PH)$_2$(Et)(I).[166] Generally less-hindered phosphines have lower barriers, but in some cases they can be measured. Cp*Ir(pz)$_2$(PPh$_3$) shows hindered rotation about the Ir–P bond.[160] The silver derivative Cp*Ir(pz)$_3$Ag(PPh$_3$) shows Ag–P restricted rotation with a $\Delta H^{\ddagger} = 35\,\mathrm{kJ\,mol^{-1}}$ and $\Delta S^{\ddagger} = -55$ eu.[160] In some cases, π-stacking effects, rather than steric hindrance, has been attributed to the source of increased barriers. The *trans*-[PtX(Me$_2$-phen)(PPh$_3$)$_2$]X complexes, which contain a monocoordinated 2,9-dimethyl-1,10-phenanthroline, represent a rare case where triphenylphosphine shows a barrier higher than $42\,\mathrm{kJ\,mol^{-1}}$.[159] Usually barriers to rotation about M-PMe$_3$ bonds are low, but there are several recent cases of relatively high barriers in analogues of Cp*Ir(2-C$_6$BrF$_4$)Br(PMe$_3$).[168] The barrier for this compound is $39\,\mathrm{kJ\,mol^{-1}}$ and for the 2-C$_6$BrF$_4$ analogue it is $38\,\mathrm{kJ\,mol^{-1}}$. The highest value of $44\,\mathrm{kJ\,mol^{-1}}$ for $\Delta G^{\ddagger}$ was found for Cp*Rh(2-C$_6$IF$_4$)I(PMe$_3$).[168]

Hindered rotation about the P–C bonds in phosphine ligands can also produce conformational isomers and DNMR spectra below room temperature.[159,163,166–179] There have been moderately successful attempts to estimate relative conformational stability using molecular mechanics methods with force fields adjusted for metal compounds.[180–185] These different conformations can produce conformational isomers that are diastereomers in complexes with chiral metal centers, such as in (**39**) and (**40**).[186] Propeller chirality, which is designated as *P* and *M*, has also been studied in triphenylsilane and triphenylstannane.[187]



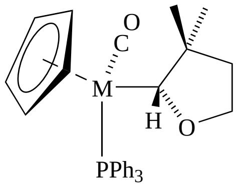
(**39**)-(*P*)



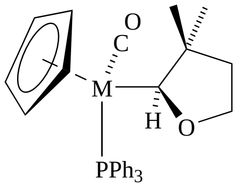
(**40**)-(*M*)

Generally one would expect the propeller chirality to be controlled by the chirality at the metal center, such that (**39**) or (**40**) would be preferred depending upon the interactions with the other ligands on the metal. There is, however, a strong influence of the conformations and configurations of the other ligands. For example, (**41**) is formed initially upon reduction of a carbene precursor and the (*R*)-stereochemistry at the metal center induces an (*R*) configuration at the carbon attached to the metal, which in turn induces a propeller chirality of (*M*) in the triphenylphosphine. This kinetic isomer can be isomerized to the thermodynamically stable isomer (**42**), which an (*S*) configuration at the carbon, but a propeller chirality of (*P*).[185] It is interesting to note that the sign of the rotation is positive for (**41**), but negative for (**42**).

The chirality associated with the PPh$_2$ analogue of this propeller-type chirality is particularly important with nonracemic chiral ligands, such as BINAP, since it influences



(**41**)-(R_{Fe},R_C,M)

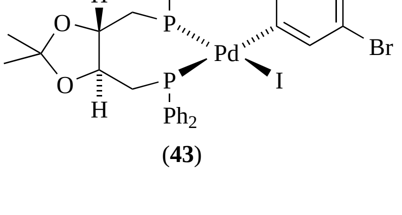


(**42**)-(R_{Fe},S_C,P)

the chiral environment when the complex is used as an asymmetric catalyst. Hindered phenyl rotation has been observed in several BINAP complexes.[186,188,189] In the case of (BINAP)$PdCl_2$, the inequivalent ortho and meta proton resonances of one phenyl group are near coalescence at 25 °C and only become sharp multiplets (at 400 MHz) on heating to 70 °C.[186] The hindered rotation of the axial phenyl group was implicated in determining the high stereoselectivity of the BINAP catalyst enantioselective hydroformylation.

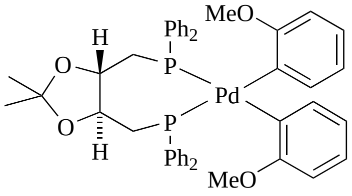
4.2 Restricted Rotation About M-aryl Bonds

As observed with carbene rotations (see Section 3), conformations of aryls can introduce additional chirality into a complex. Aryls prefer to lie orthogonal to the coordination plane in square-planar complexes. Hindered rotation of aryls in these complexes can produce atropisomerism,[190] although this description is most commonly associated with restricted rotation about C–C single bonds in biaryls. An example of hindered rotation is found in (DIOP)Pt(3,5-$Br_2C_6H_3$)(I) (**43**) in Brown's paper which provides an excellent discussion and leading references.[191] The ortho protons of the dibromoaryl are diastereotopic owing to the chirality of the DIOP ligand. These protons can be identified by their coupling to ^{31}P (6.5 Hz) and ^{195}Pt (40 Hz), but they are broad at 25 °C and sharpen at −10 °C, suggesting a barrier for Pt-aryl rotation ~64 kJ mol^{-1} using Table 1. One should note that the ^{195}Pt satellites are still somewhat broad at −10 °C. This, however, is due to chemical shift anisotropy relaxation of the ^{195}Pt nuclei rather than restricted rotation. This CSA relaxation often induces broadening in high field ^{1}H spectra where coupling to ^{195}Pt is present. This relaxation is field dependent and thus can be reduced or effectively eliminated by working at lower fields. It is important, however, to avoid mistaking CSA relaxation for hindered rotation.



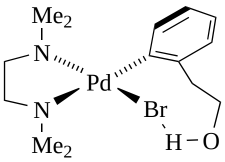
(**43**)

If the aryl is not C_2-symmetric in analogues of (**43**), diastereomeric rotamers will exist. Thus, the 2-MeO-phenyl analogue shows a 57:43 ratio of rotamers. When two aryls are present, syn and anti isomers can exist and were observed in nickel complexes.[192] The bis(2-methoxyphenyl)Pd(DIOP) (**44**) exhibits three sets of ^{31}P resonances in a ratio of 3:1:1 at ambient temperature.[191] There are two anti isomers and one syn isomer, which is readily identified owing to the nonequivalence of its ^{31}P resonances. The chirality of the bisphosphine ligand favors one of the anti isomers.



(**44**)

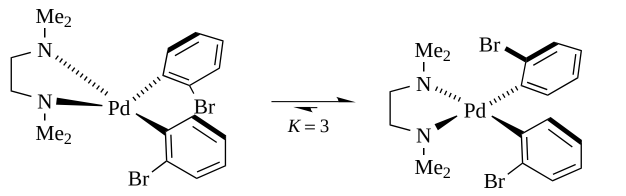
In (tmeda)PdBr{o-(CH_2CH_2OH)C_6H_4}, (**45**) aryl rotation is restricted and sharp spectra are observed in $CDCl_3$ up to 60 °C ($\Delta G^{\ddagger}$>79 kJ mol^{-1}). A number of diastereotopic features are observed owing to the retention of chirality: the two methylene groups show diastereotopic protons; and four methyl resonances are observed for the NMe_2 groups in the tmeda. An X-ray structure shows that there is an H bond from the alcohol proton to the bromide, which may account for the particularly high barrier for aryl rotation. In methanol, the barrier is lower (63 kJ mol^{-1}) owing to ionization of the bromide.



(**45**)

Atropisomerization in *cis*-[Pd(2-C_6BrF_4)$_2$(tetrahydrothiophene)$_2$] (**46**) also illustrates a situation in which dissociation can modify the barrier for syn-anti interconversion (equation 11).[193,194] In the presence of excess tetrahydrothiophene (tht), dissociation is suppressed and a syn to anti rate constant of 1.4 s^{-1} at 26 °C ($\Delta G^{\ddagger} \sim 70$ kJ mol^{-1}) was observed using a ^{19}F-SIT experiment. Considering rate changes with lower tht concentrations allowed determination of rate constants for a pathway involving dissociation and syn-anti interconversion *via* a 3-coordinate intermediate. Activation parameters (from a 40° temperature range) were obtained for the interconversion via the 4-coordinate ($\Delta H^{\ddagger} = 83 \pm 3$ kJ mol^{-1} and $\Delta S^{\ddagger} = 37 \pm 10$ J K-mol^{-1}) and 3-coordinate ($\Delta H^{\ddagger} = 77 \pm 3$ kJ mol^{-1} and $\Delta S^{\ddagger} = 28 \pm 10$ J K-mol^{-1}) complex. Note that a relatively large value of $\Delta S^{\ddagger}$ is even observed for

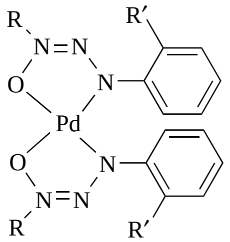
the nondissociative path, which is unusual.



(**46**) *syn* (**46**) *anti*

(11)

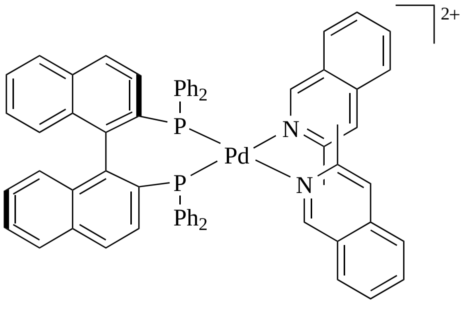
There are a number of other complexes that show restricted rotation of fluorinated phenyl groups, both in square-planar and pseudooctahedral complexes.[195–201] Situations also exist where similar syn and anti isomers exist owing to aryls attached to ligands, for example, (**47**).[202]



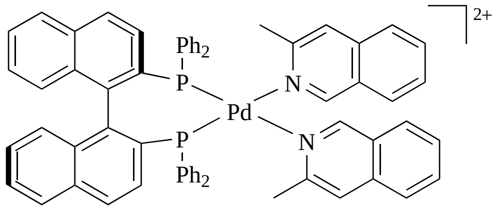
(**47**)

4.3 Restricted Rotation About M-py and M-heteroaryl bonds

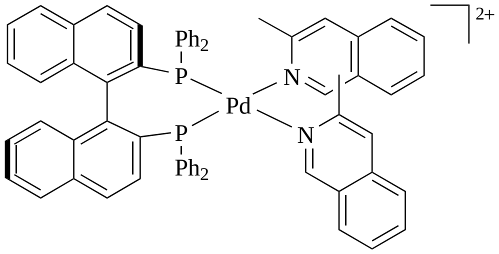
Pyridine complexes can show analogous hindered rotation to that observed with metal–aryl complexes. This has been observed for over 30 years,[203] but recent interest in supramolecular chemistry, particularly by Fujita[203,204] and Stang,[205–209] wherein bipyridyls have been used as linkers has spurred renewed interest in the phenomenon. Several articles on dynamics provide leading references for applications of EXSY and other DNMR methods in these systems.[209–211] BINAP complexes with picolines and methyl-substituted isoquinolines, which show syn and anti isomerism, have been investigated, for example, (**48**), (**49**), and (**50**).[210]



(**48**)



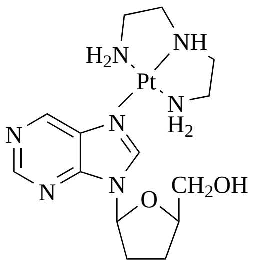
(**49**)



(**50**)

For [(BINAP)Pd(3-picoline)$_2$]$^{2+}$, $\Delta G^{\ddagger} \sim 50\,\text{kJ mol}^{-1}$ was determined for restricted rotation about the Pd–N bonds. The barrier in the analogous platinum complexes were higher, $\Delta G^{\ddagger} \sim 58\,\text{kJ mol}^{-1}$.[210] The general trend is that the barriers for the Pd–N bonds are somewhat lower than those for Pd–C bonds in analogous covalently bonded aryl complexes. This type of phenomena can also be flowed by ^{31}P NMR.[209] It would appear that one of the anti isomers is generally preferred in systems with a chiral bidentate ligand. Barriers are also observed in octahedral complexes and have been studied in ruthenium complexes.[212,213]

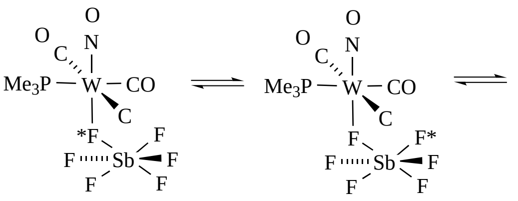
There has also been interest in restricted rotations in adenosine–Pt complexes in which lower temperatures reveal the effects of rotation in complexes such as (**51**).[214] Marzilli[215–217] has been particularly active in the analysis of dynamics of N-donor bioligands, but they have also emphasized studies of octahedral ruthenium complexes. More complicated N-donor ligands can produce multiple processes which can be observed by DNMR and in some cases hindered rotation in pendant rings can be observed.[218–220] There has been a recent review of DNMR methods applied to supramolecular systems.[221]



(**51**)

4.4 End to End Rotation About M-L Single Bonds

In the absence of steric hindrance, one would anticipate a low barrier to rotation about the single bond. The potential, however, exists for that bond to break and reform at another point on the ligand intramolecularly. Although it occurs at rates slower than observable by DNMR, N_2 has been shown to undergo an intramolecular end to end rotation using ^{15}N singly labeled dinitrogen ligand in $CpRe(CO)_2(N_2)$.[222] SIT experiments, however, demonstrated an intramolecular end to end rotation of FHF^- in *trans*-$[(PPh_3)_2Pt(Ph)(FHF)]$ which presumably occurred through a five-coordinate intermediates involving two Pt–F bonds.[223] It is also common for coordinated BF_4^-, PF_6^-, and SbF_6^- to undergo intermolecular end to end rotation or spinning.[224] (see equation 12).



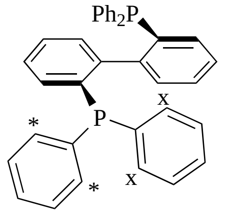
(12)

Our discussion has focused on barriers in the range available *via* the usual DNMR methods. There are specialized approaches that allow determination of lower barriers usually found in most single bond rotations,[225] such as methyl rotation.[113,226,227] Note that investigations of very low barriers involving groups with hydrogen nuclei may need to consider quantum tunneling effects.

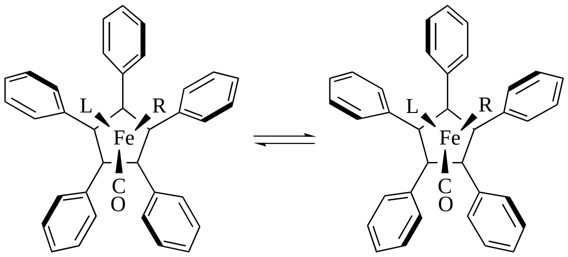
4.5 Hindered C-C Rotation and Atropisomerism

The restricted rotation about C–C bonds in biaryls can allow the isolation of axially chiral complexes that do not racemize (atropisomers) or racemize slowly and this has led to the popularity and the extensive use of ligands such as BINAP. There has also been an interest in ligands with modest barriers to interconversion. In BIPHEP (**52**), the barrier for racemization can be measured by observing the exchange between diastereotopic nuclei in the phenyl groups.[228] This requires higher temperatures and the rotation about the phenyl C–P bonds are rapid at this temperature. Hence, there are separate resonances associated with the ortho protons of the diastereotopic phenyl groups. These average at high temperature yielding a barrier of 102 kJ mol^{-1} for racemization of the biphenyl backbone. The actual measurement was carried out with a sample deuterated in the meta and para positions; however, the barrier could also have been readily determined using ^{13}C DNMR for the ipso or ortho carbon atoms.

Hindered rotation of phenyl groups in planar ligands can also produce propeller chirality. McGlinchey has contributed a large number of publications in this area which are summarized in recent reviews.[229,230] An interesting example is shown in equation (13), where a 3:1 equilibrium of diastereomers in (**53**) is observed at $-100\,°$C and the DNMR of ligand ($L = Me_2PPh$) resonances allow determination of the epimerization barrier ($\Delta G^\ddagger = 49$ kJ mol^{-1}) involving $C_{Cp}-C_{Ph}$ rotation.[231] Similar processes are also well known for ethyl substituted η^6-arenes and reference to reviews[229,232] for a more complete description.



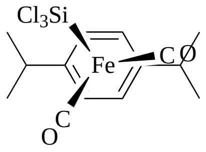
(**52**)



(**53**) *M* (**53**) *P*

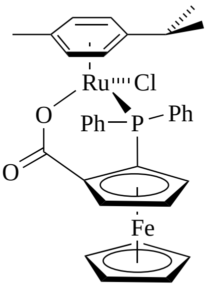
(13)

High degrees of substitution are not required, as restricted rotation has been observed in para-substituted arenes. For example, in $(1,4\text{-}C_6H_4\text{-}Pr^i_2)Fe(CO)(SiCl_3)_2$ (**54**), there are two arene proton resonances observed at $-120\,°$C, indicative of hindered rotation. At $-40\,°$C, they have coalesced to a singlet indicating a barrier of 45 kJ mol^{-1}.[233] *p*-Cymene is frequently used with ruthenium complexes owing to the ready availability of $[(1,4\text{-}C_6H_4Me,Pr^i)RuCl_2]_2$. Hindered rotation of the arene has been observed in (*p*-cymene)Ru(pfc)Cl (**55**).[234] This is particularly important since hindered rotation for the ring produces diastereomers related to arene orientation, which might be mistaken for diastereomers from different configurations at the chiral metal center.[150]



(**54**)

Atropisomers arising from hindered rotation of meso-aryl have been used in studies of metalloporphyrins. Barriers for a series of para and meta aryls in titanyl porphyrins and

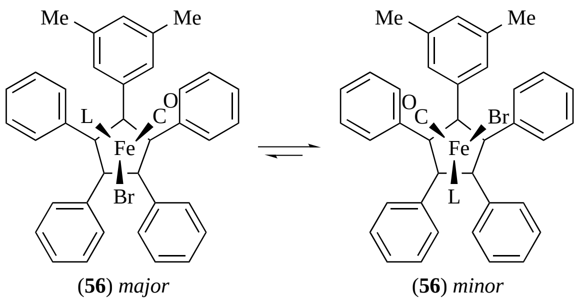


(**55**)

hydroporphyrins range from 61 to 77 kJ mol^{-1}.[233] Reference to this study will provide leading references.

5 HINDERED ROTATIONS OF η^6-ARENES, η^5-CYCLOPENTADIENYL, AND SIMILAR LIGANDS

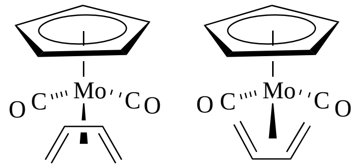
Generally, one expects a very low barrier for rotation of a η^5-cyclopentadienyl ligand. The barrier is sufficiently low that it can rarely be measured in solution. When metals with unpaired electrons are prepared, the EPR can occasionally provide information on low barriers owing to the larger 'chemical shift' separations. In the case of 19-electron (η^5-C_5Ph_4H)$Mo(CO)_2$(bis-diphenylphosphinomaleic anhydride), where the electron resides predominantly on the ligand, the barrier for ring rotation was ~13 kJ mol^{-1} at 25 °C.[234] Suitable substitutions on the rings and metal can raise the barriers to heights sufficient for them to be measured by DNMR. McGlinchey has been very active in this area and reference to his reviews are recommended.[229,230] In the previous example related to phenyl orientation, (**53**), the fluxionality associated with the helical phenyl inversion is not correlated with the tripodal rotation of the Fe(CO)(L)(R) group which has a barrier of 36-kJ mol^{-1} compared to the 49-kJ mol^{-1} for the phenyl rotation. With unsymmetrical substitution of the ring, different rotamers can be observed in complexes such as (**56**), equation (14), at low temperature.[231]



(**56**) *major* (**56**) *minor*

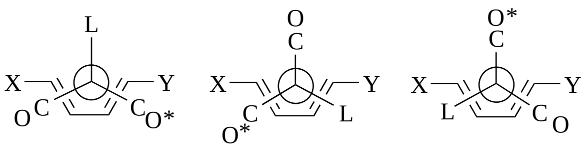
(14)

There have also been extensive studies of a η^4-diene rotation and rotamers that can be observed in complexes of dienes. In Cp complexes, the orientation relative to the Cp ligand gives rise to endo and exo isomers, for example, (**57**) and (**58**), the interconversion of which can be observed by DNMR.[235,236] Interconversions are particularly rapid when the parent structures are nonrigid. Thus the [CpMo(CO)$_2$(η^4-diene)]$^+$ complexes can be considered to be based on a square pyramid and are analogous to CpMo(CO)$_2$LX ligands, which are nonrigid themselves.[237]



(**57**) *exo* (**58**) *endo*

The stereodynamics[238–240] of (η^4-diene)Fe(CO)$_2$L (L = CO, phosphine, or phosphite) complexes are likely to be of importance in understanding the reactivity of the diene moiety, as these complexes are used in several synthetic strategies.[241,242] Theoretical analyses[243,244] have tended to consider the rearrangement in terms of rotation of the Fe(CO)$_2$L fragment relative to the diene. A number of (η^4-enone)Fe(CO)$_2$L complexes have also been investigated.[244,245] Three conformers, (**59**), (**60**), and (**61**), are expected for the unsymmetrically substituted diene complexes and analogous ones are expected for the enone complexes. The relative stabilities of the conformers can be determined by NMR (the ^{13}C for the two carbonyls are different in each conformer) and the rotamer populations are sensitive to substitution. Barriers are ~60 kJ mol^{-1} for these compounds, but one should note that six different $\Delta G^{\ddagger}$'s, as well the free energy differences between conformers, need to be considered. Several publications provide leading references.[243–251]



(**59**) (**60**) (**61**)

In complexes of this type, there is an effective rotation of the 1,3-diene. This should be distinguished from the *apparent* rotation often found for 1,5-dienes, such as COD, in which ligands are interchanged relative to double bonds by M–P or M–N bond rupture with hemilabile ligands (see Section 6).

6 NONRIGIDITY IN HEMILABILE LIGANDS

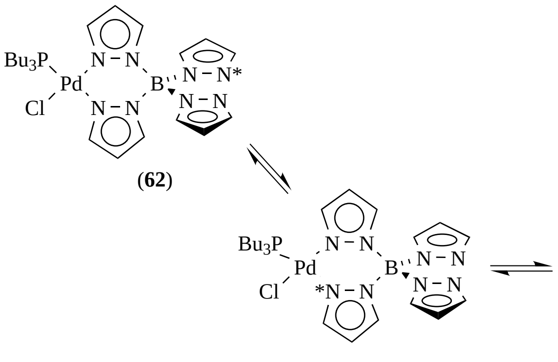
A fundamental aspect of using DNMR to study fluxional or nonrigid systems is that the observed effects should arise from an intramolecular rearrangement. Detection of an intermolecular process is most simply determined by observing resonances of the free ligand and noting whether there is an exchange with the ligand in the complex. With monodentate ligands it is not uncommon that a higher energy process will involve dissociation of a ligand, but lower energy intramolecular processes occur as well. A potential problem of adding free ligand is that a second-order process will start to occur at a sufficient rate that exceeds those of intramolecular processes that, in the absence of excess ligand, would be readily discerned. There tends to be a total focus on relative concentrations of complex and free ligand; whereas, useful important information can be obtained by following the effects of concentration by using dilutions of the solutions. Perhaps the most convenient technique is noting the retention of spin coupling with a ligand when a dynamic process is observed in the absence of an added ligand. This is most commonly used with ^{31}P coupling in phosphines or with metals having observable spin coupling, such as ^{195}Pt, ^{103}Rh, or ^{183}W. Coupling of other ligands to ^{31}P is averaged since when a ligand with a ^{31}P with spin $+1/2$ dissociates a ^{31}P with spin $-1/2$ can return and this produces an average of the components of the doublet arising from coupling to ^{31}P. In this context, one should note that if a ^{31}P with spin $+1/2$ returns, the frequency of the resonance would not change; hence, the coupled nucleus ''would not know that anything had happened.'' Hence, if broadening of a doublet from exchange of ^{31}P is involved, one may need to double the rate constant obtained from equations such as equation (3), to provide a chemically meaningful exchange rate.

If the donor that dissociates is tethered to the complex, for example, a bidentate ligand, then the same nucleus that departs, also returns to the metal so the coupling will be retained. This assumes that more rapid relaxation of the nucleus does not occur when free, which is usually the case. Consequently, unless that free:bound fraction is large (>100:1), there is little evidence that the dissociation is taking place. Thus, when donors are tethered to a complex in some way, it is quite difficult to determine if they dissociate on the NMR timescale.

There has been an increased interest in mixed-donor and hemilabile ligands owing to their successful use in catalysis owing to their electronic asymmetry or ability to provide access to an unsaturated site via dissociation of one of the termini.[252,253] Typical ligands used for catalysis that make use of their hemilability involve a phosphine and an oxygen donor, such as an ether.[254,255] A weak donor, such as an ether (if it binds at all), is relatively easily displaced, and rupture of the M–O bond and retention of the M–P bond is expected to provide an ideal hemilabile system. With *P*,*N*- ligands, either terminus could dissociate preferentially depending upon the hardness of the metal center. Since most of these systems do not involve a significant fraction of dissociated donor, it is difficult to demonstrate that a donor at a given terminus actually dissociates.

6.1 Arm-off Polydentate Ligands for Discerning Hemilability

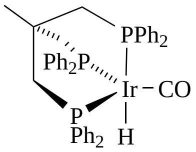
In some mechanistic studies, the relative rates of flexible versus rigid backbone bis- phosphines[256–258] were used to provide indirect evidence for hemilability in bisphosphines. In complexes with a potentially tridentate ligand that is bound by only two donors, interchange of the free and bound donors can demonstrate an intramolecular exchange process and rupture of a given bond. This can be misleading, as the proximity of the tethered free donor (the ''arm-off'' donor) may make an associative process more likely than would occur in an isolated bidentate ligand, particularly in four-coordinate d^8 systems. One might expect that κ^3 – bonding and *fac* complexes would prevail with tridentate ligands, such as Tp, HC(py)$_3$, and MeC(CH$_2$PPh$_2$)$_3$ = triphos. Some square complexes can favor κ^2-bonding with Tp and pz$_4$B$^-$. Taking PdCl(PEt$_3$)(κ^2-pz$_4$B) (**62**) as an example, there are two arm-off pyrazolyls and they show averaging with the bound pyrazolyls.[259,260] In fact, there are two processes observed. Bond rupture is promoted trans to the phosphine so that pyrazolyl broadens and starts to average with the free pyrazolyls before the pyrazolyl trans to the chloride (equation 15). This clearly shows that it is possible to rupture the Pd–N bond in an intramolecular process and the averaging with the arm-off donor allows the process to be detected. One should note that the process of rupture of the bond and the reformation is not detected by this experiment. One measures the rate of the overall process, which also involves the rotation of 3-arm-off pyrazolyl; hence it represents an upper limit of the barrier.



(15)

One might expect triphos to behave in a similar way; however, its most stable form tends to involve κ^3 bonding in a five-coordinate complex. For example, (triphos)Ir(CO)H (**63**) is trigonal bipyramidal with a carbonyl equatorial and the

hydride axial.[261] The ^{31}P spectrum exhibits a singlet at room temperature, but a triplet at -10.1δ and doublet at $-15.8\ \delta$ are observed at $-110\,^{\circ}$C. This does not necessary prove that a $\kappa^3 - \kappa^2 - \kappa^3$ process is involved, since a pseudorotation would also give the same result. Upon raising the temperature to $-80\,^{\circ}$C, however, the -15δ resonance is sharp, whereas the -10.1δ resonance is broad. If this difference in width were not just the consequence of the differences in population (the spectra were not reproduced in the paper), it could be the result of averaging with a fraction of the κ^2 form ($\sim$5% estimated). The faster exchange of that P would follow from the expected greater lability of the phosphorus trans to hydride.

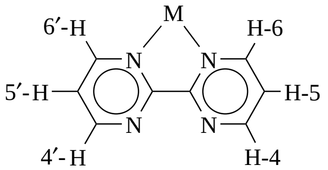


(**63**)

There have been a number of (triphos)Rh complexes that are fluxional and that could rearrange via formation of a κ^2-triphos or via the loss of another ligand.[262–264] In most cases, it is not clear which mechanism is dominant.

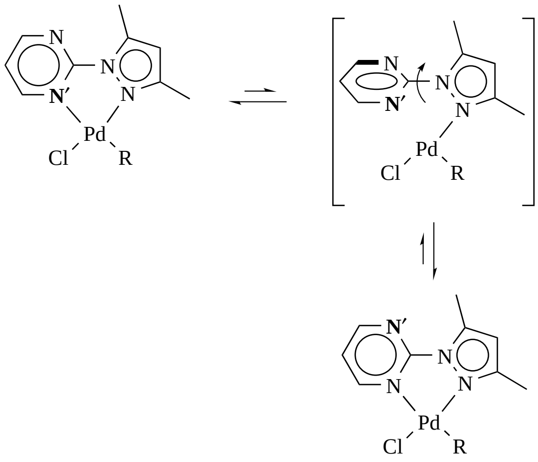
6.2 Pyrimidines and Triazines as Detectors of Hemilability in Analogs of Bipy

Ligand systems with pyrimidines have, in effect, internal ''arm-off'' donors that present less of a problem of potentially increasing the rate of Pd–N bond rupture via a second-order process from the proximate donor. Gogoll and Backvall[265] showed that 2-2′-bipyrimidyl (bpm) (**64**) was useful in this regard. Hence interconversion of the H-4 and H-6 is indicative of Pd–N bond rupture.[265]

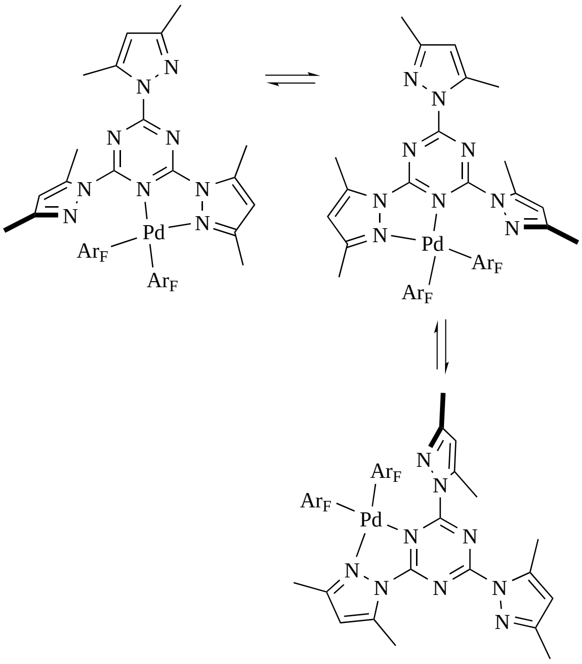


(**64**)

Pyrazolylpyrimidines (pzpm)[266–269] also provide a method for detecting the Pd–N bond rupture (see equation 16). This has been extended to tri-substituted triazines,[270] wherein Pd–N bond rupture can be detected, but which also allows the metal to pass around the entire ligand via a series of (1) metallotropic shifts involving retention of the triazene N–Pd bond and (2) pyrazolyl ligand assisted metal ''hurdling'' from one triazene N to another (see equation 17). The subject of metals shuttling from one nitrogen atom to another has been extensively investigated by Elguero[270,271] and Orrell.[23]



(16)

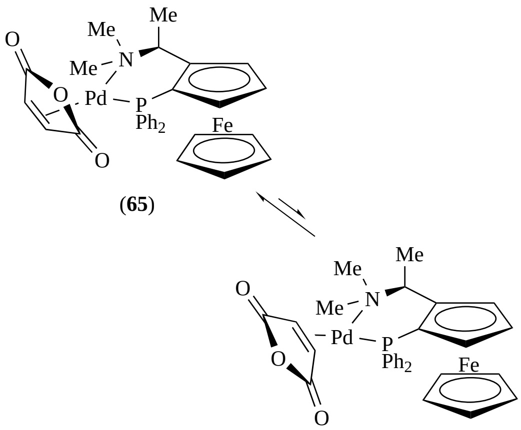


(17)

6.3 Amine Inversion as a Detector of Hemilability

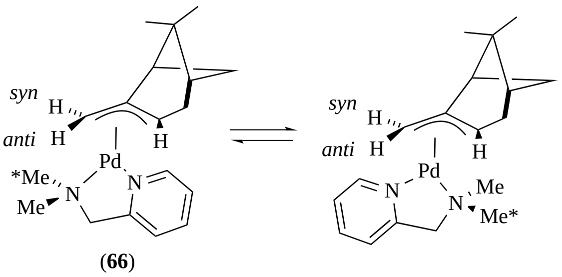
One of the most reliable methods for detecting hemilability is available for ligands with dimethylamino groups as donors. In many cases, the methyl groups will be diastereotopic owing to an unsymmetrical substitution pattern in the complex. If the metal–nitrogen bond ruptures, rapid pyramidal inversion at the nitrogen interchanges the methyl groups and upon reforming the M–N bond, the chemical environments of the methyl groups are interchanged. Thus, even though an intermediate of lower hapticity might only be formed in minute quantity, it provides a pathway for equilibration of environments. (*Note that here again the k derived from equation (3) is one-half of the constant for bond rupture.*) An illustrative example is shown in equation (18), where

a (PTTF)Pd(maleic anhydride) (**65**) shows a process that interconverts a major and minor conformer.[272,273] The methyl groups are diastereotopic in both conformers so that at low temperatures there are four N-methyl resonances. Two sets of the methyl groups exchange as the ligand rotations giving rise to two resonances corresponding the average of those above the coordination plane and those below it. At still higher temperatures (at 100 °C these resonances coalesce to a single broad resonance ($\Delta G^{\ddagger} \sim 73\,\text{kJ mol}^{-1}$)), this averaging of the diastereotopic methyl groups can be attributed to Pd–N bond rupture.



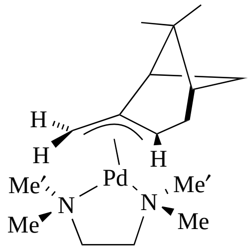
(18)

The *apparent* rotation of the ligands in (η^3-$C_{10}H_{15}$) Pd(Me_2NCH_2py) (**66**) has been investigated using EXSY (equation 19).[267] The important features are that: (1) the anti protons of the allyls exchange among themselves but not with the syn protons between isomers; (2) N-Methyl groups exchange between isomers, *but not within a given isomer*. This requires that the Pd–N bond is not ruptured. The observation can be accommodated by: (1) rupture of the py–N–Pd bond; (2) rotation about the Pd–*N*(Me_2) bond; (3) isomerization within the T-shaped intermediate; and (4) reformation of the py–N–Pd bond. It also can be accommodated by: (1) rupture of the more substituted Pd–allyl bond; (2) rotation about the Pd–*C*H_2 bond; (3) isomerization within the T-shaped intermediate; and (4) reformation of the allyl–Pd bond. Thus, this experiment shows that neither the Pd–*C*H_2 nor Pd–*N*Me_2 is broken in the process.



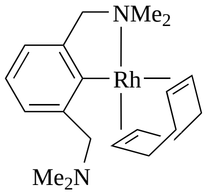
(19)

The *apparent* rotation of the ligands in (η^3-$C_{10}H_{15}$) Pd(TMEDA) (**67**) was also investigated using EXSY spectra.[265] The methyl groups were assigned using NOE experiments. Methyl groups on different nitrogen atoms were exchanging at 25 °C but not those on the same nitrogen atom. This was then consistent with cleavage of the Pd−allyl carbon bond, but showed that the Pd–N bonds did not rupture in the process. At higher temperatures, however, all four methyls showed mutual exchange. Addition of chloride increased the rate of exchange and, at −15 °C, exchange of the methyl groups on the same nitrogen occurred rapidly. This suggests that the chloride can promote Pd–N bond rupture and is consistent with the formation of a four-coordinate arm-off TMEDA complex.



(**67**)

Studies of arm-off (COD)Rh[2,2′-$C_6H_3(CH_2NMe_2)_2$] (**68**) have also suggested interconversion proceeds *via* a T-shaped three-coordinate intermediate.[274] Other *apparent* rotations observed in $[(COD)Rh(bidentate)]^+$ complexes appear to via breaking of Pd–N or Pd–P bonds.[275]



(**68**)

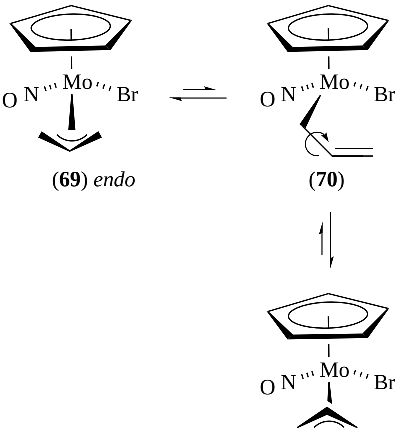
7 ALLYL REARRANGEMENTS

Allyl complexes were amongst the earliest studied nonrigid complexes, and there are a number of reviews on their rearrangements.[13,276,277] Interest has been particularly high owing to their importance in catalysis[277] and synthesis,[278] with palladium and molybdenum complexes playing leading roles.

$CpMo(CO)_2(\eta^3$-allyl) complexes show a planar allyl rotation analogous to that found for the diene in $[CpMo(CO)_2(\eta^4$-diene$)]^+$ complexes.[279] Endo−exo isomerism is observed and interconversion occurs rapidly at room temperature

($\Delta G^{\ddagger}_{endo\rightarrow exo} = 63.5\,\mathrm{kJ\,mol^{-1}}$). In the electronically asymmetric complex [CpMo(CO)(NO)(η^3-allyl)]$^+$, however, this barrier increases dramatically to $\Delta G^{\ddagger}_{endo\rightarrow exo} = 94\,\mathrm{kJ\,mol^{-1}}$. This corresponds to an increase in room temperature half-life for interconversion of 10^{-2} s to 4×10^{3} s; nevertheless, the principal path for interconversion is still a planar rotation.[280]

In the halide derivatives, for example, CpMo(NO)(Br)(η^3-allyl), however, an $\eta^3-\eta^1-\eta^3$ or $\pi-\sigma-\pi$ rearrangement is the lowest energy path for endo–exo interconversion. These complexes show 'static' NMR spectra at ambient temperature and the temperature must be raised to observe broadening; $\Delta G^{\ddagger}_{endo\rightarrow exo} = 81.5\,\mathrm{kJ\,mol^{-1}}$ for CpMo(NO)(Br)(η^3-C_3H_5) (equation 20). Thus, when enantiomerically pure CpMo(NO)(X)(η^3-allyl)-type complexes are isolated, they do not racemize on a timescale of days, even though they are rearranging on a timescale of seconds. Another feature is that the electronic symmetry at the metal results in the σ-bond only being formed cis to the nitrosyl, as in (**70**). This has proven useful since the coordinatively unsaturated intermediate can bind to aldehydes and then go on to react to give homoallyllic alcohols in high enantiomeric purity.[281–284]



(**69**) *endo* (**70**) (**71**) *exo*

(20)

Virtually all of the stereochemical nonrigidity of the allyls in square-planar (η^3-allyl)Pd^{II} complexes derives from $\pi-\sigma-\pi$ rearrangements rather than rotation. There are, however, *apparent rotations* which derive from hemilability of the nonallyl ligands rather than the allyl,[265,277,285,286] as was observed for other complexes (Section 6). In most cases, there is not a large preference for the σ-bond to form at one terminus or the other. Large trans effects from the other ligands in unsymmetrical (η^3-allyl)PdXY can produce a modest preference for breaking of the Pd-π-bond trans to one of the ligands.

In cases with similar trans-effect ligands, substituents on the terminus reduce the rate of σ-bond formation at the substituted terminus. Thus, one can expect an increase of 4–12 $\mathrm{kJ\,mol^{-1}}$ in $\Delta G^{\ddagger}$ per methyl substituent.[287] Two effects tend to produce a $\Delta\Delta G^{\ddagger}$ for σ-bond formation at the different termini of $\approx$20 $\mathrm{kJ\,mol^{-1}}$ in 1,1-dimethyl-substituted allyls: (1) the stability order of 1° > 2° > 3° M–C bond and (2) the decreased stability of π-M–C bonds on substitution. Hence, one would generally expect the ease of formation of the σ-bonded intermediate at the unsubstituted terminus to increase in the order 1,1-dimethylallyl < 1-methylallyl < allyl.

Another feature that is crucial in considering $\eta^3-\eta^1-\eta^3$ rearrangements in monosubstituted allyls is the effect on the chirality and stereochemistry. In crotyl complexes, formation of a σ-bond at the unsubstituted terminus provides a path for racemization for the stereogenic center at the substituted terminus (equation 21). Formation of the σ-bond at the monosubstituted terminus, however, results in conversion to a different isomer (equation 22). The most stable isomer is the syn isomer (**72**) and, in the absence of a substituent on the central carbon, the anti isomer (**74**) will only occur to the extent of $\approx$5%. Thus if one considers complexes like (acac)Pd(allyl), some racemize, whereas others only isomerize because there is no path for racemization (equation 23).[288] These concepts have been used effectively by Bosnich in the design of systems for asymmetric allylic alkylation.[289] These concepts also allow the rationalization of why certain substrates give low enantiomeric yields. It should be noted here that the planar rotation found in some of the molybdenum complexes retains the chirality in the allyl moiety.

(23)

Exchange of the ligands in XYPd(allyl) can give the appearance of rotation of the allyl.[265,277,285,286] Although rearrangements in many allyl–Pd and – Rh complexes meet

the requirement for intramolecularity to be classified as fluxional or stereochemically nonrigid, there are a number of intermolecular processes which can give rise to DNMR spectra. Multiple paths, some of which are second order, have been found in the palladium allyl systems.[276,283]

8 HAPTOTROPIC REARRANGEMENTS IN RINGS

The movement of metals about five-, seven-, and eight-membered rings has been studied extensively since the 1970s. Often, the lowest barrier process involves the metal migrating about on one side of the ring and moving to the immediately adjacent position, as seen with $(C_7H_7)Ru(CO)_3$ (**77**) (equation 24) and as discussed earlier for $CpFe(CO)_2(\eta^1\text{-}C_5H_5)$ (equation 2). Theoretical interest in these rearrangements[290,291] increased together with the study of sigmatropic rearrangements in organic chemistry in the 1970s and early- 1980s, so that early reviews are still the most comprehensive.[10,13] There was sufficient activity in the area that one review was devoted solely to η^1-Cp compounds with main group elements.[292] Fortunately, there has been a recent review which provides coverage up to 2000.[293] Several recent reports also provide some leading references.[294–296] The migration around the rings led to the slang term ‘‘ring whizzers’’, but *haptotropic* appears to be currently popular. Although (**77**) migrates via a series of 1,2-shifts, other substituents on the metals can make other processes feasible.[294] There is an interesting class of compounds that contain two migrating groups (*diatropic*) where a metal migrates on one side of a ring while a second group migrates on the other. A 1,2-shift of the iron accompanied by a shift of the boron in (**78**) is the lowest energy process ($E_a = 71\ \text{kJ mol}^{-1}$), but other migrations occur at higher temperature.[295] Although the Sn moiety migrates rapidly in $(C_7H_7)SnPh_3$ via a 1,4-shift, in the chromium tricarbonyl analogue (**79**) that migration path is blocked; nevertheless, a slower 1,3-shift of Sn occurs along with a 1,2-shift of Cr was observed by SST.[296] Owing to recent interest in chiral organometallics, these rearrangements that restrict the metal to one side of the ring or produce populations of isomers relative to specific substituents can become important. For example, the migrations observed in (η^1-indenyl) complexes result in racemization (equation 25). Generally one expects the metal to be restricted to one side of the ring; however, the results observed by Gladysz[97] for olefins and Harman[109] with aromatics indicate that there is a real possibility of migration to the opposite face via an agostic C–H intermediate.

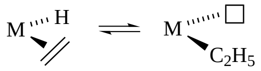
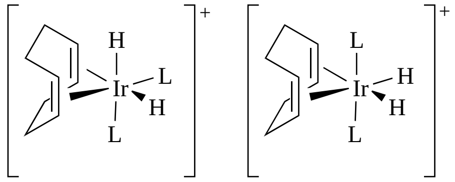
9 HYDRIDE–ALKENE COMPLEXES AND AGOSTIC INTERACTIONS

One of the most important reactions in organometallic chemistry is the *Insertion* of an alkene into a metal–hydride bond and its reverse, *β-Hydride Elimination* (equation 26). Brookhart has carried out extensive studies in this area where the process can be studied by DNMR.[297]



(26)



(**80**) (**81**)

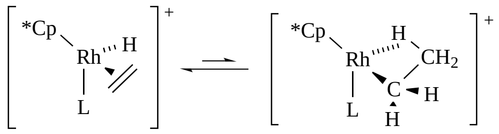
9.1 Hydride–Alkene Complexes

The hydride must be in the proper orientation relative to the alkene in order for it to insert. Thus, if the hydride is trans to the alkene or if it is cis to the alkene and the metal–H bond cannot get oriented properly to the C–C axis, it will not insert. Thus, the cis–cis isomer (**80**) allows insertion more readily than the cis–trans isomer (**81**) of $[(cod)(PPh_3)IrH_2]^+$.[298] Hydride migration was observed as early as 1971,[299] but the most interesting simple cases are those discovered by Werner[300,301] and developed by Brookhart,[302–304] that is, $[Cp^*Rh(L)(ethylene)(H)]^+$. For $L = (MeO)_3P$, the propeller rotation of the ethylene occurs with a barrier of $\approx 40\ \text{kJ mol}^{-1}$. Note that the rotation averages the ^{13}C resonances of the alkene, but since the Rh is chiral, the protons are diastereotopic and two sets average independently. At higher temperatures, however, the alkene protons average with the hydride,

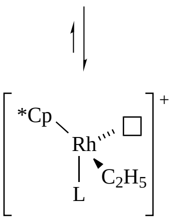
indicating a $\Delta G^{\ddagger}_{234} = 50.2\,\text{kJ mol}^{-1}$ for the β-migratory insertion.

9.2 Agostic Ethyl Complexes

For a wide range of phosphite and phosphine ligands in the $[\text{Cp}^*\text{Rh(L)(ethylene)(H)}]^+$ system, the stable structure is that of the terminal alkene hydride (**82**); however, stereochemical nonrigidity is observed. One would presume that there is a transition state in which the hydride being transferred is attached to both the metal and the alkene (**83**) (equation 27). When viewed as a metal interaction with the C–H σ-bond in the ethyl complex this is termed an *agostic interaction*. When L is another alkene rather than a phosphine or phosphite, however, the agostic complex is the ground state, as shown in equation (28). Thus, $[\text{Cp}^*\text{Rh(ethylene)}_2\text{H}]^+$ (**85**) is a transition state or intermediate in the stereochemical nonrigidity exhibited by $[\text{Cp}^*\text{Rh(ethylene)(CH}_2\text{CH}_2\text{-}\mu\text{-H)}]^+$ (**86**). The agostic hydrogen is readily characterized in these complexes by a reduced $^1J(^{13}\text{C}-^1\text{H})$ compared to that found in other Rh–alkene complexes and a reduced $^1J(^{103}\text{Rh}-^1\text{H})$ compared to a terminal rhodium hydride.

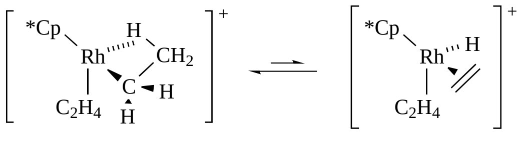


(**82**) (**83**)



(27)

(**84**)



(28)

(**85**) (**86**)

The conversion from agostic hydride to terminal hydride occurs with a $\Delta G^{\ddagger} < 15\,\text{kJ mol}^{-1}$. Averaging of the agostic hydride with the other protons of the methyl in the ethyl group occurs with a $\Delta G^{\ddagger} = 35.5\,\text{kJ mol}^{-1}$ and apparently occurs via opening of $[\text{Cp}^*\text{Rh(ethylene)(CH}_2\text{CH}_2\text{-}\mu\text{-H)}]^+$ to a normal ethyl complex $[\text{Cp}^*\text{Rh(ethylene)(CH}_2\text{CH}_3)]^+$ (**51**) having a low barrier to rotation of the methyl group. An 'in place' rotation of the agostic methyl could also occur.[304] This process only equilibrates the hydride with the methylene protons proximal to the hydride; ethylene rotation allows equilibration with both ends of the alkene.

9.3 Other Agostic Complexes

One would anticipate an analogous situation with allyl hydrides and propene complexes. Indeed, one can find allyl hydrides, propene complexes, agostic propene, propene hydrides, and isopropyl complexes. Green[36,58] has effectively reviewed this area in his analysis of the evaluation of rate constants in these systems. Substantial effort is required to examine the possible factors relating exchange rates.[58] Again it is necessary to be quite careful to delineate rate and rate constant, since mass balance requires the forward and reverse rates between two sites of different population to be the same, whereas the rate constants are proportional to reciprocal populations. The reader is referred to the original literature[36,58] for an exposition on the difficulties which can arise. Diene hydrides also show similar agostic systems for which a study by Bennett and Brookhart provides an excellent review of the literature in this area.[305]

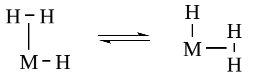
10 HYDRIDE AND DIHYDROGEN COMPLEX EQUILIBRIA

Metal hydrides were among the earliest fluxional compounds to be studied. The more recent discovery of dihydrogen complexes and stereochemical nonrigidity in complexes containing both hydride and dihydrogen ligands has provided one of the areas of most intense interest in DNMR in recent years.[306–311]

Hydrides in complexes with coordination numbers of five and higher often show fluxional characteristics typical of other nonrigid complexes,[21] such as Fe(CO)_5 (equation 1). This area has been reviewed previously.[20,306–311] A feature that was not appreciated originally was that some ''polyhydrides'' actually existed as hydride–dihydrogen complexes. Extraordinarily stable dihydrogen ligands can be found with cationic complexes such as $[\text{Cp}^*\text{Ru(dppm)H}_2]^+$ (ddpm = $\text{Ph}_2\text{PCH}_2\text{PPh}_2$).[312] This complex has an H–H bond length ($r_{\text{HH}} = 1.10$ Å) intermediate between that found in more weakly bound H_2 complexes ($r_{\text{HH}} < 1.00$ Å) and dihydrides ($r_{\text{HH}} >\simeq 1.50$ Å). The inverse correlation of J_{HD} and bond length has been used as a convenient measure r_{HH}, for example, $J_{\text{HD}} = 21$ Hz for $[\text{Cp}^*\text{Ru(dppm)H}_2]^+$.

In the case of hydride–dihydrogen complexes, one can observe stereochemical nonrigidity wherein the effects of scrambling of the nuclei between the hydride and dihydrogen ligands can be observed (equation 29). The first example of this was reported by Crabtree[313] for $[(\text{benzoquinolyl})(\text{PPh}_3)_2\text{Ir(H}_2)(\text{H})]^+$. In most cases it appears that the mechanism involves the formation of a very low

concentration intermediate of trihydride, but the formation of an η^3-H_3 intermediate has been also suggested. The observation of temperature-dependent averaged J_{H-D} couplings are indications that an intermediate in modest concentration is formed in some cases, for example, $[(diphos)_2Os(H_2)(H)]^+$.[314] Both $[(CO)L_3ReH_4]^+$ and $[(CO)L_3ReH_2(\eta^2\text{-}H_2)]^+$ tautomers can be observed, and thus the mechanism of interconversion can be studied.[315] Perhaps the most comprehensive study of a single complex has been that of $L_3Fe(H)_2(\eta^2\text{-}H_2)$. This study encompasses theory and provides leading references.[316]



(29)

One should note that in these complexes there are multiple nonrigid processes: (1) the dihydrogen undergoes either a tunneling or spinning motion, with a low barrier (4–8 kJ mol^{-1}); (2) the parent seven-, eight-, or nine-coordinate structures are often fluxional themselves; and (3) hydride–dihydrogen equilibria occur. These studies are often complicated by several factors other than those discussed in earlier sections. The short H–H bonds in the dihydrogen complexes give rise to short T_1 relaxation times from dipolar effects. This can cause difficulties in spin saturation transfer experiments, as well as in-line shape analysis, owing to the effect on T_2, that is, it produces inherently broad natural line-widths, which are temperature dependent. In T_1 determinations, exchange with hydrides (SIT) can artificially lengthen the observed T_1. Furthermore, the effects of quadrupolar nuclei cannot always be ignored (this is particularly true with Re, Mn, and Co complexes). Finally, some trihydride species can give rise to bizarre quantum mechanical exchange phenomena which produce incredibly large couplings between the hydrogen nuclei.[317,318]

11 SIX-COORDINATION AND NONRIGIDITY

Just as one found that $Fe(CO)_5$ is fluxional (equation 1), one anticipates that most five-coordinate structures including hydrides would be fluxional. As expected, early ^1H and ^{31}P NMR studies showed that $HRhL_4$ complexes were fluxional.[306] For metals coordinated by seven or more ligands, stereochemical nonrigidity is generally observed. Although ML_7 compounds typically have barriers <17 kJ mol^{-1},[319] DNMR can be observed in pseudo-seven-coordinate complexes,[237] for example, $CpMo(CO)_2LH$ (assuming Cp occupies three coordination positions). As the coordination number increases, the number of possible rearrangement mechanisms increases and low barriers for fluxionality are the norm. The 'rotation of polyhedral faces' is a convenient starting point, but alternatives involving conversions of triangular faces to diamonds or squares have been suggested. The two or more environments expected for protons in ReH_9^{2-}, ReH_8L^-, and ReH_7L_2 have not been observed. With chelating tridentate phosphines, however, the tungsten analogs $W(L_3)H_6$ have yielded multiple barrier processes showing sequential averaging of environments (≈29 kJ mol^{-1} and 42 kJ mol^{-1}).[320] The complexes not only have the many rearrangement paths available for nine-coordinate complexes, but also have those available in lower coordination numbers by formation of eight- or seven-coordinate transient intermediates containing dihydrogen.

Most six-coordinate structures would be expected to be rigid. Isomerization rates of *cis* to *trans* $M(^{13}CO)(CO)_4(L)$ (M = Cr, W) are over 100 kJ mol^{-1} and the reactions are intramolecular, with the kinetics of the tungsten compound suggesting an internal twist mechanism for this higher barrier process.[321] Nevertheless, some six-coordinate dihydrides of iron and ruthenium show stereochemically nonrigid behavior.[322] For example, a low-temperature limiting spectrum is observed at −50 °C for $Fe[PPh(OEt)_2]_4H_2$ and shows both cis and trans isomers. Hydride–dihydrogen equilbria which allows conversion to five-coordination could also rationalize the low barriers for some octahedral dihydrides.[322] SST experiments have also indicated a dihydride intermediate in rearrangements of pseudooctahedral $Re(CO)(NO)L_2(H_2)$.[323]

Fluxionality has also been observed in chelated octahedral complexes.[21,324,325] In some cases, this can be attributed to hemilability of the ligands and rearrangement of a five-coordinate intermediate. Dithiolene chelates are an exception and tend to exist as trigonal prismatic compounds, but are still nonrigid.[326] One of the most interesting octahedral systems, where five-coordinate intermediates are less likely, involves the fluxionality of $Fe(CO)_4(SiMe_3)_2$ and the $Fe(CO)_4(SnMe_3)_2$ analogue.[327] Interestingly, $Fe(CO)_4(BCat)_2$, where BCat = $BO_2C_6H_3$-4-*t*-Bu, and $Fe(CO)_4(BCat)(SnMe_3)$ appear to be rigid at room temperature.[328]

12 KETONE AND ALDEHYDE COMPLEXES

The binding of organic carbonyl compounds to Lewis acids has a dramatic effect on the rates and selectivities of reactions at the carbonyl center. The use of organometallic Lewis acid centers promises to have significant advantages in catalysis of reactions of ketones and aldehydes.[329,330] Electronically asymmetric systems, such as $[CpRe(NO)(PPh_3)]^+$, provide preferred orientations (**87**) and (**88**) as a consequence of overlap of the *d* orbital HOMO (**25**) with the acceptor π^*-orbitals of the carbonyl. Unfavorable interactions with the Cp ring make the conformer with a N–Re–O–C torsion angle ≈0° significantly more favorable energetically.[331,332] Another

feature, however, is a process by which the metal effectively migrates 'from one lone pair to the other' (equation 13). This might be considered as inversion of the lone pair or rehybridization of the orbitals as the metal moves. The barrier for this interconversion is quite low. There are relatively few examples where DNMR could be used to analyze this barrier. Decoalescence of the methyls in *trans*-Cl_2(py)Pt(η^1-O=CMe_2) by ^{1}H and ^{13}C NMR[333] gives a $\Delta G^{\ddagger}_{199}$ of $\approx$40 kJ mol^{-1}. An even lower estimated $\Delta G^{\ddagger}_{199}$ of 25 kJ mol^{-1} is found from a T_c of $-140\,°$C in the ^{13}C NMR for ^{13}C-enriched [CpRe(NO)(PPh_3)(O=CMe_2)]$^+$.[332] Although most strong Lewis acids tend to bind ketones as η^1 species, Harman showed in 2001, that TpRe(CO)(L) systems bind the ketones as η^2 species and thus tend to orient them as found with olefins in Section 2.

(**88**)

13 COMMENTS

This review has emphasized selected topics that illustrate principles rather than enumerating examples. Many topics of current interest, such as carbonyl rearrangements, metal–carbonyl cluster rearrangements, and naked metal-cluster rearrangements, were not covered. Topics were selected to illustrate the importance of stereochemical nonrigidity in reactivity and the potential for affecting stereochemistry in reaction products. Table 2 provides a brief list of sources for leading references for some additional topics. The reader is referred to earlier reviews for more comprehensive coverage.[10,13,19–24,306,310]

Equation (31) illustrates fluxionality in a bimetallic compound with a conventional ligand having an unusual bonding mode.[334] This provides a caveat regarding the potential for unexpected intermediates and the real need to consider other modes of binding when considering bidentate chelates. Biphep, BINAP, and similar ligands, for example, have shown bidentate binding modes that involve *P*,*C* rather than *P*,*P* coordination.[363–370]

Table 2 Leading references for additional selected topics on stereochemically nonrigid molecules

(31)

For those planning the use DNMR to evaluate barriers, the evaluations of sources of error covered in Section 1.1 and other published articles should be consulted.[16,36,37,42,43] A caveat to consider the definition of rate constant carefully is in order.[16,39] The author recommends the use of equation (3) and substitution into the Eyring equation as the most reliable method for obtaining an experimental value for $\Delta G^{\ddagger}$. Owing to the large errors, which can arise, the use of coalescence temperatures and rate expressions at T_c should be avoided at all costs. As primitive as it may seem, reference to Table 1 can provide a fairly accurate value for $\Delta G^{\ddagger}$ in most cases.

1 INTRODUCTION

One of the major challenges to the solid-state chemist is the prediction of the properties of a material given its chemical formula. As examples of how poor present methodology is in this area, consider the following two cases. Was it possible to predict the crystal structure and properties of $YBa_2Cu_3O_7$ and $Nd_2Fe_{14}B$ before these two materials were synthesized? The structure of the first could perhaps have been anticipated from our knowledge of oxide chemistry (it has a defect perovskite structure), but the fact that it is a 95 K superconductor could not. For the second example, probably neither its structure nor its very interesting and commercially important magnetic properties could have been predicted before its synthesis and characterization. In a closely related problem, one is also constantly searching for new ways to classify and organize the properties of systems that are already known. Perhaps the largest area of activity has been in studies that attempt to organize and understand the crystal structures of known compounds. Pauling summarized[1] the ideas current in the structural chemical world in 1929 with his seminal paper containing a set of rules. Laves listed some more qualitative considerations as to how atoms pack in solids.[2] The first Pauling rule introduced the concept of an ionic radius and the idea of a coordination environment that is set by the ratio of anion to cation radii, r_+/r_-. Certain critical values, $(r_+/r_-)_{crit}$, delineate the boundaries between four and six and between six and eight coordination. One way of exploring the validity of such an idea is shown[3] in Figure 1, a plot of pairs (r_+, r_-) and a symbol that identifies the lowest energy crystal structure. The database used is the collection of binary octet systems AB that are found in the B1 (rocksalt), B2 (CsCl), B3 (sphalerite or zincblende), or B4 (wurtzite) structure types. This is an example of a structure map that uses the values of r_+ and r_- as indices. In fact, as may be seen, although examples with higher coordination numbers are associated in general with larger values of r_+/r_-, the quantitative separation of structures using the solid lines, $(r_+/r_-)_{crit}$ of Pauling's theory, is poor. A better separation is obtained by employing a Mendeleevian philosophy, by drawing the boundaries (the dashed lines) between one structure type and another without regard for any preconceived theory. This article will show the utility of such ideas in crystal chemistry, and will highlight the type of index that needs to be employed to accurately sort the properties of systems from each other. Many of the examples will be structure maps in that structures are being delineated, but other properties such as heats of formation and reaction, and other materials properties, will be discussed as well. Firstly, it is worthwhile to review the types of crystal structures adopted by inorganic solids.

2 CRYSTAL SYMMETRY OF INORGANIC SOLIDS

For crystal symmetry analysis, inorganics can be divided into two: compounds of ternary and higher oxides and compounds containing halides and noble gases are classed as inorganics, and the remainder are classed as intermetallics. One of Laves' principles[2] states that structures aim at the highest symmetry. Figure 2 shows the distribution of compounds by crystal system.[4,5]

The crystal symmetry population patterns for inorganics and intermetallics are different. For inorganic compounds, 50% fall into biaxial crystal systems (anorthic, monoclinic, and orthorhombic); for intermetallics this is 22%. The distribution of compounds by crystal symmetry class for inorganics and intermetallics is about the same (Figure 3). Sixty percent of inorganics belong to the following eight crystal symmetry classes: 2, 5, 7, 8, 15, 20, 27, and 32. For intermetallics, 70% of the compounds fall into seven crystal symmetry classes: 5, 8, 15, 20, 27, 31, and 32. In both cases, these classes belong to the highest symmetry class of the crystal system: (The highest symmetry classes for each crystal system are: $2 = \bar{1}$ anorthic, $5 = 2/m$ monoclinic, $7 = mm2$ orthorhombic, $8 = mmm$ orthorhombic, $15 = 4/mmm$ tetragonal, $20 = \bar{3}m$ rhombohedral, $27 = 6/mmm$ hexagonal, $31 = \bar{4}3m$ cubic, $32 = m3m$ cubic.)

Over 75% of inorganics and 95% of intermetallics crystallize in crystal structures having 90° and 120° interaxial angles of the unit cell. The residual compounds for inorganics are mainly oxides, halides, and sulfides, while those for the intermetallics are Se, Te, and S compounds. These compounds represent the 'boundary' compounds between the inorganics and the intermetallics.

Space group statistics for inorganic compounds (Figure 4(a)) show that 33% crystallize in eight space groups:

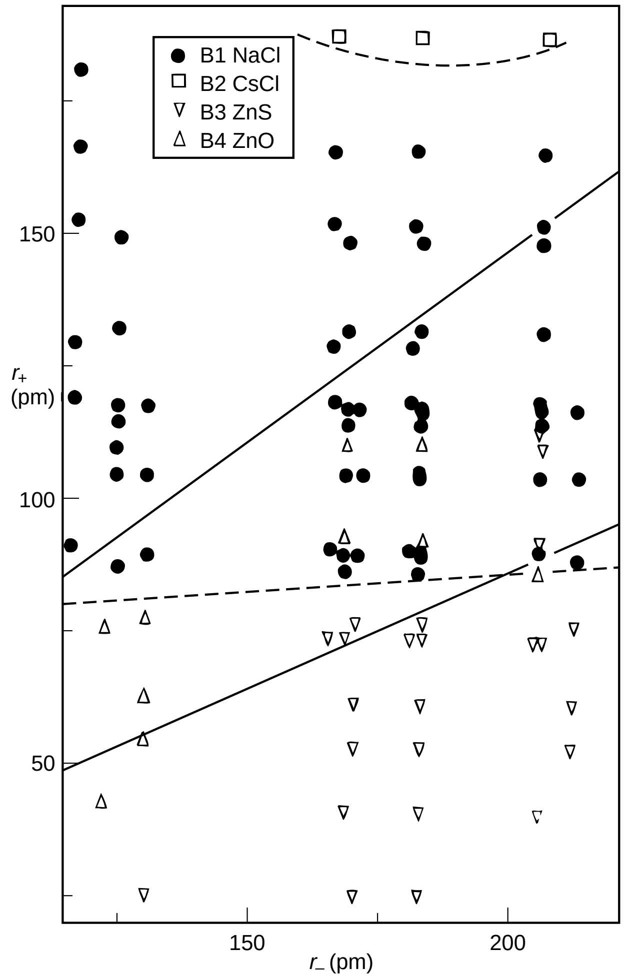

Figure 1 A structure map for the AB octets using the crystal radii, $r_\pm$, as indices

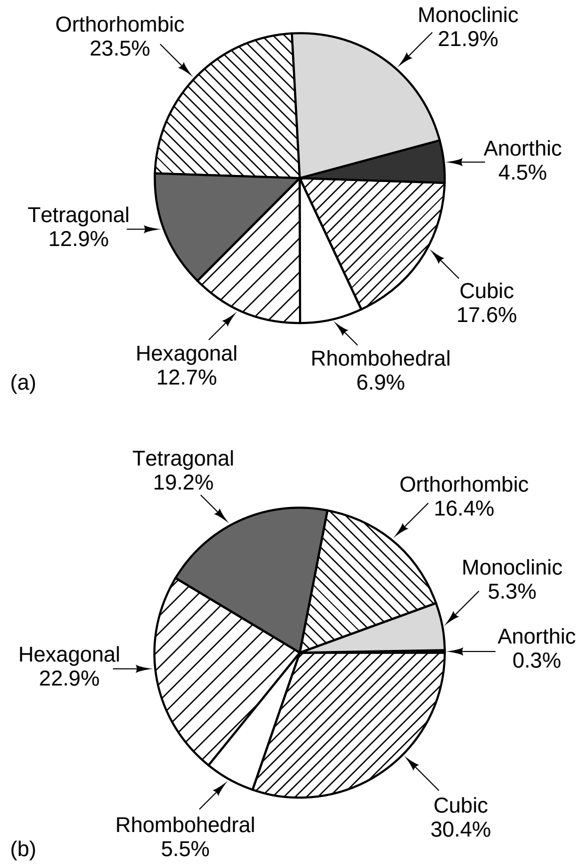

Figure 2 Distribution of compounds by crystal system for (a) inorganics and (b) intermetallics

2 ($P\bar{1}$), 12 ($C2/m$), 14 ($P2_1/c$), 15 ($C2/c$), 62 (*Pnma*), 194 ($P6_3/mmc$), 225 ($Fm3m$), and 227 ($Fd3m$), while those for intermetallics (Figure 4(b)) show that over 50% of all intermetallic compounds crystallize in the following eight space groups: 62 (*Pnma*), 139 ($I4/mmm$), 166 ($R\bar{3}m$), 191 ($P6/mmm$), 194 ($P6_3/mmc$), 221 ($Pm\bar{3}m$), 225 ($Fm\bar{3}m$), and 227 ($Fd\bar{3}m$).

For both classes of compounds (inorganics and intermetallics), their seven and eight space groups represent 3.0% and 3.5% of all 230 space groups, respectively. Each of the remaining space groups (223, 222) has less than 2%, most of them having a frequency of less than 1%. The only lower symmetry space group that is preferred for both classes is space group *Pnma* (Figure 4(b)).

The distribution of unaries (chemical elements) by their crystal systems is shown in Figure 5(a). Similar distributions of crystal systems for intermetallics are shown for binary, ternary, and quaternary compounds (Figures 5(b–d)). These figures show that for intermetallics, in the first approximation, alloying additional different elements to unaries, which then moves them to binaries, ternaries, and so on, does not significantly change the symmetry distribution.

3 THE CHOICE OF INDICES AND STRUCTURE MAPS

Much of the textbook organization of chemical properties relies heavily on the classification of the elements themselves as arranged in the periodic table. Thus, one useful set of indices is one that strings the elements together in a way that reflects this. Pettifor's index[6] makes use of the periodic classification and Figure 6 shows how the string is threaded. Figure 7 shows the separation[7] of the structures of the AB binaries using this index for both A and B. Of course, the 'Periodic Table' index includes in it details such as electron count, orbital ionization energy, ionic size, and so on, and indeed all properties that vary systematically in this way.

The first structure maps designed to sort the structures of solids did not use the concept of size per se, but used two different indices, those of AB electronegativity difference

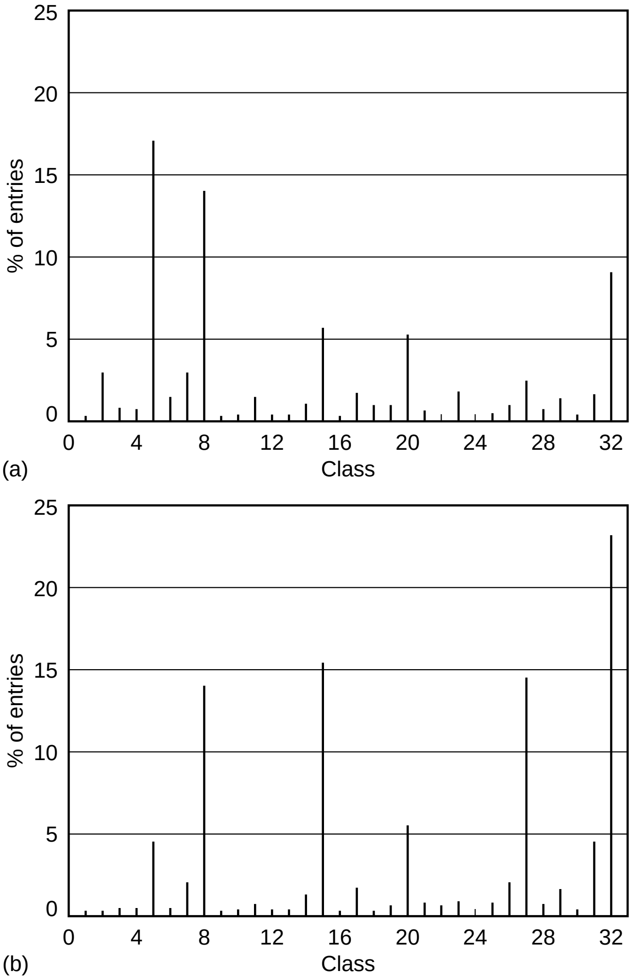

Figure 3 Distribution of compounds by crystal symmetry class for (a) inorganics and (b) intermetallics

($\Delta\chi$) and the average, $\tilde{n}$, of the principal quantum number, n, of the valence electrons on the A, B atoms. Two of these Mooser–Pearson diagrams[8] are shown in Figures 8 and 9. Notice that for the AB octets such indices sort the structures of the three different coordination number structures from each other well, and also separate the wurtzite structure from the sphalerite structure. The wurtzite structure is found for the more ionic examples.

The strikingly successful structure map for the octets of Phillips and van Vechten[9] used two indices that were derived from measured spectroscopic properties of solids. A virtually perfect separation for these materials was achieved by dividing the experimentally measured band gap into two parts that reflect chemical bonding ideas, namely, into 'covalent' (E_c) and 'ionic' (E_i) contributions. In order to understand the origin of the division, it is necessary to briefly examine the broad contributions to such energy gaps from simple orbital considerations. Consider the molecular orbital diagram of Figure 11 for a diatomic molecule (perhaps the hypothetical HHe species) in which one atom is more electronegative than the other. This implies that the α values (using the language of Hückel theory) of the 1s orbitals are not the same. A secular determinant needs to be solved to obtain the energy levels of the molecule. This is shown in equation (1), where β is the interaction integral between the orbitals on adjacent atoms.

$$\begin{vmatrix} \alpha_1 - E & \beta \\ \beta & \alpha_2 - E \end{vmatrix} = 0 \qquad (1)$$

The roots of this determinant are $E \approx [(\alpha_1 + \alpha_2) \pm ((\alpha_1 - \alpha_2)^2 + 4\beta^2)^{1/2}]/2$. If Δ is written as the energy difference between bonding and antibonding levels, then this expression leads to the relationship $\Delta^2 = (\Delta E)^2 + 4\beta^2$. For the homonuclear case where $\Delta E = 0$, then $\Delta = 2\beta$. In the extended solid with energy bands rather than two individual levels, Δ is some average excitation from the bonding to

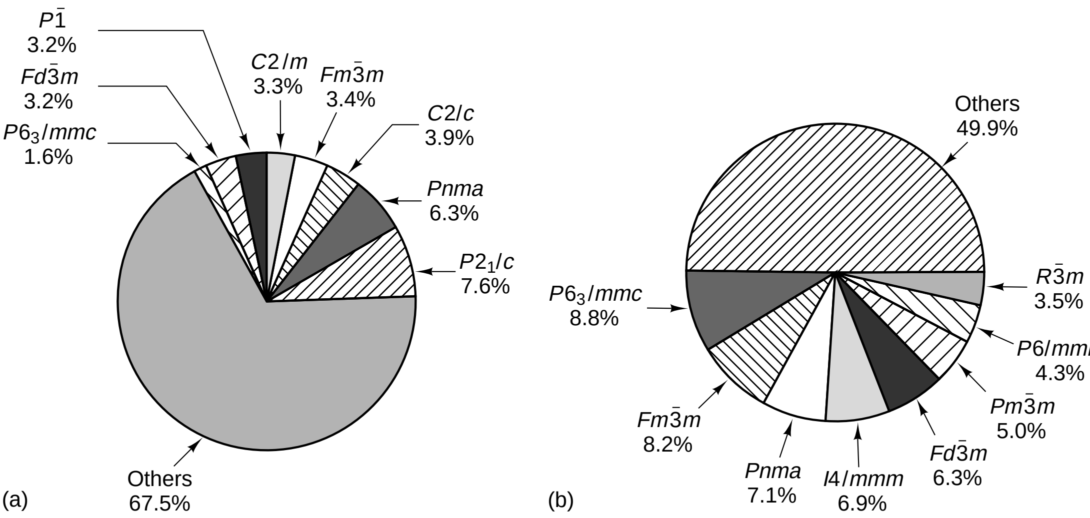

Figure 4 Distribution of the most frequently occurring space groups for (a) inorganics and (b) intermetallics

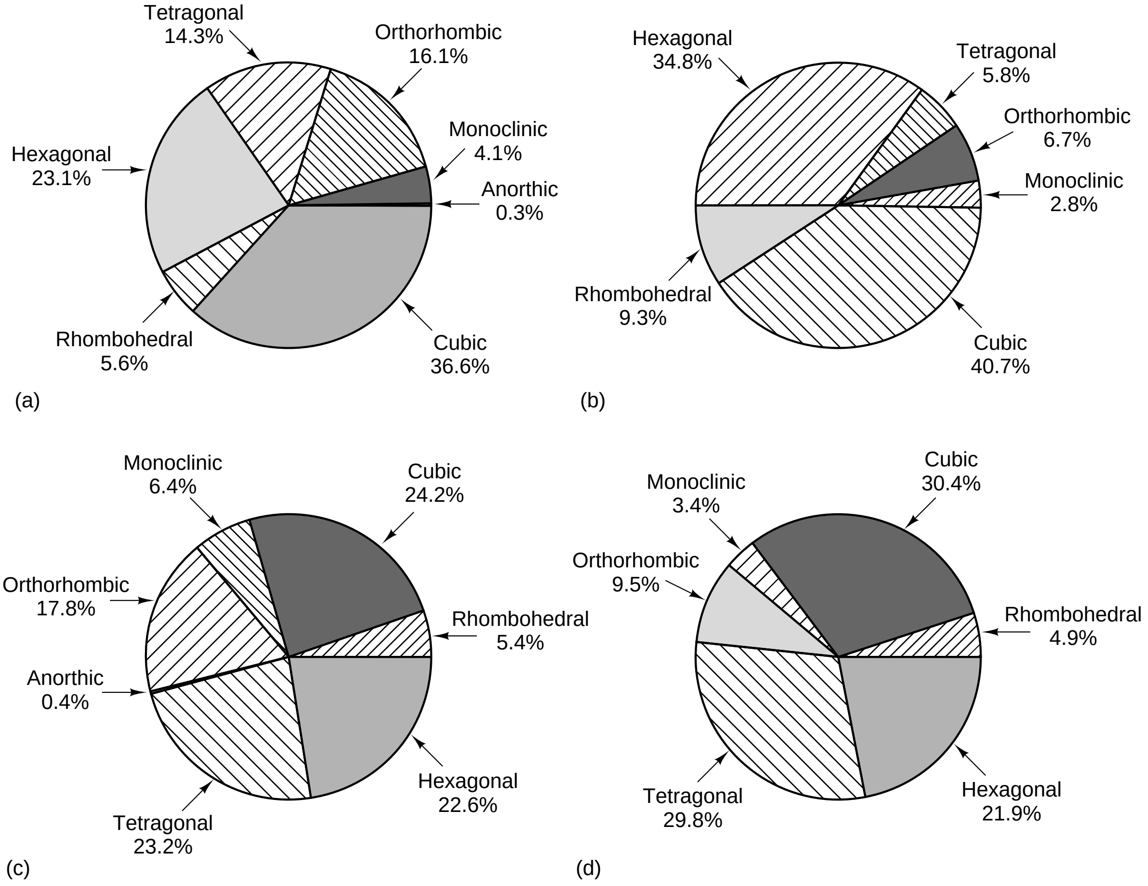

Figure 5 Distribution of intermetallic compounds by crystal system: (a) unaries (elements), (b) binaries, (c) ternaries, and (d) quaternaries

antibonding band rather than the actual band gap itself, extracted from spectral measurements. Using the measured values of Δ for the elements and assuming that the covalent contribution and the internuclear separation, d, are related by $E_c \approx d^{-2.5}$, leads to evaluation of values of E_c for all of the AB examples, and from measurement of Δ, for values of E_c and E_i for all the AB octets. The Phillips–van Vechten plot of these pairs is shown in Figure 10, and is extremely successful in sorting four- and six-coordinate structures.

The concept of atomic or ionic ‘size’ is one that has been debated for many years. The structure map of Figure 1 used the crystal radii of Shannon and Prewitt[10] and these are generally used today in place of Pauling’s radii. Shannon and Prewitt’s values come from examination of a large database of interatomic distances, assuming that internuclear separations are given simply by the sum of anion and cation radii. Whereas this is reasonably true for oxides and fluorides, it is much more difficult to generate a self-consistent set of radii for sulfides, for example.[11] A set of ‘radii’ independent of experimental input would be better. The pseudopotential radius is one such estimate of atomic or orbital size.

Figure 12 shows the idea[12] of the pseudopotential. The coulombic attraction of a valence electron by the nucleus is screened by the core. However, this still strong attraction is counterbalanced by the Pauli repulsion of the valence electrons by those of the core. The result is a fairly weak potential that has a minimum and a crossing point, the latter occurring where attractive and repulsive forces exactly cancel. This crossing point can be used as a measure of the ‘size’, r_l, of the orbital defined by the pseudopotential. For the valence orbitals of an atom, r_s, r_p, and (where appropriate) r_d are orbital parameters that define atomic properties. Figure 13(a) shows a structure map for the same AB octet database as in Figure 1. Here the value of r_σ is just the sum of the s and p radii (equation 2), the simplest estimate of atomic size.

$$r_\sigma = r_s + r_p \tag{2}$$

Clearly the separation into structural types is somewhat better than when using the ionic radii. The pseudopotential radius for orbital l is also related to other atomic parameters. Since r_l^{-1} has units of energy, it is not surprising to find that it scales nicely with the spectroscopically observed multiplet-averaged ionization energy for that atomic orbital. Recalling the Mulliken definition of electronegativity, it is then easy to see that an estimate of an atomic electronegativity comes from

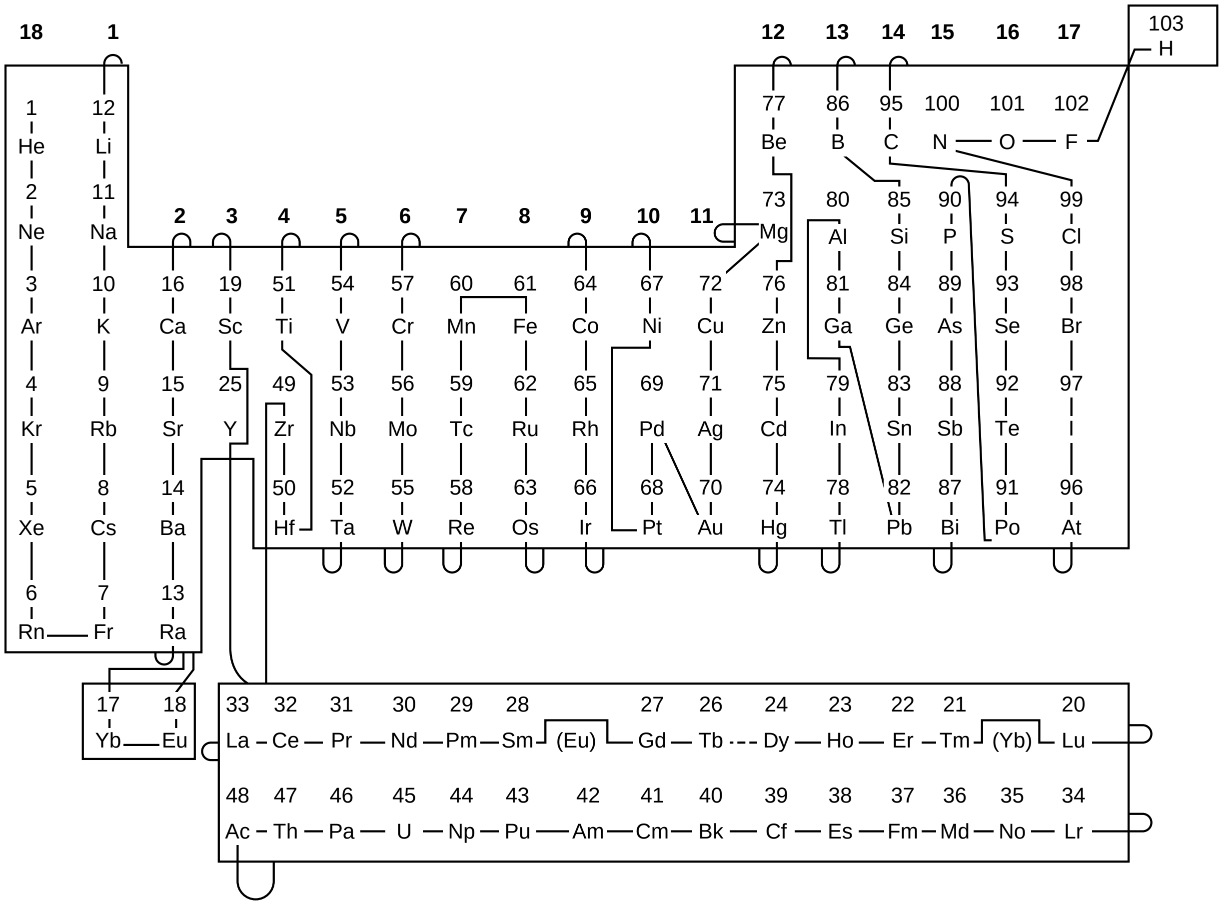

Figure 6 The ordering of elements used to define Pettifor's index. (Reproduced by permission of IPC from Pettifor[6])

an expression of the form shown in equation (3).

$$\chi = A(r_\mathrm{s})^{-1} + B(r_\mathrm{p})^{-1} + C(r_\mathrm{d})^{-1} \qquad (3)$$

Figure 13(b) shows the structure map for the AB octets using such an electronegativity index with A = B, C = 0. The structural sorting[3,13] is just as good as that in Figure 13(a) and presents an interesting dilemma. Pauling presented his structural rules[1] in terms of the radius ratio of anion to cation, a mechanical model. This philosophy is fine for understanding the trends of Figure 13(a), but the ideas of electronegativity, especially in the Mulliken sense, are generally associated with electronic rather than with steric arguments. Thus, there will always be a problem in trying to answer the question why solids have the structures they do. Since size and electronegativity are so closely related, an argument cast in one language may be immediately transformed into one in the other. The pseudopotential radii may be used in the construction of two new, and very useful, indices, the Zunger–Cohen parameters, R_σ and R_π (equations 4 and 5),[14] and their closely related Bloch–Schattemann analogs, R_H and ΔR_CT, (equation 5).[15]

Zunger–Cohen
$$r_\sigma = r_\mathrm{s} + r_\mathrm{p}, \qquad r_\pi = |r_\mathrm{s} - r_\mathrm{p}|$$
$$R_\sigma = |r_\sigma^\mathrm{A} - r_\sigma^\mathrm{B}|, \qquad R_\pi = |r_\pi^\mathrm{A} + r_\pi^\mathrm{B}| \qquad (4)$$

Bloch–Schattemann
$$\left.\begin{aligned} R_\mathrm{H} &= R_\sigma \\ R_\mathrm{CT} &= \left(r_\mathrm{s} + \left(\frac{1}{2}\right) r_\mathrm{p} - \left(\frac{1}{8}\right) r_\mathrm{d}\right) \\ \Delta R_\mathrm{CT} &= |R_\mathrm{CT}^\mathrm{A} + R_\mathrm{CT}^\mathrm{B}| \end{aligned}\right\} \qquad (5)$$

$R_\mathrm{H} = R_\sigma$ is a measure of the size mismatch or electronegativity difference between A and B. R_π is a measure of 'orbital nonlocality', namely, how different in spatial extent are the s and p orbitals located on the same atom. Figure 14 shows[15] a structure map for the binary octet compounds using R_σ and R_π as indices. Straight lines were used to separate one domain from the next. The separation is excellent. The octet compounds MgS and MgSe lie in the B3 region close to the border with the B1 (rocksalt) structure. There are similar problems sorting these two systems in Figures 13(a) and (b). However, the free energy of the B1–B3 phase transition is close to zero for these examples.

Four types of structure maps have been presented here for the octets. Ignoring those of Figures 1 and 13, which

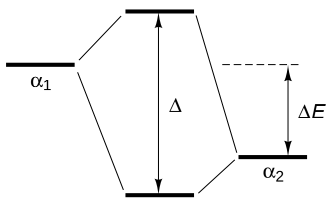

Figure 11 Orbital interaction diagram for two atomic orbitals of different electronegativity

have indices associated with one atom only, there are some interesting similarities between the other three plots. This is to be expected since E_i, $\Delta\chi$, and R_σ all measure the electronegativity difference. Certainly the orbital nonlocality, R_π, is expected to increase as the atoms become heavier and thus scale with $\tilde{n}$. E_c is expected to decrease as the elements become heavier and thus scale inversely with R_π and $\tilde{n}$. Figure 15 shows[15] a more adventurous structure map for 356 binary nonoctet compounds using R_σ and R_π. Straight lines were used to separate one domain from the next, as in Figure 14. The structural separation is quite impressive. The indices are, however, unable to separate the NiAs type ($B8_1$) from the MnP type (B31). The two structures are, however, closely related in geometrical terms. The distortion of the metal and nonmetal frameworks of NiAs gives the zig-zag metal and nonmetal chains in MnP. Similarly, the CrB (B33) and FeB (B27) types are not sorted one from another. These two structures are related by the mode of linkage of trigonal prisms of metal atoms. The occurrence of both pairs

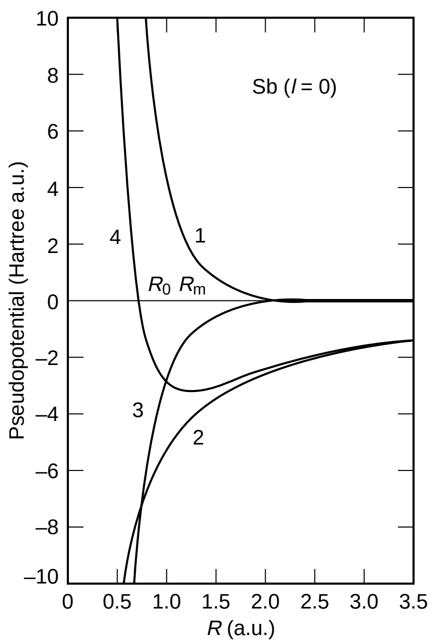

Figure 12 The various parts of the pseudopotential: (1) is the Pauli repulsion between the electrons in the valence orbital (Sb, $l = 0$ in this case) with the core; (2) is the coulomb attraction of the electrons for the nucleus screened by the core to give (3); (4), the pseudopotential, is the sum of (1) and (3); R_0 is the crossing point of the pseudopotential. (Reprinted from Ref. 12. © 1981, with permission from Elsevier)

of structural types depends critically on the number of valence electrons, which are not mimicked sufficiently by the variation in the pseudopotential radii. The separation is not perfect, but it turns out that some of the compounds listed in the existing database do not exist (CuF and FeC), or only have the structure indicated when small quantities of impurity are present. The true success of the sorting is around 2%. Figure 16 shows[15] structure maps for binary compounds with 9, 10, and 11 valence electrons. The structural sorting is more effective here if the indices $|r_p^A - r_p^B|$ and R_π^{-1} are used.

The identification of the ingredients that determine the adoption of either the normal or inverse spinel structure for oxides of formula AB_2O_4 is an old problem. The spinel structure may be envisaged as being a hybrid of sphalerite and rocksalt structures in that it is based on a cubic close-packed array of oxide ions in which the metal atoms occupy some of the octahedral and tetrahedral interstices. The normal and inverse variants are distinguished by which interstices the metal ions occupy. In the 'normal' arrangement, the A ions occupy one-eighth of the tetrahedral holes and the B atoms one-half of the octahedral holes. In the 'inverse' arrangement, all of the A ions and one-half of the B ions have changed places. In terms of structural popularity, most spinels are of the normal type, but there are several with the inverse structure. There are others where the best description is of a disordered variant somewhere between the two. Table 1 gives some examples. The traditional approach to the spinel problem[16] involves calculation of the *Crystal Field Stabilization Energy* (CFSE) for the relevant d electron configurations to give a value of the difference in CFSE, Δ(CFSE), which favors the inverse structure (A(oct)B(tet)B(oct)) over the normal one (A(tet)B_2(oct)). Naturally this approach is limited to solids containing ions that have an asymmetric d orbital occupancy. Thus d^0 (high spin), d^5, and d^{10} ions (in fact, the majority of the database) are excluded from consideration. The general view of transition metal–ligand interaction is one where the major interactions are between the ligand orbitals and the valence $(n+1)$s, p orbitals on the metal, with the d orbitals playing a smaller role. A similar picture emerges from the form of a structure map[17] using the s and p pseudopotential orbital radii of the A and B metals, namely, r_σ as an index (Figure 17). The normal and inverse structures are quite well separated by the use of these indices. Of the four 'normal' errors in the 'inverse' region, two correspond to poorly characterized systems and two are real errors. No such clean separation of structure type is achieved if the crystal radii of Shannon and Prewitt are used. One of the most interesting observations is that a mixture of normal and inverse examples is found at the boundary between the two regions. It turns out that for all of these, the variant actually found is the one predicted to be more stable from

Table 1 Some examples of materials with the spinel structure[a]

A	B_2								
	Al	Ga	In	Ti	V	Cr	Mn	Fe	Co

[a]Listed is the distribution parameter x, which determines the site occupancies in the normal structure (0.0), inverse structure (1.00), and structures in-between.

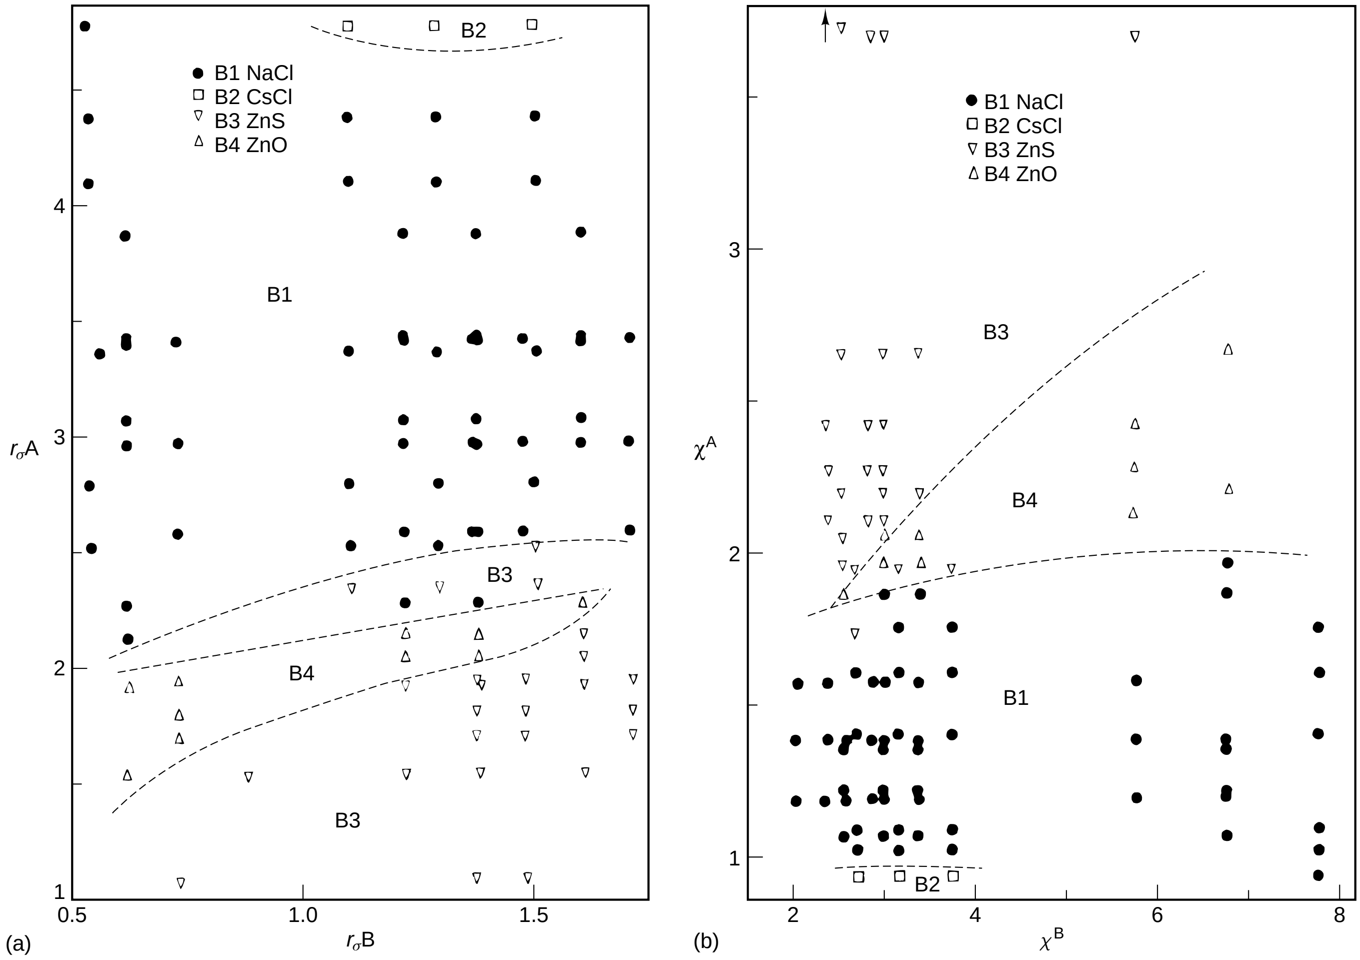

Figure 13 Structure maps for the AB octets (same database as in Figure 1) using (a) r_σ (equation 1) as an index and (b) the electronegativity (defined as in equation 3) as an index

consideration of Δ(CFSE). So the dominant effect is, as in main group octet compounds, associated with the electronic demands of the valence s and p orbitals. Only at the boundary between the two regions, where the energy difference that distinguishes one arrangement over the other is not large, are the forces associated with the d orbitals important. The structure map is a very useful way to gain insights into this problem. The spinels (around 187 known examples) are mainly oxides and chalcogenides, but some halides and cyanides adopt this structure too. There are, however, only 80 that contain asymmetric d orbital configurations for which the crystal field model can make a prediction with a success rate of 67/80 (13 errors). The structure map gives a total of four errors out of 187 examples.

Perhaps the most comprehensive analysis of structure type comes from the work of Villars and his collaborators.[18–20] The observation that different structure maps were required for different electron counts was noted earlier. Thus, the total number of electrons will be important as an index. The concept of atomic size as defined through the use of the pseudopotential radius has already been discussed. This will be the second index. The third index chosen by Villars is the electronegativity, defined not through the reciprocals of the pseudopotential radii, as in equation (3), but taken directly from the experimental values of the multiplet-averaged ionization energies of the atoms themselves. This is shown for the binary systems A_xB_y in equation (6).

$$\text{Villars}\quad \left.\begin{aligned} \overline{N}_{\text{v}} &= xN_{\text{v,A}} + yN_{\text{v,B}} \\ \Delta\chi &= 2x(\chi_{\text{A}} - \chi_{\text{B}}) \\ \Delta R &= 2x(R_{\text{A}} - R_{\text{B}}) \end{aligned}\right\} \qquad (6)$$

Figure 18 shows[21] a structure map for the octets using these indices. In fact, this is a slice through the three-dimensional plot using all three. Shown are both transition metal and main group examples. These indices are sufficient to sort both types of compound. The reader is referred to the literature cited in Villars,[22] where further aspects of structural sorting are

described. These diagrams are often referred to as quantum structural diagrams (QSD).

4 THERMODYNAMIC PROPERTIES

It is well known that the structural part of the energy of a solid, namely, the energy difference between two polymorphs, is considerably smaller than the heat of formation itself. For TiO_2, for example, the energy difference between the rutile and anatase forms is about 2 kcal mol^{-1}, whereas the heat of formation of rutile is close to 225 kcal mol^{-1}. One interesting feature of the structure maps, therefore, is that they contain energetic information too. With reference to Figure 19, the heat of the reaction, shown in equation (7)

$$AB + CD \longrightarrow AD + CB \quad (7)$$

is proportional[23] to the difference in the lengths of the heavy lines connecting the two pairs of compounds (equation 8)

$$\Delta H_R = a_x(d_{AD,CB} - d_{AB,CD}) = a_x \Delta d(\lambda) \quad (8)$$

where λ is a scaling factor between the R_σ and R_π scales shown in Figure 19 (equation 9).

$$d^2_{AB,CD} = |(R_\sigma^{AB} - R_\sigma^{CD})^2 + \lambda^2(R_\pi^{AB} - R_\pi^{CD})^2| \quad (9)$$

The agreement with experiment is good for the whole database of alkali halide and alkaline-earth oxides and

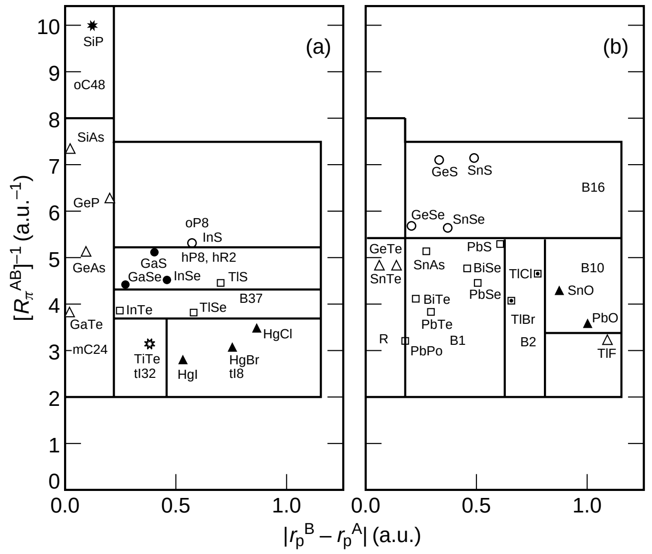

Figure 16 A structure map for 9-, 10-, and 11-electron AB compounds using the indices $|r_p^A - r_p^B|$ and R_π^{-1}. (Reprinted from Ref. 15. © 1981, with permission from Elsevier)

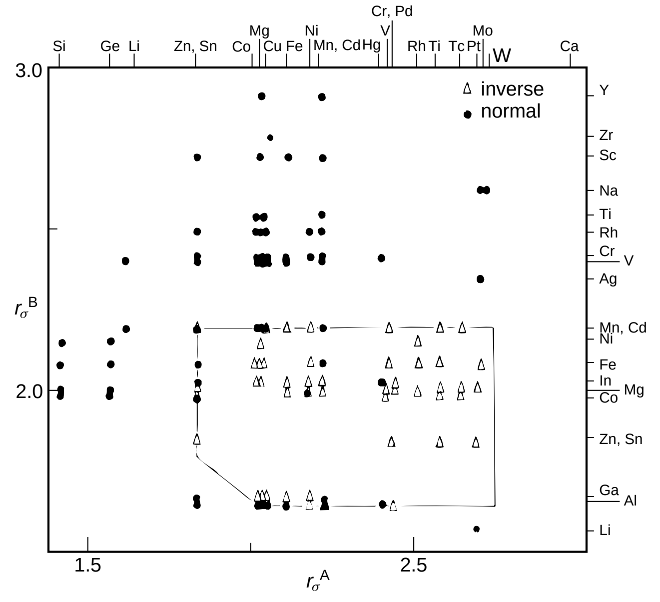

Figure 17 Structure maps for the AB_2O_4 spinels using r_σ (equation 2) as an index

chalcogenides, with the exception of reactions involving BeO and to a lesser extent MgS and MgSe, three compounds, in fact, that are misplaced on the Zunger plot of Figure 13. Errors are also found for reactions involving LiF. The function χ^2

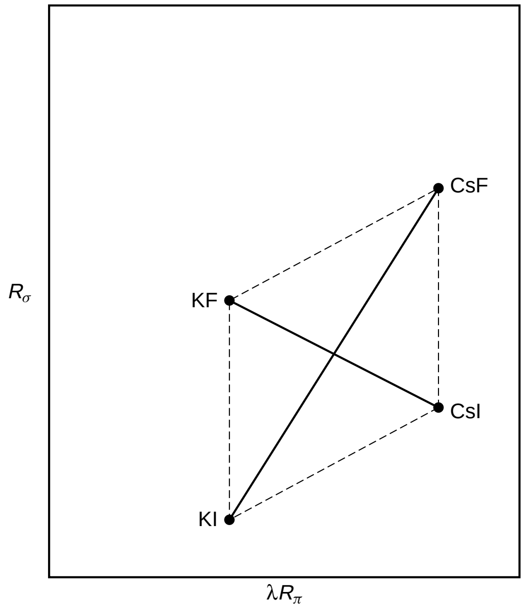

Figure 19 An R_σ/R_π plot and the heats of reaction of equation (7)

(equation 10) was minimized with respect to the parameter for all N reactions.

$$\chi^2 = \sum_1^N \left\{ \frac{(\Delta H_R^i - a_x \Delta^i(\lambda))}{E(\Delta H_R^i)} \right\}^2 \quad (10)$$

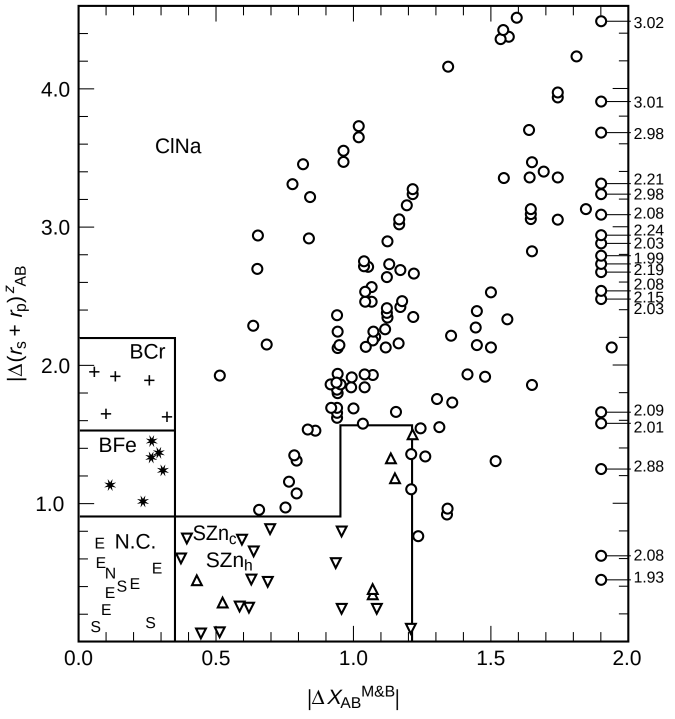

Figure 18 A structure map (or quantum structural diagram, QSD) for the AB octets using Villars' indices. (Reproduced by permission of Elsevier from Villars[21])

Table 2

Model	Δn	Δd
a_x or a_n (kcal mol^{-1})	2.08	8.28
λ	–	4.4
$N = 78, \chi^2 =$	81.3	37.7
$N = 100, \chi^2 =$	162.2	94.2
Total number predicted		
outside experimental error	29	22
involving BeO	4	4
involving MgX	5	4
involving LiF	11	9
others	9	5

ΔH_R^i is the experimentally determined heat of reaction, associated with an experimental error $E(\Delta H_R^i)$. The value of $\lambda = 4.4$ (Table 2) shows that both R_σ and R_π are important.

Perhaps the traditional way of looking at the energetics of such reactions uses the concept of hard and soft acids and bases and suggests an alternative expression for ΔH_R (equation 11)

$$\Delta H_R = a_x[(n_A + n_B) - (n_C + n_D)] \quad (11)$$

where n is the principal quantum number. As Table 2 shows, this is a much poorer model. As a final point, it is worth noting that although equation (9) works well for the group 1 and 2 systems with their group 17 and 16 counterparts, respectively, it is not applicable to differences in the heats of formation of transition metal-containing systems. It is interesting to find, therefore, that the heat of the reaction of equation (12) for the spinel minerals correlates with the differences in R_σ as shown in equation (13).

$$AB_2O_4 + CD_2O_4 \longrightarrow AD_2O_4 + CB_2O_4 \quad (12)$$

$$\Delta R = |R_\sigma^{AD_2O_4} - R_\sigma^{CB_2O_4}|^2 - |R_\sigma^{AB_2O_4} - R_\sigma^{CD_2O_4}|$$

where

$$R_\sigma^{AB_2O_4} = r_\sigma^B - r_\sigma^A (13)$$

The energetic correlation for the spinels is shown[24] in Figure 20, along with the corrections that follow from consideration of the d orbital occupation through the differences in CFSE.

Certainly one of the most basic properties of alloys is whether they actually exist, or, alternatively stated, have a positive or negative heat of formation. The scheme devised by Miedema[25] is a very impressive one in this regard. The model (Figure 21) is based on a 'macroscopic atom' view of alloy formation. The 'atomic cells' of the A and B components are first rearranged with a small change in shape but without any change in volume. There is a difference in chemical potential (identified with the chemist's concept of electronegativity) between the two metals, and as a result a small amount of charge transfer takes place. In response to this charge transfer,

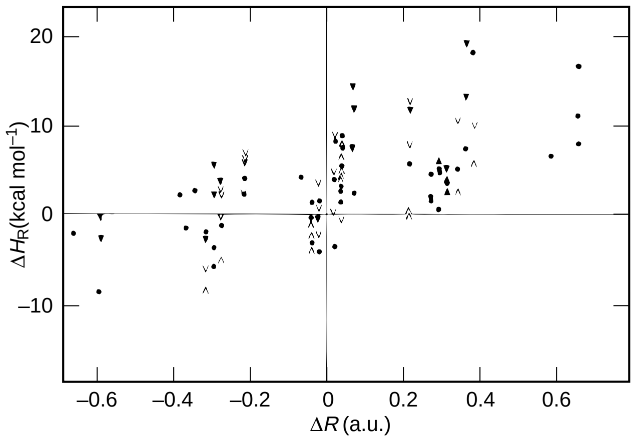

Figure 20 The heats of reaction of the spinel minerals from equation (13)

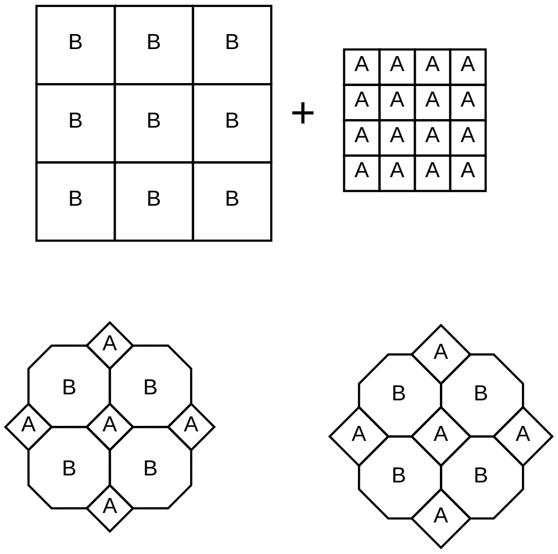

Figure 21 The 'macroscopic atom' model of Miedema. First, atomic cells are taken from each metal to form the alloy with a small change in shape but not volume. In the second step, the atomic volumes adjust to the new environment

the atomic volumes change a little in a second step. The major suggestion of the theory is that the driving force for alloy formation arises via the transfer of electrons from the energy levels associated with the more electropositive metal to those of the more electronegative atom. One of the atomic indices of use in measuring this effect should then be associated with the electronegativity of the element. As a first approximation, the work function of the metal, ϕ, is used, although Miedema refined its value to give a better agreement with experiment. The contribution to the heat of formation from this source depends upon $-(\Delta\phi)^2$. There is a second contribution to the heat of formation. This is positive and thus represents an

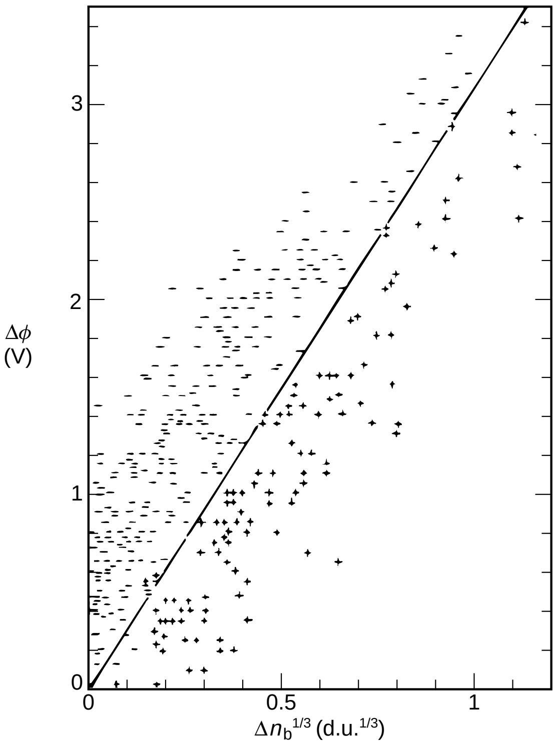

Figure 22 The correlation with experiment for equation (14). A minus sign indicates that there is at least one stable binary compound between the elements, that is, that $\Delta H < 0$. A plus sign indicates that there is no stable binary compound known and also that there is limited solubility (<10%) of the two metals

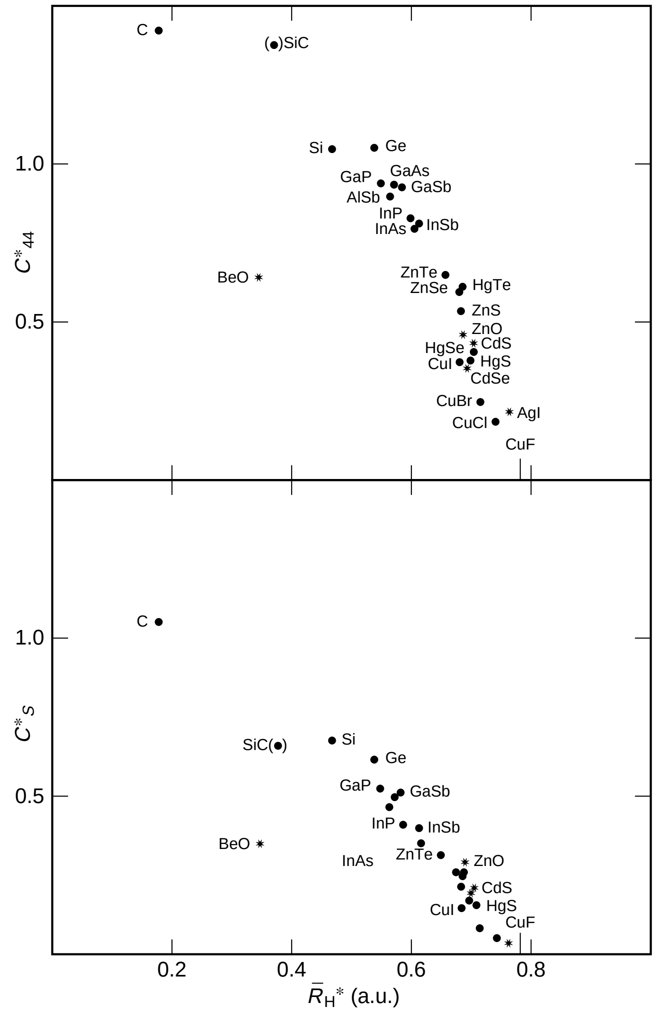

Figure 23 R_σ (R_H) versus cubic shear moduli of tetrahedrally coordinated octet solids. (Reprinted from Ref. 14. © 1981, with permission from Elsevier)

energy penalty on forming the alloy. Since electron density is continuous across the boundaries of the cells in the pure A and pure B systems, but certainly discontinuous for the AB alloy in the cell model of Figure 21, a readjustment of electron density at the cell boundaries is necessary for it to be continuous in the AB alloy too. The energy cost associated with this process is proportional to $+(\Delta n_\mathrm{b}^{1/3})^2$ where Δn_b is visualized as the electron density discontinuity at the boundary between A and B cells. The term $\Delta n_\mathrm{b}^{1/3}$ is a second index. The combination of the two effects leads to a heat of formation (equation 14) written as

$$\Delta H = f(c)[-P(\Delta\phi)^2 + Q(\Delta n_\mathrm{b}^{1/3})^2] \quad (14)$$

where $f(c)$ is a term that allows for changes in stoichiometry. Irrespective of the physical origin of the indices, it is clear that the two indices for each element i, ϕ_i and $n_\mathrm{b}^{1/3}$, may be regarded as two general parameters with which to represent the heat of formation. The agreement with experiment for transition metal–transition metal alloys is shown in Figure 22 and is very impressive. For transition metal–main group alloys, the theory has to be modified slightly,[22] but a good predictive model remains.

5 PROPERTIES

Industry is highly interested in new materials that possess new or improved properties. The use of structure maps and other diagrammatic tools aid in this quest. Below are described the uses of such maps in the search for property-specific materials. In the sections on stable quasicrystals, high-T_c superconductors, and ferroelectrics, the applications of the quantum structural diagrams (QSD) described above will be used. In these classes of materials, the analysis starts with the compilation of the diagrammatic coordinates as described in equation (6). For these unusual types of order, the existence of diagrammatic regularities implies, at least, that the same factors that control local structure and stability in ordinary compounds also determine the tendency to these types of order and probably a connection as well.

In terms of other indices, the parameter R_σ is a good one[14] for the correlation of the cubic shear moduli of solids, as shown in Figure 23. The variation in the axial ratios of compounds with the wurtzite structure are well correlated[14] (Figure 24) with the parameter ΔR_{CT}.

5.1 Stable Quasicrystals

Rabe and coworkers[22,26] have used QSDs to analyze stable ternary quasicrystals. They have plotted the 10 known stable quasicrystals: $CuLi_3Al_6$, $Ga_{20}Mg_{37}Zn_{43}$, $A_{15}Cu_{20}Al_{65}$ (A = Fe, Ru, Os), $Cu_{15}Co_{20}Al_{65}$, $Co_{15}Ni_{15}Al_{70}$, (Mn, Re)Pd_2Al_7, and the recently discovered $Al_{43}Mg_{43}Pd_{14}$.[27] For the first nine, the diagrammatic coordinates are computed and plotted on the QSD, as shown in Figure 25. All 10 quasicrystals, including $Al_{43}Mg_{43}Pd_{14}$, fall into the restricted range $-0.6 \le \overline{\Delta X} \le 0.3$ and $-0.2 \le \overline{\Delta R} \le 0.7$, which they designated the QSD quasicrystal condition. Predictions for new quasicrystals have been produced by screening two kinds of candidate composition lists: new combinations based on compositions of known quasicrystals[22,26,28,29] and known intermetallic compounds as possible crystalline approximants.[21,22] The predictions by Price,[24] based on the new combinations approach, led to the discovery of four new metastable quasicrystals.[28]

5.2 High-T_c Superconductors

Villars[30] and Phillips[31] have applied QSD to the systematization of compounds possessing high-T_c superconducting properties. These results are presented in Figure 26. Figure 26(a) shows the two-dimensional plot $\overline{\Delta X}$ versus $\overline{\Delta R}$ and Figure 26(b), the Mathias[32] plot T_c versus N_v. Figure 26(a) show three islands, A, B, and C, each being characterized by particular ranges of $\overline{\Delta X}$, $\overline{\Delta R}$, and N_v. Island A is dominated by binaries with the cP8 (Cr_3Si) (A15) structure type, but in addition has five other structure types. Island B contains compounds having the cF8 (NaCl) (Bl) structure type. These simple binary compounds (island B) are five times more likely to have $T_c > 10$ K than the binaries that have the NaCl structure type but that do not have the restriction of $\overline{\Delta R}$ and $\overline{\Delta X}$. Island C contains the Chevrel (M_xMo_6X, where X is usually a chalcogenide) and perovskite (ABO_3) phases and the ternary cuprate superconductors as well ($La_{2-x}Sr_xCuO_4$).

5.3 Ferroelectricity

In their analysis of ferroelectric compounds using QSD, Villars *et al.*[33] studied 175 ternary ferroelectric and antiferroelectric oxides. These compounds were divided into three sets: F_1 with $T_c > 500$ K with 50 representatives, F_2 with 22 compounds with $300\,\text{K} < T_c < 500$ K, and F_3 with 103 representatives containing pseudoternaries and quaternary oxides with $T_c > 500$ K. The calculation of $\overline{\Delta X}$ and $\overline{\Delta R}$ for the pseudoternaries and quaternaries with $T_c > 500$ K (set F_3) was performed by combining the two most chemically similar elements into a single 'element' with weighted average N_v, X, and R. Figure 27 shows that the resulting $\overline{\Delta X}$ and $\overline{\Delta R}$

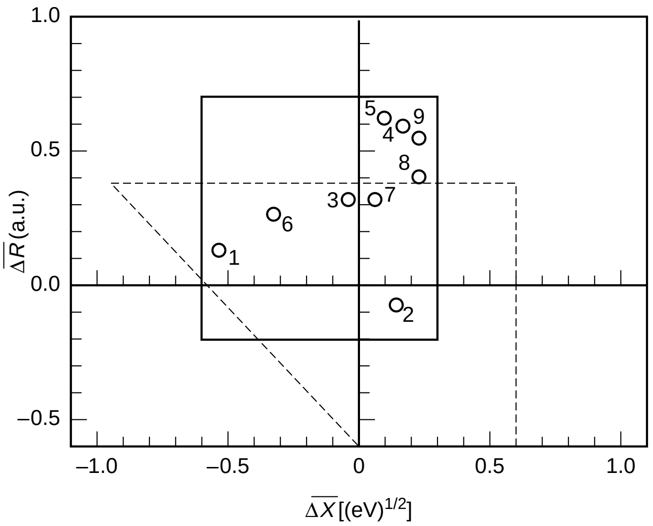

Figure 25 A QSD projection on the $\overline{\Delta X} - \overline{\Delta R}$ plan for nine quasicrystals (numbering given in Table 1 of Villars[22]). The dashed lines show segments of the boundary of the $\overline{\Delta X} - \overline{\Delta R}$ zone defining the quasicrystal conditions based on cI162 compounds.[28] (Reprinted with permission from K.M. Rabe, J.C. Phillips, P. Villars, and I.D. Brown, *Phys. Rev.*, 1992, **B45**, 7650. © American Physical Society. http://pra.aps.org)

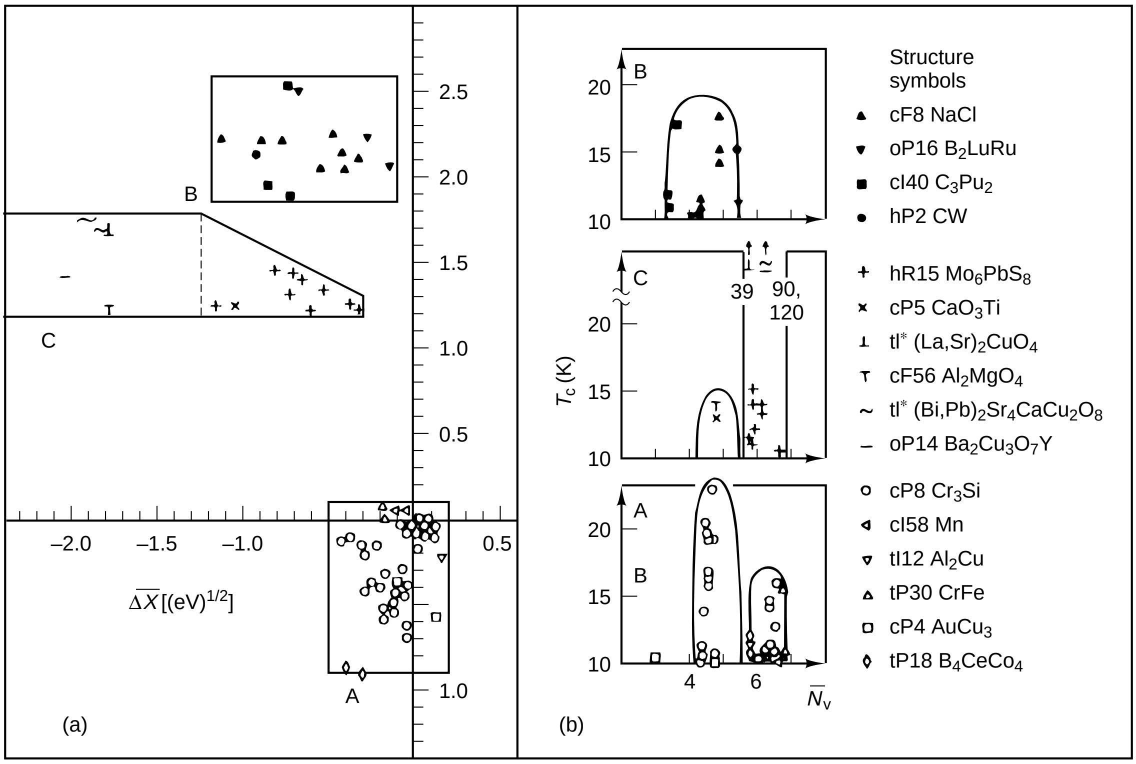

Figure 26 Plots for 67 high-T_c superconductors: (a) $\overline{\Delta X} - \overline{\Delta R}$ quantum structural diagrams, and (b) Mathias plot T_c versus N_v. See text for information on islands A, B, C. (Reproduced by permission of Academic Press from Phillips.[31])

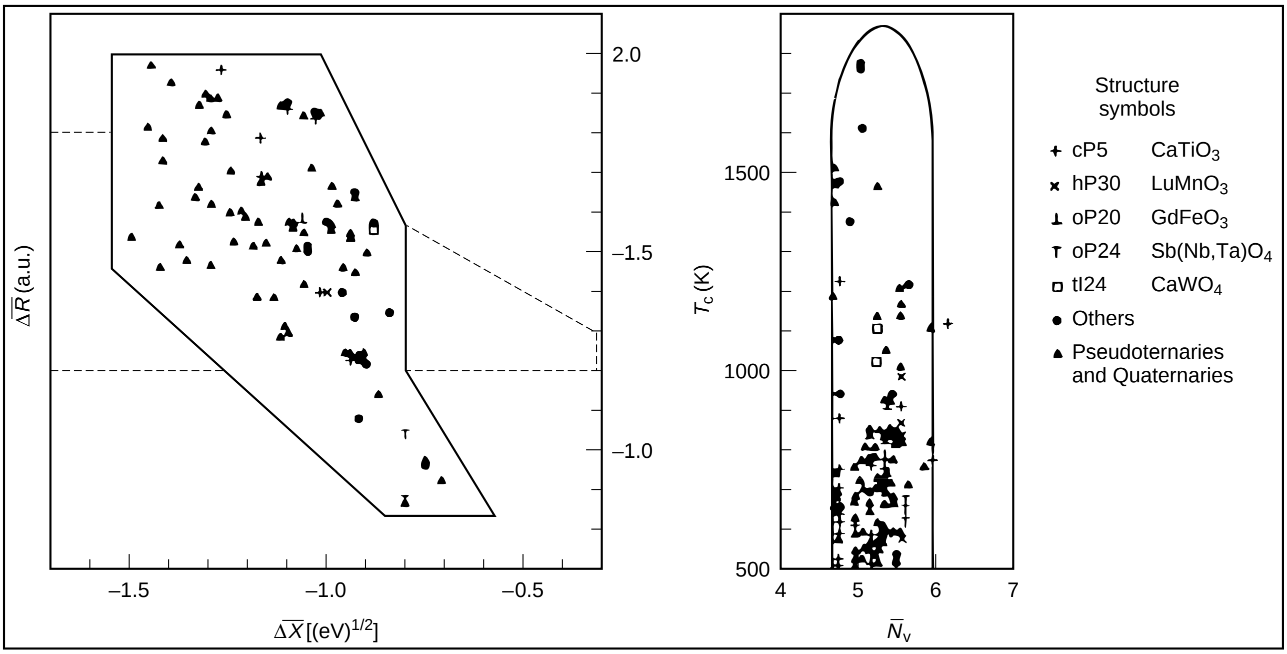

Figure 27 QSD and Mathias plots for 175 high-T_c ferroelectrics and antiferroelectrics. Pseudoternaries and quaternaries with $T_c > 500$ K (set F_3) are represented by solid triangles; the ternaries with $T_c > 500$ K (set F_1) are represented by a variety of symbols distinguishing different structure types, as shown in the legend (all scales are expanded by a factor of 2 relative to Figure 26). The outline for the island C from Figure 26 is shown as a dashed line to facilitate comparison of ferroelectric and superconducting domains. (Ref. 33. Reproduced by permission of Taylor & Francis)

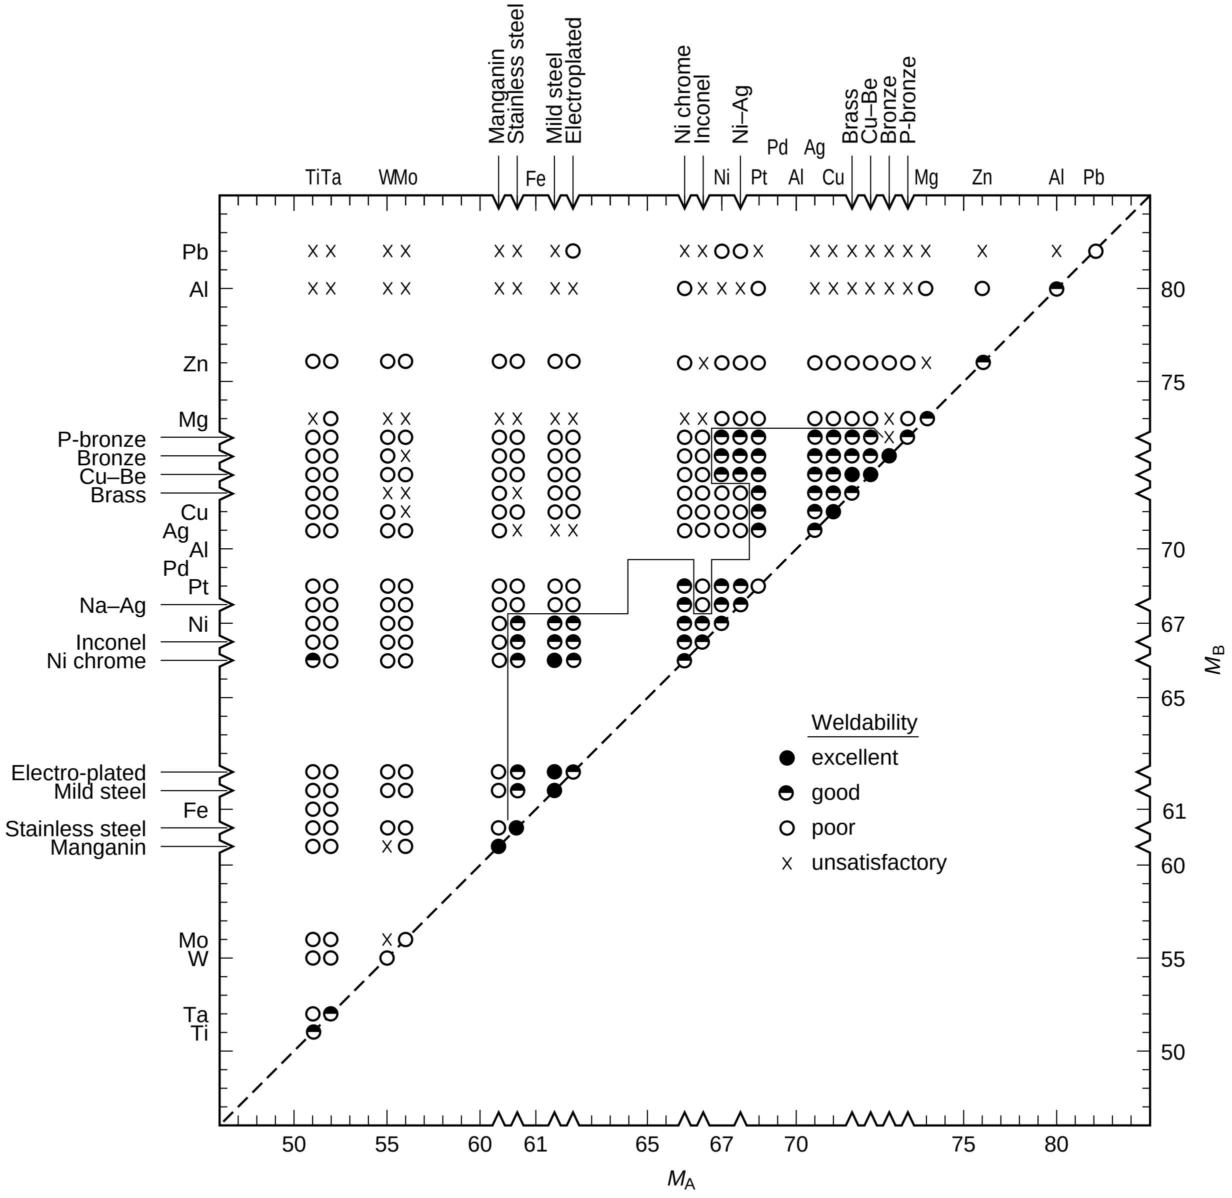

Figure 28 Weldability property plots. (Reproduced by permission of the Institute of Metals from Pettifor.[34])

values for the ternaries, pseudoternaries, and quaternaries with $T_c > 500\,K$ (sets F_1 and F_3) are confined to one very small region of the QSD. The area occupied by the set F_1 is particularly small, while the inclusion of set F_3 requires a slight displacement of the left-hand boundary to larger values of $|\overline{\Delta X}|$. This figure also shows a Mathias population plot for T_c versus N_v for the 153 compounds belonging to the sets F_1 and F_3. This Mathias plot shows a very narrow peak, even narrower than is found for superconductors, for which such plots are usually made. The narrowness of this peak is consistent with the excellent localization in the ($\overline{\Delta X}$, $\overline{\Delta R}$) diagram, showing the conditions for high-T_c ferroelectricity are limited to a very small volume of QSD ($\bar{N}_v$, ΔX, ΔR space).

5.4 Weldability

Pettifor[34] shows, in a Mendeleev (M_A vs. M_B) weldability plot (Figure 28) for AB intermetallics, the separation between compounds having excellent, good, poor, and unsatisfactory weldability properties. It can be observed that domains of excellent weldability are clearly defined.

5.5 High-temperature, High-strength Materials

In the selection of materials for high-temperature structural applications, information on two properties is necessary.

These properties, which are insensitive to processing, are the melting temperature (T_m) and the specific gravity (ρ). Compounds with high T_m have high stiffness, high strength, and a low thermal expansion coefficient, while those with low ρ have high specific strength and specific stiffness.[35] Fleischer[35] has plotted T_m versus ρ for a series of intermetallic compounds grouped by structure type; two such plots are shown in Figure 29. These plots show that by using intermetallics crystallizing in certain structure types, new compounds can be designed, for example, intermetallics that have both high T_m and high ρ (aerospace applications). From these plots, it is clearly seen that cF8 NaCl-type intermetallics (Figure 29(a)) would be better suited for such aerospace applications than the cP4 $AuCu_3$ type (Figure 29(b)).

5.6 Electrical Conductivity

Kiang and Liu[36] have found a connection between the electrical conductivity (ϕ), the fractional number of bonds (n), and the electronegativity difference ($\Delta X_{\mathrm{Pauling}}$) for binary compounds. Figure 30 shows a projection of the electrical conductivity contours. This figure is intended to show the trend of the variation of the degree of ionicity and the degree of covalency of a bond in binary compounds.

5.7 Other Properties

Pettifor maps, two-dimensional plots (M_A vs. M_B) (see Figures 6 and 7), have lead to good structural separation of pseudobinary and ternary compounds. The following stoichiometries have been plotted and discussed elsewhere:[37] AB, AB_2, AB_3, AB_4, AB_5, AB_6, AB_{11}, AB_{12}, A_2B_3, A_2B_5, A_2B_{17}, A_3B_4, A_3B_5, A_3B_7, A_4B_5, and A_6B_{23}. These maps have been used by alloy designers to predict new ternary or quaternary systems with a desired structure type and property, for example, cubic Cu_3Au-type alloys, which have better mechanical properties at high temperature than the brittle noncubic Al_3Ti or $AiTi_3$ binary systems.[38] The two-dimensional maps[39] for A_2B_{17}, AB_{11}, AB_{12}, and AB_{13} structure types have been used to search for Fe-based

1 INTRODUCTION

Sulfur has been known since ancient times. The German and Scandinavian words for sulfur (*schwefel*/*svovel*/*svavl*) derive from the Indo-European *suelphlos*, which is derived from *swel*, meaning to burn slowly. The Latin sulpur may have the same origin. Sulfur has also been thought to be derived from Sanskrit *sulveri*, meaning the enemy of copper. The Greeks burnt elemental sulfur to 'purify the atmosphere' and recognized its usefulness in medicine. Brimstone was a major force in the destruction of Sodom and Gomorrah. From the thirteenth to the mid-nineteenth century, gunpowder (made from $NaNO_3$, charcoal, and sulfur in 75:15:10 weight ratio) was important in military affairs although, subsequent to this, it was replaced by nitroglycerine and cordite. Metal sulfides were among the earliest inorganic pigments (e.g. ultramarine). The alchemists regarded metals as being derived from sulfur and mercury, with higher sulfur contents resulting in less metallic properties. Sulfur is an essential element for life, and is a minor constituent of a number of proteins; typical human consumption is ca. 100 mg per day. For many years the extent of the industrialization and gross national product of many countries could be closely equated with their sulfuric acid production. Important events in the history of sulfur chemistry are shown in Table 1. Physical properties of atomic sulfur are shown in Table 2.

The range of oxidation states and compounds available to sulfur includes S^{-2}, S^{0}, S^{II}, S^{IV}, and S^{VI}; examples of species in each of these categories are given in Table 3. Industrial uses are illustrated in Figure 1. There is an extensive bibliography of sulfur chemistry including Gmelin,[3] Mellor,[4] monographs,[5,6] and good coverage in advanced inorganic chemistry texts.[1,2,7]

2 ELEMENTAL SULFUR

2.1 Natural Occurrence

Sulfur is a relatively common element and occurs naturally as the element (in the caprock of salt domes and in the basin deposits in Poland), in metal sulfides (Table 4), and in sulfates such as gypsum. Furthermore, the sulfur deposits in natural gas and crude oil are now also becoming increasingly significant commercially. The world reserves of sulfur are believed to be in excess of 2×10^9 tonnes.[8,9]

2.2 Production

The production of sulfur parallels the development of chemistry. In the 1700s, sulfur mining was undertaken on a steadily increasing scale. In the nineteenth century, demand for sulfur increased dramatically with volcanic derived sulfur (mostly from Sicily) providing for the emergent chemical industry. The Frasch process revolutionized the production of sulfur and ensured a stable supply from the turn of the century. Worldwide production of sulfur is estimated to be in excess of 60 million tonnes annually; the three main sources of production are (1) recovery from crude oil and gas, (2) direct mining/Frasch recovery of the element, and (3) roasting of metal sulfides, in particular, pyrites. In addition, there is an increasingly large amount of sulfur obtained from SO_2 in flue gases.

Recovery of sulfur from crude oil is achieved by treating the H_2S using the Claus process. The H_2S is reacted with air/oxygen according to equation (1).

$$\begin{aligned} H_2S + 1.5O_2 &\longrightarrow SO_2 + H_2O \\ 2H_2S + SO_2 &\longrightarrow 3S + 2H_2O \end{aligned} \qquad (1)$$

The remaining unconverted H_2S (up to 40%) is passed through a number of reactors containing alumina/copper/molybdenum catalysts to achieve full conversion of the hydrogen sulfide to sulfur.

Sulfur, which is present in the limes of America and Iran, can be obtained by the Frasch process, which involves pumping superheated steam (160–170 °C) deep into the sulfur-rich rocks. The sulfur becomes molten and is then forced up to the surface using compressed air (Figure 2). Between 2000 and 5000 gallons of water are needed for each ton of sulfur that is recovered. Once pumped up on to the surface, the molten sulfur is cooled in layers in gigantic 'sulfur vats' to give solid blocks up to 60 feet high.

Alternatively, heating iron pyrites (FeS_2) to 1200 °C with exclusion of air gives sulfur and liquid FeS by the 'Outokumpu' process.

As a consequence of environmental concerns associated with burning fossil fuels during the latter part of the twentieth century, greater efforts have been made to recover sulfur from

oil and gas. The majority of elemental sulfur is now obtained by this route rather than Frasch mining.

The industrial uses of sulfur have been discussed.[8,10,11]

2.3 Homocyclic Sulfur Compounds

2.3.1 Neutral Sulfur Homocycles

Preparation and Structure. There is a wide range of sulfur allotropes.[12,13] Apart from the many different crystalline forms of S_8, several other sulfur rings have been reported[14] and a new allotrope S_{14} was recently described[15] Historical names and properties of some of the common allotropes (*see Allotrope*) are given in Table 5.

Cyclo-S_8 crystallizes in orthorhombic (α) and two monoclinic (β, γ) forms (Figure 3 illustrates the packing in the α and γ forms). The α form is stable up to 96 °C; liquid sulfur above this temperature is usually cooled to give β sulfur. However, if liquid sulfur is quenched, the familiar plastic sulfur, believed to consist of S_n chains, is obtained.

The crown structure of *cyclo*-octasulfur, S_8, is only one member of an homologous series of S_n ($n =$ 6–26) rings (Figure 4). Additionally, cyclic sulfur oxides[16] such as S_6O and S_7O_2 and mixed sulfur–selenium systems[17] are known. These latter compounds are of some commercial significance, with applications as diverse as antidandruff shampoos, fireworks, and polymerization inhibitors.

The preparation of S_n rings can be accomplished by a variety of routes (see equation 2).[14,18] Acid hydrolysis of thiosulfate was originally used for the preparation of S_6, which is separated from S_7 and S_8 by recrystallization from toluene. An alternative method is the thermal decomposition (at room temperature) of diiodosulfane, S_2I_2 (formed in

situ), which gives a 36% yield of S_6 and minor amounts of higher *cyclo*-sulfanes after purification (equation 3). S_6 is obtained as orange–red crystals that readily decompose at room temperature. Some of the larger rings are more stable and so can be prepared from molten S_8. For example, if commercial sulfur is heated to 200 °C, cooled to ca. 150 °C, and finally quenched by pouring into liquid nitrogen, a mixture of S_7, S_{12}, S_{18}, and S_{20} rings is obtained. The individual compounds are, however, only obtained after painstaking recrystallizations. An alternative route to S_{18} is the reaction of $S_{10}Cl_2$ with H_2S_8, but in this case the preparation of the starting materials is very tedious.[19]

$$Na_2S_2O_3 + 2HCl(aq) \longrightarrow \frac{1}{n}S_n + SO_2 + 2NaCl + H_2O \quad (2)$$

$$S_2Cl_2 + 2KI \longrightarrow S_2I_2 + 2KCl \longrightarrow \frac{1}{n}S_{2n} + I_2 \quad (3)$$

Fortunately, rational syntheses based upon reactions of Cp_2TiS_5 with chlorosulfanes (and consequent elimination of Cp_2TiCl_2, *see Metathesis*, salt elimination) have been developed (Figure 5).[14,20] The Cp_2Ti fragment is isolobal (*see Isolobal Analogy*) (*see also Isoelectronic*) with the sulfur

Table 3 Typical oxidation states and geometries for sulfur

Oxidation number	Coordination number	Geometry	Examples
−2	2	Angular	H_2S
−1	2	Angular	H_2S_2
0	2	Ring	S_n
I	2	Angular	S_2Cl_2, RSCl
II	2	Angular	Me_2S, H_2S
	3	Pyramidal	Me_3S^+

atom, and thus this compound is actually a stable analog of S_6. This approach has been extended to enable the formation of Se_5S, Se_5S_2, and Se_7 by treatment of Cp_2TiSe_5 with SCl_2, S_2Cl_2, and Se_2Cl_2, respectively. The use of transition metal complexes as synthetic reagents in this way will no doubt be more widespread in the future. Surprisingly, the preparation of S_6 from Cp_2TiS_5 is not the best route (probably because pure SCl_2 is difficult to obtain). Reaction of S_2Cl_2 with H_2S_4 gives S_6 (equation 4) but H_2S_4 is difficult to obtain; the preferred route is reaction of S_2Cl_2 with KI as shown in equation (3).

$$S_2Cl_2 + H_2S_4 \longrightarrow \underset{85\%}{cyclo\text{-}S_6} + 2HCl \qquad (4)$$

Eight-membered, and larger, sulfur–selenium rings may be obtained from melts of the elements, by reaction of chlorosulfanes with hydrogen selenide (or vice versa), from selenous acid, or by decomposition of mixtures of Se_2I_2 and S_2I_2, although many of these reactions give rise to mixtures of isomers (equations 5–7).

$$Se_2Cl_2 + H_2S_n \longrightarrow Se_nS_{12-n} + 2HCl \qquad (5)$$

$$2H_2S + SeO_2(aq) \longrightarrow Se_nS_{8-n}\downarrow + 2H_2O \qquad (6)$$

$$\frac{S_2Cl_2}{Se_2Cl_2} + KI \longrightarrow \frac{S_2I_2}{Se_2I_2} + KCl \longrightarrow Se_nS_{8-n} + I_2 \qquad (7)$$

The cyclic sulfur oxides are normally prepared by oxidation of their parent sulfur rings using peroxyfluoroacetic acid (equations 8 and 9), although when S_8 is treated with excess acid, S_7O_2 and SO_2 are obtained, suggesting that ring contraction proceeds via a currently uncharacterized oxidized eight-membered ring.

$$S_n + CF_3CO_3H \longrightarrow S_nO + CF_3CO_2H \quad n = 6\text{–}10 \qquad (8)$$

$$S_n + 2CF_3CO_3H \longrightarrow S_nO_2 + CF_3CO_2H \quad n = 7, 9 \qquad (9)$$

As can be seen in Figure 4, all of the species consist of puckered rings with variable bond angles and distances.

Table 5 Names of allotropes of sulfur

Old and present names	Accepted name	Features

High symmetry rings such as S_8 or S_6 have normal S–S bond distances (ca. 2.05 Å) and torsional angles (ca. 85°); however, lower symmetry species can be quite distorted. The most interesting example in this regard is S_7, which would be expected to have C_2 symmetry like cycloheptane, but actually has C_s symmetry with four of the sulfur atoms in a plane and consequently one torsional angle of close to 0°. The S–S distances for the four coplanar sulfur atoms are unusually short, and this may imply some π bonding contributions.

An empirical rationalization of the structure of S_7 has been provided by Gillespie.[21] A convenient starting polyhedron is a cube. Figure 6 also shows how the structure of S_7O and S_7I^+ may be related to that of S_7.

The structures of mixed sulfur–selenium rings are similar to their sulfur analogs. Structures in which the number of

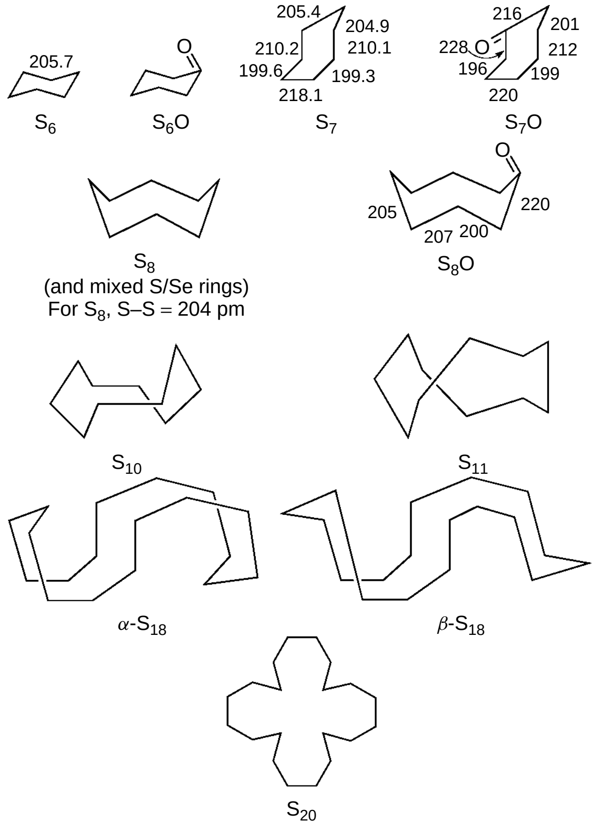

Figure 4 The structures of S_n and S_nO rings

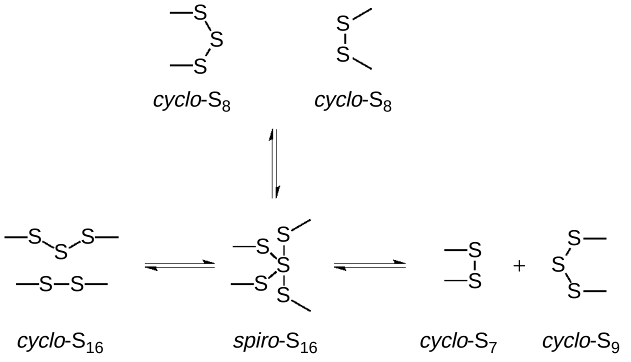

Figure 7 Potential mechanism for the formation of S_7 and S_9 from S_8

S–Se bonds is minimized appear to be favored, and the rings thus consist of chains of sulfurs attached to chains of selenium atoms, in contrast to the *cyclo*-sulfur imides (*see* ***Sulfur–Nitrogen Compounds***) where S–N bonds are favored over N–N bonds.

Cyclo-sulfur rings are yellow or pale orange, low-melting solids (Table 6) of variable stability. For example, S_9 decomposes above 0 °C, while S_6 and S_7 are only moderately stable at room temperature. Their thermal stability decreases in the order S_{12}, S_{18}, S_{20} (years) > S_6, S_9, S_{10}, S_{11}, S_{13} (days) ≫ S_7 (minutes). Their interconversion reactions ($S_n \rightarrow S_m, m \neq n$) have been studied in some detail. Thermal as well as photochemical reactions are possible, and a number of mechanisms have been proposed (Figure 7). (1) Radical, consisting of ring opening ($S_n^{ring} \rightarrow S_n^{chain}$), polymerization ($S_n^{chain} \rightarrow S_\infty^{chain}$), and depolymerization ($S_\infty^{chain} \rightarrow$ mixture of $S_m^{ring} + S_n^{ring}$). (2) Isomerization/transfer, which involves formation of an intermediate ($S_8 \rightarrow S_7S$) with a similar structure to S_7O followed by sulfur transfer ($S_7S + S_8 \rightarrow S_7 + S_9$). (3) Dimerization followed by dissociation. It seems likely that this latter pathway is important at moderate temperatures (≤150 °C), while there is evidence for radical intermediates in photochemical reactions and at higher temperatures. The various sulfur rings may be analyzed by HPLC using a simple reverse-phase column and methanol as the eluent; the larger rings give longer retention times. In addition, each ring has a very characteristic Raman spectrum

Table 6 Molecular properties of sulfur allotropes

S_x	Colour	Space group	S–S bond (pm)	Bond angles (°)	Torsional angles (°)	Mp (°C)

(*see Raman Spectroscopy*) which allows detection in mixtures (Figure 8).[17]

Reactions. Sulfur is a relatively reactive element, with the majority of the reactions proceeding with cleavage of one or more S–S bonds, usually as a result of nucleophilic attack (Figure 9). It forms compounds by direct reaction with virtually every element (the exceptions being the noble gases, nitrogen, iodine, iridium, platinum, and gold). It burns in air with a blue flame, in fluorine to give SF_6, and in chlorine to give S_2Cl_2. Triplet sulfur (which is responsible for the blue flame of sulfur) can be formed by the photochemical activation of CS_2 or COS. Sulfur is not especially reactive with water (which does not wet it), but it does dissolve in liquid ammonia to give complex mixtures of anions (*see* ***Sulfur–Nitrogen Compounds***). *Cyclo*-S_6 is known to be more susceptible to nucleophilic attack than *cyclo*-S_8, and this feature may be of utility in organic synthesis. Oxidation reactions of sulfur rings have already been mentioned and the formation of cyclo cations is discussed below.

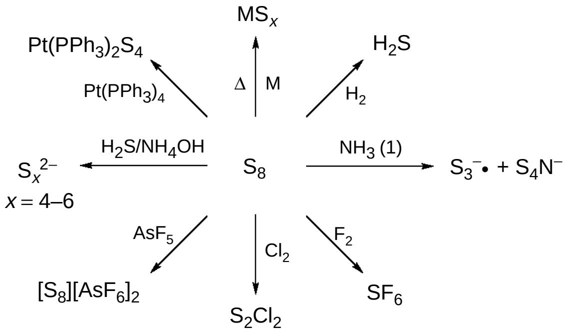

Figure 9 Reactions of S_8

2.3.2 Homocyclic Cations

It was observed in 1804 that sulfur reacts in oleum to give intense blue, red, or yellow solutions depending on the time of reaction and the concentration. Tellurium and selenium also give rise to deeply colored solutions in concentrated sulfuric acid. The identity of the species responsible for these colors was in doubt until quite recently. In the past few years, some quite remarkable cations have been isolated.[21] Since

Table 7 Group 16 cations

M_4^{2+}	S_4^{2+}	Se_4^{2+}	Te_4^{2+}	$Te_2Se_2^{2+}$	
M_6^{2+}	–	–	–	S_3Se^{2+} $Te_2Se_4^{2+}$ $Te_3S_3^{2+}$	$Se_6Ph_2^{2+}$ Se_6I^+
M_6^{4+}	–	–	Te_6^{4+}	–	$Se_6I_2^{2+}$ S_7I^+ $(S_7I)_2I^{3+}$
M_8^{2+}	S_8^{2+}	Se_8^{2+}	–	$Se_6Te_2^{2+}$	– Se_9Cl^+
M_{10}^{2+}	–	Se_{10}^{2+}	–	–	–
M_{19}^{2+}	S_{19}^{2+}	–	–	–	–

the various cations down group 16 relate to each other in this section, examples from each element will be discussed. Table 7 gives examples of the known species. Many of the S_x^{n+} cations' electron counts fall between those of (group $16)_x$ and S–N molecules, for example S_8, S_8^{2+}, and S_4N_4 are 48, 46, and 44 electron species, respectively. Apart from the difficult synthetic chemistry, the various cations have thus presented substantial problems theoretically, and the empirical treatment developed to rationalize their structures has been discussed in an excellent review of this area.[21]

A number of synthetic routes are available (*see Superacid*). For success, the final anion has to be insufficiently basic to react with the cation. The cations are usually extremely sensitive to nucleophilic attack, and so solvents such as SO_2, AsF_3, and HSO_3F and counterions like $AlCl_4^-$, AsF_6^-, and SO_3F^- are essential. Typical oxidations are shown in Figure 10. Although many of the methods are logical, it is worth noting the preparation[22] of S_{19}^{2+}. Mixed cations may also be prepared by use of alloys, reaction of an element with a cation of a different element, or reaction between cations of two different elements. Halogen substituted monocations are obtained[23,24] if the oxidation is carried out in the presence of the halogen and by several other routes, for example, reaction of excess sulfur with $I_2Sb_2F_{11}$ or by reaction of I_2 with a previously prepared cation, $S_x(AsF_6)_2$ ($x \sim 19$).

Some solid-state structures are shown in Figure 10. The M_4^{2+} cations have a total electron count of $22e^-$ or 11 pairs. Using *Wade's Rules*, a planar cation can be derived from an octahedron by removal of two opposite vertices and may be described as *iso-arachno*. Support for a planar structure with extra electron density in the ring are the slightly short M–M bonds in M_4^{2+} (e.g. in S_4^{2+}, S–S = 1.98 Å, vs. 2.04 Å in S_8).

The $Te_3S_3^{2+}$ cation contains 34 electrons ($5n + 4$) and is based on a trigonal prism with two bonds broken or on P_4S_3 with one vertex removed. The Te_6^{4+} cation has, surprisingly, a symmetrical structure. This can be rationalized as a trigonal prism with any one of three bonds being broken (or all three broken to an equal extent). Figure 11 illustrates the relationship of M_6^{n+} structures; notice that more electrons result in more open geometries. The structure of S_7I^+ is analogous to that of S_7O. Two forms of M_8^{2+} cations have

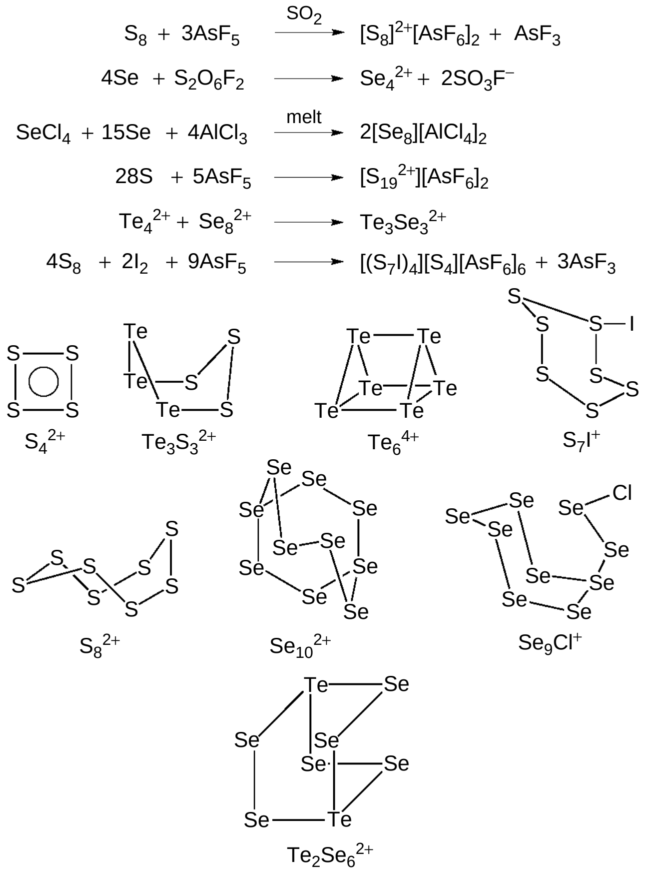

Figure 10 Preparation and structures of E_n^+

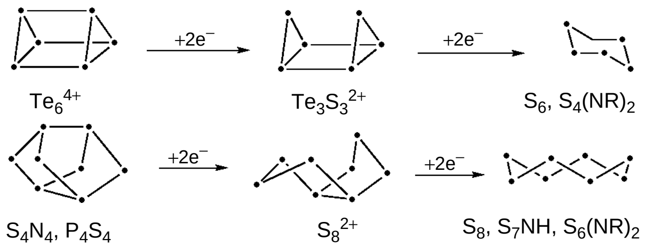

Figure 11 Relationship between the structures of some cyclic sulfur-containing molecules

now been observed. $Te_2Se_6^{2+}$ is based upon a cube with three bonds broken, while S_8^{2+} is related to cuneane with three bonds broken. To rationalize the structure of S_{19}^{2+}, see an excellent review.[17]

The solution structures of group 16 cations have been probed by ^{77}Se and ^{125}Te NMR.[25,26] Both Se_8^{2+} and $Te_2Se_6^{2+}$ retain their (different) solid-state conformations in solution. However, the Se_{10}^{2+} cation does appear by ^{77}Se NMR to undergo structural isomerism with two resonances whose relative intensities are temperature dependent.

The reaction of $[Se_4][AsF_6]_2$, $[Se_8][AsF_6]_2$, or $[Se_{10}][AsF_6]_2$ with $M(CO)_6$ (M = Mo or W) gives $[M_2(CO)_{10}Se_4][AsF_6]_2$ in which two $[M(CO)_5Se_2]^+$ cations are linked by long Se···Se bonds (3.015 Å).[27] The Se_4^{2+} cation also provides a source of the Se_2 group in the synthesis[28] of $[FeW(CO)_8Se_2][SbF_6]_2$. Reaction of Se_4^{2+} with PhSeSe Ph results in a boat conformation $Se_6Ph_2^{2+}$ ring. The usefulness of group 16 cations in organic synthesis has been described. For example, the preparation[29] of perfluorinated sulfides, selenides, and tellurides from C_2F_4 (equation 10).

$$[S_8][AsF_6]_2 + C_2F_4 \longrightarrow (C_2F_5)_2S_x \quad x = 2, 3 \tag{10}$$

More recently, the oxidizing power of S_n^{2+} cations has been demonstrated.[30] Reaction of S_8^{2+} with hydrocarbons proceeds with insertion of sulfur into a C–H bond (e.g. CH_4 gives methanethiol); toluene is converted into a series of isomeric dimethylbiphenyls, while reaction with CO gives COS.

2.3.3 *Sulfur Vapor*

Sulfur vapor (generated from α-S_8, HgS, or electrochemically) contains a range of S_n species ($n = 1$–10).[31] At higher temperatures, significant amounts of S_2–S_6 are formed. There have been a number of spectroscopic studies on sulfur vapor; Raman studies identified bands due to S_6–S_8 and ionization potential measurements have been compared with UV/Vis studies (see), particularly for S_2, which is an important constituent at high temperatures and low pressures.

2.3.4 *Liquid Sulfur*

Liquid sulfur is a very complex equilibrium system.[32,33] For example, at the melting point it is a clear yellow color, but at its boiling point it is opaque and deep red. Furthermore, it undergoes viscosity changes as the temperature is raised, going through maxima at 159 °C and 185 °C. From EPR and magnetic susceptibility studies it appears that there are no radicals present at low temperature but significant quantities at high temperature. At its melting point, sulfur consists of mostly *cyclo*-S_8 and, as the temperature is raised, various chain length sulfur species are formed. The presence of long-chain S_n species accounts for the weak EPR, the intense color, and the viscosity of high-temperature liquid sulfur, but it is apparent from the literature that the system is still not fully characterized.

3 SULFUR OXIDES

The sulfur oxides include[34] the simplest species SO, SO_2, SO_3 through to very sulfur-rich species such as S_8O (Figure 12), although the di- and trioxide are undoubtedly the most important commercially. We have already mentioned (Section 2.3) that *cyclo*-S_n rings may be oxidized using peroxyfluoroacetic acid to give S_nO and S_nO_2.

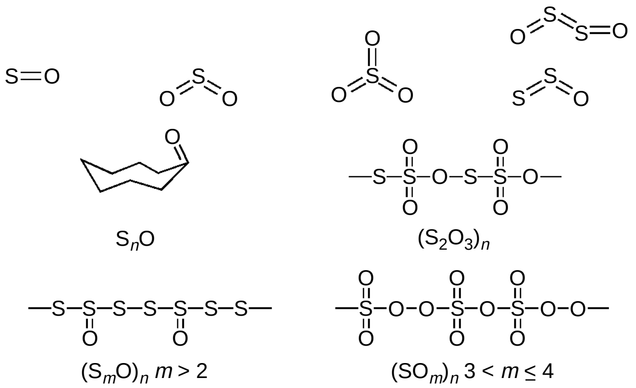

Figure 12 The range of sulfur oxides

3.1 Sulfur Dioxide

3.1.1 *Commercial Preparation*

SO_2 is obtained commercially most commonly by the combustion of sulfur, typically by spraying fine droplets of sulfur into a combustion chamber along with dry air (ΔH −297 kJ mol^{-1}). Both single- and two-stage combustion processes are used. Single-stage processes use an excess of O_2/air, whereas two-stage systems use ca. 90% of the required air in the first stage and add additional O_2 in the second combustion. The two-stage system produces SO_2 that contains virtually no nitrogen oxides.

SO_2 is also obtained commercially from metal sulfide ores by roasting in fluidized bed furnaces (equation 11). The reaction is carried out at 650–1100 °C, with the resultant SO_2 being filtered electrostatically to remove ash and then freed of As_2O_3 impurities before being used in the preparation of SO_3.

$$2FeS_2 + 5.5O_2 \longrightarrow Fe_2O_3 + 4SO_2 \tag{11}$$

Sulfur dioxide is converted to SO_3 and ultimately to sulfuric acid using the double contact process, which is based upon the equilibrium between SO_2 and SO_3 (equation 12).

$$SO_2 + \tfrac{1}{2}O_2 \longrightarrow SO_3 \quad \Delta H = -99.0\ \text{kJ mol}^{-1} \tag{12}$$

The equilibrium is slow except in the presence of a catalyst. Typically, vanadium catalysts, which consist of $VO(SO_4)$ supported on kieselguhr, are used to push the equilibrium to the right-hand side. Since the equilibrium shifts in favor of the starting materials with increasing temperature, as low a temperature as possible (ca. 425 °C) is employed, together with continuous removal of the SO_3 by absorption into sulfuric

acid. The overall production of sulfuric acid from sulfur is very exothermic, and the energy produced is usually converted into superheated steam.

3.1.2 *Physical Properties, Molecular Structure, and Bonding*

SO_2 is a poisonous, colorless gas with a sharp odor (Table 8); it condenses (−10 °C) to give a colorless liquid and ultimately (ca. −76 °C) white crystals. It has a bent structure (S–O bond length 143.2 pm, O–S–O ca. 119.5° in the gas phase), and is dipolar (1.62 D). It is believed to be only slightly associated in the liquid state, and adopts an orthorhombic form as a solid. The bond lengths and angle in the solid agree well with those determined for the gas by microwave spectroscopy and electron diffraction. Valence bond and molecular orbital calculations agree with the observed bond length, being somewhat shorter than a simple S=O double bond. Vibrational spectroscopy reveals the three expected IR and Raman fundamental vibrations, and force constant calculations suggest a bond order of ca. 1.93.

3.1.3 *Reactions of SO_2 with Main Group Species*

The oxidation of SO_2 to SO_3 (equation 12) is undoubtedly the most important commercially, but there is also quite a large chemistry of SO_2 that merits mention (Figure 13).

With chlorine or fluorine, SO_2X_2 is obtained while I_2 and liquid SO_2 form a weak complex in which SO_2 acts as a Lewis acid. Larger mixed S–O–X species may also be formed

Table 8 Physical properties of sulfur dioxide

(a) Gaseous Property	Temp. (°C)	Value
Melting point	−75.48	−75.48 °C(1.256 Torr)

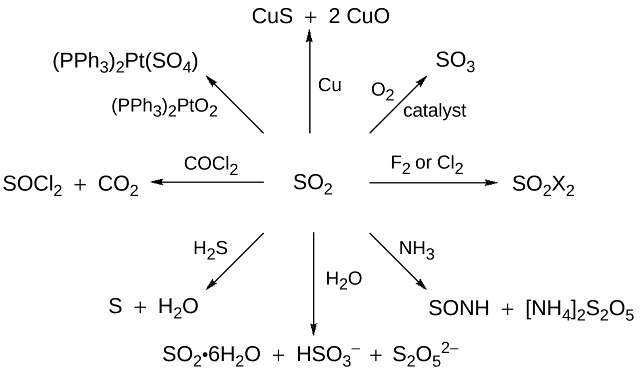

Figure 13 Reactions of SO_2

(equation 13).

$$S_2O_6F_2 + SO_2 \longrightarrow S_3O_8F_2 \quad (13)$$

SO_2 is reduced by carbon at 350 °C to give sulfur, and by hydrogen (catalytically) to give H_2S and sulfur. Hydrogen sulfide also reduces SO_2 at high temperature (300 °C), as mentioned above in the Claus process. SO_2 is oxidized by $HClO_3$ to give sulfuric acid and ClO_2, and may be oxidized to $SOCl_2$ using PCl_5.

SO_2 dissolves in water to give 'sulfurous acid', which according to Raman spectroscopy contains large amounts of solvated SO_2 as well as HSO_3^-, H_3O^+, and $S_2O_5^{2-}$. With ammonia and amines, quite complex reactions, which are not fully understood, occur. In the gas phase, ammonia and SO_2 react according to equation (14).

$$3SO_2 + 3NH_3 \longrightarrow SONH + [NH_4]_2[S_2O_5] \quad (14)$$

In solution, tertiary amines and SO_2 give simple complexes, with the SO_2 behaving as a Lewis acid. Hydrogen halides also react to form complexes of the formula $SO_2{\cdot}HX$, although it is thought that these are simple dipolar adducts.

SO_2 is oxidized by nitric oxides, as exemplified in the Lead Chamber Process (equation 15). This process is only operated in special cases nowadays, because of the low final acid concentration that is achievable (no more than 78%), although it only requires modest temperatures and so may be utilized again in the future.

$$SO_2 + 2NOHSO_4 + 2H_2O \longrightarrow 3H_2SO_4 + 2NO \quad (15)$$

3.1.4 *Reactions of SO_2 with Metals and Metal Complexes*

The gas reacts with metals (As, Sb, Mg, Zn, Cd, Tl, Pb, Mn, Ni, Co, Ag, etc.) reductively to give metal sulfides and metal oxides, although secondary reactions often lead to sulfates or sulfur formation.

In aqueous solution, SO_2 is reduced to dithionite by a range of metals or sodium hydride. With metal halides, SO_2 forms complexes and may behave as an electron donor (e.g. with $AlCl_3$, $SnBr_4$, or $TiCl_4$) or undergo solvolysis (equation 16)

$$VF_5 + SO_2 \longrightarrow VOF_3 + SOF_2 \qquad (16)$$

or with alkali metal halides with formation of fluorosulfites, MSO_2F.

Sulfur dioxide was first obtained as a coordinated ligand by a hydroxide abstraction reaction of a bisulfite complex (equation 17) in 1936.[35]

$$[Ru(NH_3)_5(SO_3H)]^- \longrightarrow [Ru(NH_3)_5SO_2]^{2-} \qquad (17)$$

Subsequently, an enormous range of complexes of SO_2 has been prepared (mostly by simple displacement reactions of labile ligands) and it has been suggested that SO_2 displays one of the most extensive ranges of coordination mode for any ligand. Some examples of SO_2 coordination modes are given in Figure 14. The orbitals involved in the two most common modes are illustrated in Figure 15. The area has been reviewed;[36,37] organometallic aspects, especially involving migratory reactions (e.g. Figure 16), have been of particular interest in recent times.[38] There has also been

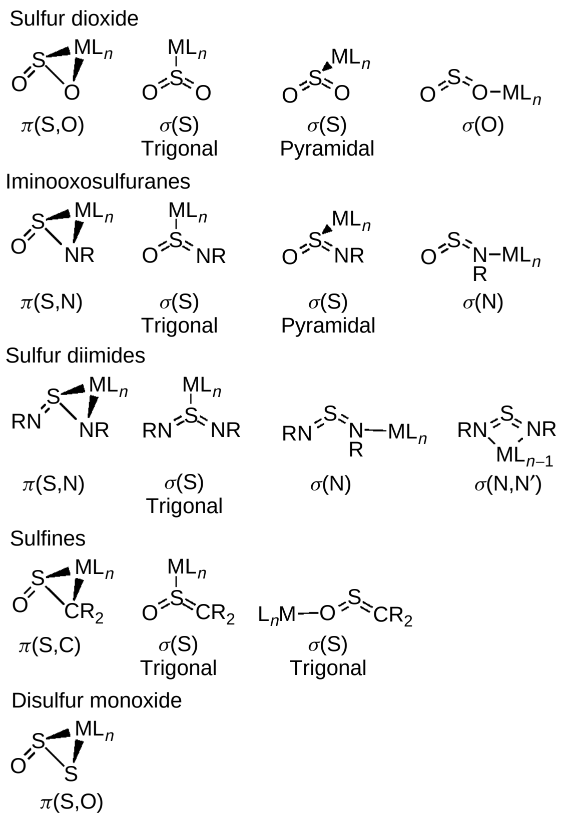

Figure 14 Coordination modes of SO_2 and related ligands

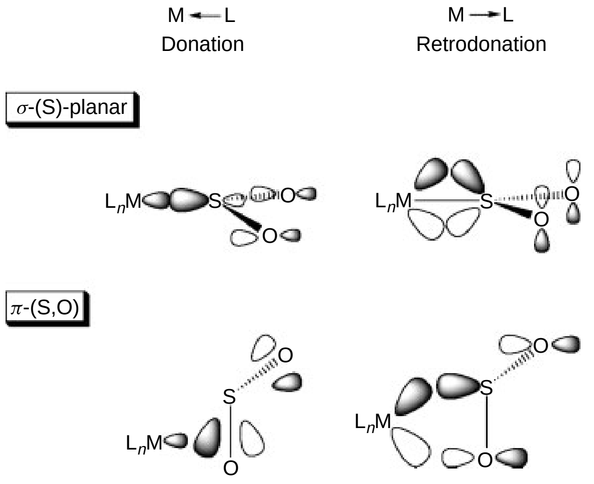

Figure 15 Orbitals involved in SO_2 coordination

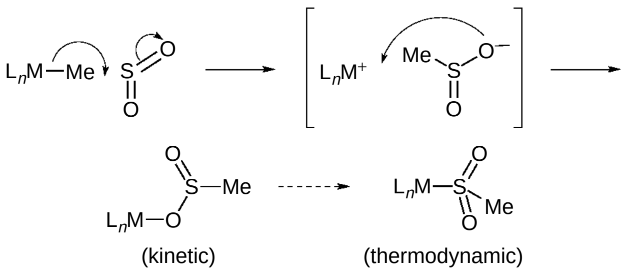

Figure 16 Mechanism for the insertion of SO_2 into transition metal alkyls

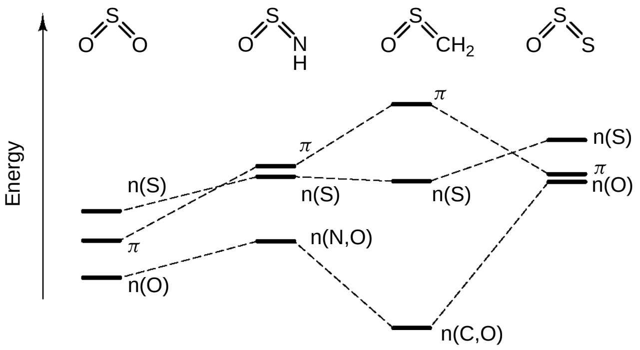

Figure 17 MO scheme for SO_2 and analogs

substantial interest in the synthesis of analogs of SO_2 and Figure 14 illustrates some of these; the electronic factors influencing the stability of the various analogs have been discussed. In general, the replacement of one oxo group does not lead to major geometric changes, but the energies of the orbitals capable of donating to metal centers go up on replacement of the oxygen atom by other groups (Figure 17). For example, for HNSO and HNSNH, the nitrogen

lone pair is more nucleophilic than the equivalent orbitals on oxygen.

3.2 Liquid SO_2 as a Solvent

Liquid SO_2 (Table 8) dissolves many inorganic and organic compounds;[39] generally, covalent compounds are the most soluble since the dielectric constant of SO_2 is much lower than that of water or ammonia. Although poisonous, SO_2 as the liquid may be handled without great difficulty using glassware equipped with rotary PTFE taps. It has been extensively used as a solvent for the preparation of group 16 cations[40] and S–N cations, as well as for the preparation of $(SN)_x$.[41]

3.3 Environmental Problems and SO_2

There is currently great concern about the environmental effects of airborne sulfur dioxide.[42–44] Although SO_2 is released into the atmosphere from natural sources such as volcanoes, the majority (ca. 200 million tonnes per year) is man-made either from industrial processes or domestic use such as coal and oil burning. The long-term consequences of large-scale release of SO_2 into the atmosphere are undoubtedly severe, and have been the subject of much public debate. The most objectionable aspect of the problem is that often the 'acid rain', which results from SO_2, occurs hundreds of miles from the source.

In the future, it seems likely that most processes that currently entail the discharge of SO_2 will have to be adapted with the introduction of 'scrubbers'. Two main methods can be employed for this: either the reduction of SO_2 to sulfur using the Claus process or, alternatively, neutralization using 'milk of lime' (equation 18) to give either calcium sulfite or, with complete oxidation, calcium sulfate (gypsum).

$$SO_2 + Ca(OH)_2 \longrightarrow CaSO_3{\cdot}\tfrac{1}{2}H_2O + \tfrac{1}{2}H_2O$$
$$SO_2 + Ca(OH)_2 + \tfrac{1}{2}O_2 + H_2O \longrightarrow CaSO_4{\cdot}2H_2O \qquad (18)$$

Unfortunately, the gypsum produced by the latter process is inferior to natural gypsum and cannot be used as a substitute in all cases.

3.4 Sulfur Trioxide

3.4.1 Commercial Preparation and Significance

The commercial significance of SO_3 for the preparation of sulfuric acid has already been mentioned, and this is the most important aspect of its industrial chemistry. However, substantial amounts of pure SO_3 are prepared commercially for use in the manufacture of, for example, chloro- and fluorosulfonic acids, thionyl chloride, and as a sulfonating agent. Pure, liquid SO_3 is obtained industrially by distillation from oleum.

3.4.2 Physical Properties, Molecular Structure, and Bonding

Sulfur trioxide exists in at least three different solid modifications, as well as a liquid and a gas (Figure 18).

In the gas phase,[45] the molecule is mainly monomeric; it is trigonal planar (D_{3h}) with three equivalent bond lengths (ca. 1.43 Å from microwave spectroscopy), with a bond order that is formally greater than 2.

Liquid SO_3 may be prepared in the laboratory by a similar method to the industrial process. When completely dry, it remains as a liquid for many months but traces of water (as low as 10^{-3} mol%) catalyze the polymerization to β-SO_3. In the liquid, the monomeric[46] species is in equilibrium with a trimer, S_3O_9, which has a similar, nonplanar, structure to the trimer in γ-SO_3.

Three reasonably well-defined modifications of solid SO_3 exist. γ-SO_3, which is often described as 'ice-like', is orthorhombic[47] and consists of cyclic trimers with traces of monomeric SO_3 included. With even traces of water, γ-SO_3 or liquid SO_3 polymerize to give glistening needles of monoclinic β-SO_3.[48] This modification is believed to consist of a mixture of different chain length polymers; if warmed, it melts with depolymerization between 32–45 °C. α-SO_3 has a higher melting point than the other solid forms and consists of higher polymers, almost certainly in a layer structure.

3.4.3 Reactions of Sulfur Trioxide

Sulfur trioxide is extremely reactive, behaving as a powerful oxidant and Lewis acid. Indeed, many of its reactions involve initial adduct formation followed by rearrangement. We have already discussed the formation of sulfuric acid, and other typical reactions are shown in Figure 19. Chloro- and fluorosulfonic acids (XSO_3H) are used as mild chlorinating and fluorinating agents and, in the case of the latter, for polishing lead crystal.

3.5 Other Sulfur Oxides

3.5.1 Lower Oxides

Cyclic sulfur oxides S_nO ($n = 6$, 8, 9 10) are normally prepared by oxidation of their parent sulfur rings using peroxyfluoroacetic acid (equations 8 and 9) in an inert solvent

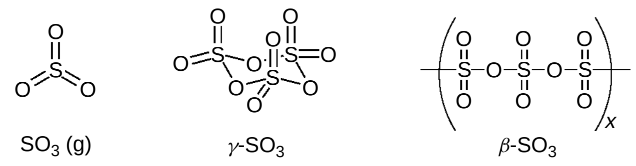

Figure 18 Modifications of SO_3

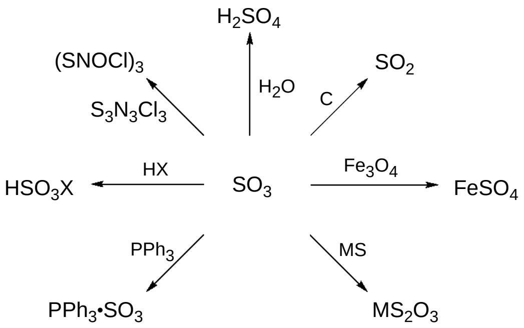

Figure 19 Reactions of SO_3

such as CS_2 or CH_2Cl_2, although in some cases the dioxide (e.g. S_7O_2) may also be obtained. S_8O has also been prepared by the reaction of thionyl chloride with H_2S_7 at −40 °C (equation 19).

$$SOCl_2 + H_2S_7 \longrightarrow S_8O + 2HCl \quad (19)$$

The compounds whose structures are shown in Figure 4 are orange or dark yellow and decompose at, or around, room temperature to give sulfur and sulfur dioxide.

There are very few reactions known for S_nO species, although adducts with Lewis acids ($SnCl_4$, $SbCl_5$) have been prepared.[49] The structure of $[SnCl_4(S_8O)_2]$ is a distorted octahedral arrangement of four chlorine and two oxygen coordinated *cis*-S_8O ligands.[50]

Sulfur monoxide, obtained by the reaction of SO_2 and sulfur, has been observed in the gas phase but is very short lived.[51] S_2O_2 has a slightly longer lifetime (half-life a few seconds) and mixtures of both gases may be obtained by subjecting SO_2 to a microwave discharge. S_2O is one of the decomposition products of SO and may also be prepared by a number of other routes,[52] such as burning sulfur in low pressure of oxygen or passing SO_2 through a high voltage discharge.

SO, S_2O, and S_2O_2 are stabilized as ligands in metal complexes. The coordination chemistry of SO and S_2O has been developed by preparations that involve formation of the ligand from suitable precursor complexes. The most common method involves oxidation of a coordinated S_n ligand. The first example of an S_2O complex was reported by Schmidt and Ritter[53] and subsequently refined by Rauchfuss[54] (Figure 20), and extended to the corresponding S_2O_2 complex. A dinuclear complex of S_2O has been isolated. SO complexes may also be obtained by the reaction of thionyl chloride, *trans*-stilbene episulfoxide, or thiirane *S*-oxide with metal complexes.

The oxidation of S_2 complexes is a somewhat limited approach, and a more general route[55] may be the nucleophilic attack of H_2S upon iminooxosulfurane complexes, which has been developed by analogy with the equivalent hydrolysis reactions (Figure 21 and 22).

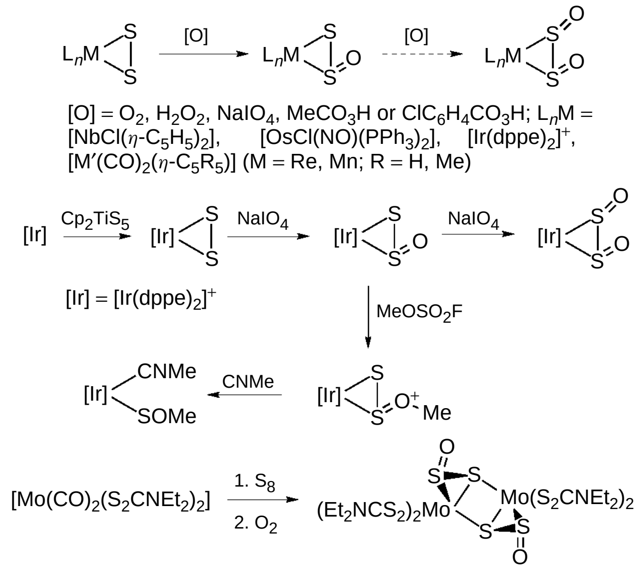

Figure 20 Preparative routes to S_2O and S_2O_2 complexes

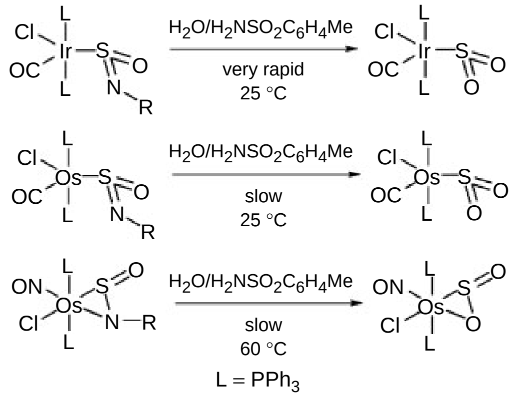

Figure 21 Reactions of iminooxosulfuranes with H_2O

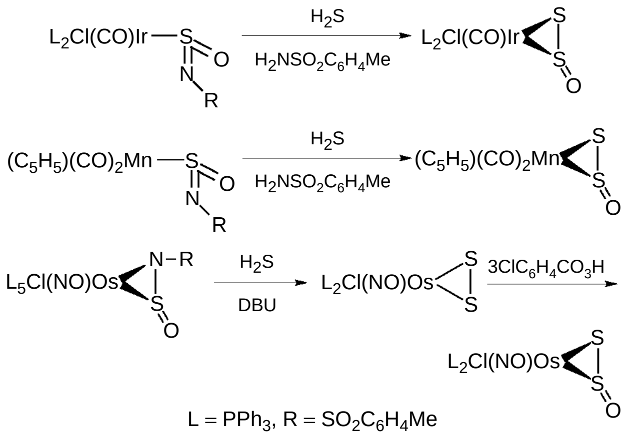

Figure 22 Reactions of iminooxosulfuranes with H_2S

The chemistry of coordinated S_2O has yet to be studied in any real detail. Simple oxidation or reduction to coordinated S_2O_2 or S_2 is known. The bulk of the information is derived from the reactions of $[Ir(dppe)_2(S_2O)]^+$.[54] Reaction with PPh_3 gives phosphine oxide and phosphine sulfide, together with $[Ir(dppe)]^+$; the initial reactivity suggests that the exocyclic sulfur atom is the most electrophilic. Alkylation at this sulfur atom gives $[Ir(SSOMe)_2(dppe)_2]^{2+}$.

SO can coordinate in a number of modes;[56] apart from simple σ donation (bent), it may bridge two or three metal centers (via sulfur) and there is one example of a fully characterized edge-on bridging mode. From X-ray crystal structural studies[57] it appears that the coordinated S_2O ligand behaves as a π-acid, as it has a substantially lengthened S–S bond compared to the free S_2O.

3.5.2 *Higher Oxides*

A number of higher, polymeric oxides are known. In general, these are structurally related to β-SO_3 by random substitution of oxo bridges by peroxo bridges. Monomeric SO_4 has been studied by matrix isolation and is believed to have an O_2SOO (peroxo) structure.

3.6 Oxoacids

3.6.1 *Sulfuric Acid and Sulfates*

The oxoacids of sulfur are summarized in Table 9.

Industrially, sulfuric acid remains an extremely important material; world production is estimated at ca. 150×10^6

Table 9 The common oxoacids of sulfur

Formula	Name	Ox. states	Schematic structure[a]	Salt
H_2SO_4	Sulfuric	VI		Sulfate, SO_4^{2-}; H-sulfate, $HOSO_3^-$
$H_2S_2O_7$	Disulfuric	VI		Disulfate, $O_3SOSO_3^{2-}$
$H_2S_2O_3$	Thiosulfuric	IV, 0, (or VI, -II)		Thiosulfate, SSO_3^{2-}
H_2SO_5	Peroxomonosulfuric	VI		Peroxomonosulfate, $OOSO_3^{2-}$
$H_2S_2O_8$	Peroxydisulfuric	VI		Peroxydisulfate, $O_3SOOSO_3^{2-}$
$H_2S_2O_6$	Dithionic[a]	V		Dithionate, $O_3SSO_3^{2-}$
$H_2S_{n+2}O_6$	Polythionic	V, 0		Polythionate, $O_3S(S)_nSO_3^{2-}$
H_2SO_3	Sulfurous[a]	IV		Sulfite, SO_3^{2-}; H-sulfite, $HOSO_2^-$
$H_2S_2O_5$	Disulfurous[a]	V, III		Disulfite, $O_3SSO_2^{2-}$
$H_2S_2O_4$	Dithionous[a]	III		Dithionite, $O_2SSO_2^{2-}$

[a]Acids only exist as salts.

tonnes per year. The majority of this acid is prepared from SO_2, but increasingly, because of environmental considerations, sulfuric acid is recycled. If the levels of impurities are low, the acid is evaporated in stages to the appropriate concentration and any organic impurities destroyed by oxidation. Alternatively, if the acid is heavily contaminated, it is concentrated and thermally decomposed (to H_2O, SO_2, and O_2) under oxidative or reductive conditions, depending on the nature of the impurities. Oxidative processes have the advantage that they liberate CO_2. Metal sulfates also provide a source of sulfuric acid. For example, gypsum or calcium sulfate (from the manufacture of phosphoric acid) can be reacted with coal; the calcium oxide is utilized for the manufacture of Portland cement (equation 20).

$$4CaSO_4 + 2C \longrightarrow 4CaO + 4SO_2 + 2CO_2 \quad (20)$$

Alternatively, sulfuric acid can be prepared from the iron(II) sulfate waste, which is obtained during the manufacture of TiO_2 (equation 21).

$$2FeSO_4{\cdot}7H_2O \longrightarrow Fe_2O_3 + 2SO_2 + \tfrac{1}{2}O_2 + 14H_2O \quad (21)$$

Commercially, sulfuric acid has many important applications (Figure 23). The largest proportion is used in the manufacture of phosphorus and nitrogen based fertilizers. It is also used in the manufacture of inorganic sulfates, HF, B_2O_3, and a range of organic compounds, as well as in the petrochemical industry for the refining of raw paraffin.

Anhydrous sulfuric acid (Table 10) has a very high dielectric constant and electrical conductivity as a consequence of autoionization (equations 22 and 23), which occurs via two different equilibria.

$$2H_2SO_4 = H_3SO_4^+ + HSO_4^- \quad (22)$$

$$2H_2SO_4 = H_3O^+ + HS_2O_7^- \quad (23)$$

For equation (22), the equilibrium constant is ca. 3×10^{-4}, which is 10^{10} greater than the analogous reaction for water, and comparable with anhydrous H_3PO_4. Equation (23) can be considered as 'self-dehydration', and involves dissociation of the acid to H_2O and SO_3 with subsequent reaction of SO_3 and

Table 10 Properties of sulfuric acid

Freezing point	10.371 °C
Boiling point	290–317 °C

Heat of fusion (10.37 °C)	2560 cal mol^{-1}

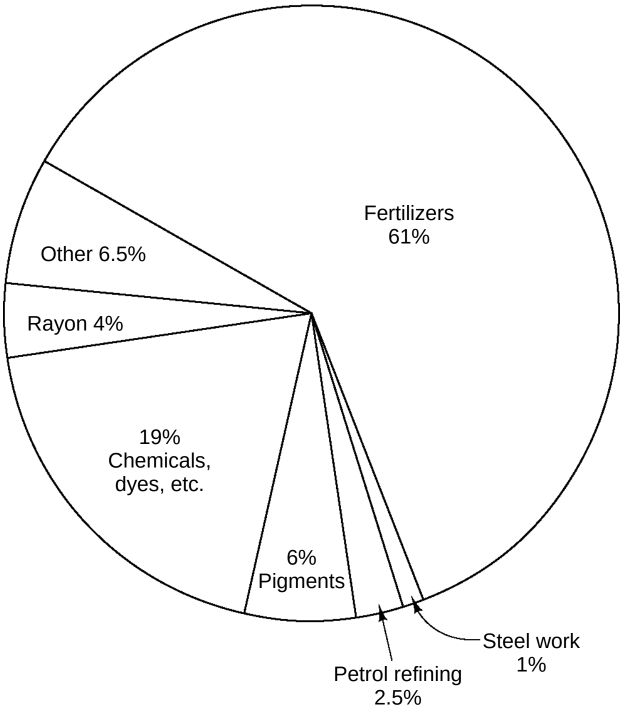

Figure 23 Uses of H_2SO_4

HSO_4^-. From these comments, it is clear that sulfuric acid is a complex mixture of species in equilibrium.

Aqueous sulfuric acid behaves as a strong acid in most systems and forms salts with most metals by a variety of routes, such as reaction of the acid with the metal, neutralization of a metal oxide or hydroxide, or decomposition of metal carbonates. In organic synthesis, it is most well known for its use with nitric acid as a reagent for the nitration of aromatics (equation 24) via the NO_2^+ cation.

$$2H_2SO_4 + HNO_3 \longrightarrow NO_2^+ + H_3O^+ + 2HSO_4^- \quad (24)$$

Many metal sulfates are known, and often exist in Nature. Apart from gypsum ($CaSO_4$), Epsom salts ($MgSO_4{\cdot}7H_2O$) are a common feature of many households and were recommended by Mrs Beeton's book of household management for the treatment of constipation and as bath salts! The sulfate ion is tetrahedral and has a large coordination chemistry, forming monodentate (O coordinated) and bidentate (O,O′chelating or O,O′ bridging) complexes that have characteristic vibrational spectra.[58]

3.6.2 *Sulfurous Acid*

H_2SO_3 exists in trace amounts in aqueous solutions of SO_2 but has never been isolated. However, sulfites are well known and usually stable. Sodium sulfite is used extensively commercially. It is obtained by reacting SO_2 with NaOH

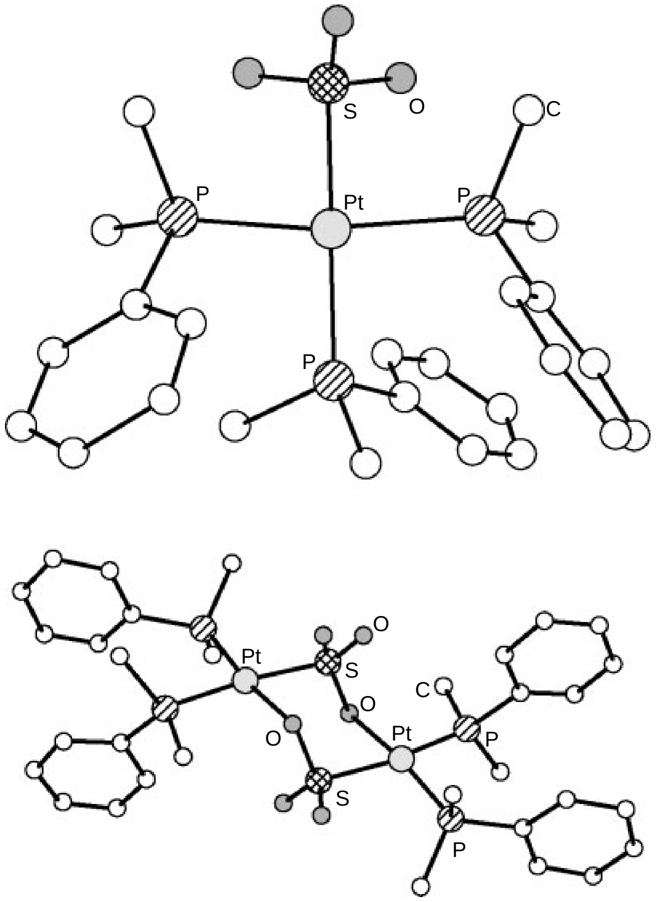

Figure 24 Monodentate and bridging SO_3^{2-} complexes[59]

and is used as a reducing agent in photography, for the preservation of foods, the treatment of boiler water, and in the textiles and paper industry. The sulfite ion is pyramidal and displays a number of coordination modes. Interestingly, apart from monodentate coordination through sulfur, and bidentate coordination through two oxygen atoms, dinuclear compounds with S=O coordination have recently been characterized (Figure 24).[59] Protonation of sulfite to give HSO_3^- appears to occur at the sulfur rather than at an oxygen atom. The sulfite and bisulfite anions are both moderately strong reducing agents, as exemplified by the well-known reaction (equation 25) used in volumetric analysis.

$$HSO_3^- + I_2 + H_2O \longrightarrow HSO_4^- + 2H^+ + 2I^- \qquad (25)$$

3.6.3 *Thiosulfuric Acid*

Anhydrous thiosulfuric acid may be obtained, at low temperatures, by a number of routes (equations 26 and 27), but attempts to prepare the aqueous acid by acidification of metal thiosulfates invariably fail as a result of the rapid decomposition of the acid by water.

$$Na_2S_2O_3 + 2HCl \xrightarrow{Et_2O/-78\,°C} 2NaCl + H_2S_2O_3{\cdot}2Et_2O \qquad (26)$$

$$HSO_3Cl + H_2S \longrightarrow HCl + H_2S_2O_3 \qquad (27)$$

Stable thiosulfates can be obtained by a number of routes, such as addition of sulfur to a sulfite (equation 28), or the reduction of sulfides (equation 29).

$$\underset{(\text{or } NH_4^+)}{Na_2SO_3} + S \longrightarrow Na_2SO_4 \qquad (28)$$

$$2Na_2S + Na_2CO_3 + 4SO_2 \longrightarrow 3Na_2S_2O_3 + CO_2 \qquad (29)$$

The thiosulfate anion is structurally very similar to sulfate and has a range of coordination modes (Figure 25). Two examples of S-bonded thiosulfate complexes[60] are shown in Figure 26 and 27, and the substitution chemistry of $[OsO_2(S_2O_3)_2]^{2-}$ is summarized in Figure 28. Thiosulfates have a diverse range of applications. Both sodium and
